where N_0 is the original number of muons at time $t = 0$, $N(t)$ is the number remaining at time t, and τ is the mean lifetime (a proper time interval), which is about 2 μs for muons. Since muons are created (from the decay of pions) high in the atmosphere, usually several thousand meters above sea level, few muons should reach sea level. A typical muon moving with speed $0.998c$ would travel only about 600 m in 2 μs. However, the lifetime of the muon measured in Earth's reference frame is increased according to time dilation (Equation 1-26) by the factor $1/(1 - v^2/c^2)^{1/2}$, which is 15 for this particular speed. The mean lifetime measured in Earth's reference frame is therefore 30 μs, and a muon with speed $0.998c$ travels about 9000 m in this time. From the muon's point of view, it lives only 2 μs, but the atmosphere is rushing past it with a speed of $0.998c$. The distance of 9000 m in Earth's frame is thus contracted to only 600 m in the muon's frame as indicated in Figure 1-31.

It is easy to distinguish experimentally between the classical and relativistic predictions of the observations of muons at sea level. Suppose that we observe 10^8 muons at an altitude of 9000 m in some time interval with a muon detector. How many would we expect to observe at sea level in the same time interval? According to the nonrelativistic prediction, the time it takes for these muons to travel 9000 m is (9000 m)/$0.998c \approx 30$ μs, which is 15 lifetimes. Substituting $N_0 = 10^8$ and $t = 15\tau$ into Equation 1-29, we obtain

$$N = 10^8 e^{-15} = 30.6$$

We would thus expect all but about 31 of the original 100 million muons to decay before reaching sea level.

According to the relativistic prediction, Earth must travel only the contracted distance of 600 m in the rest frame of the muon. This takes only $2\ \mu s = 1\tau$. Therefore, the number of muons expected at sea level is

$$N = 10^8 e^{-1} = 3.68 \times 10^7$$

Thus, relativity predicts that we would observe 36.8 million muons in the same time interval. Experiments of this type have confirmed the relativistic predictions.

The Spacetime Interval

We have seen earlier in this section that time intervals and lengths (= space intervals), quantities that were absolutes, or invariants, for relatively moving observers using the classical Galilean coordinate transformation, are not invariants in special relativity. The Lorentz transformation and the relativity of simultaneity lead observers in inertial frames to conclude that lengths moving relative to them are contracted and time intervals are stretched, both by the factor γ. The question naturally arises: Is there *any* quantity involving the space and time coordinates that is invariant under a Lorentz transformation? The answer to that question is yes, and as it happens, we have already dealt with a special case of that invariant quantity when we first obtained the correct form of the Lorentz transformation. It is called the *spacetime interval*, or usually just the *interval*, Δs, and is given by

Experiments with muons moving near the speed of light are performed at many accelerator laboratories throughout the world despite their short mean life. Time dilation results in much longer mean lives relative to the laboratory, providing plenty of time to do experiments.

$$(\Delta s)^2 = (c\Delta t)^2 - [\Delta x^2 + \Delta y^2 + \Delta z^2] \qquad \textbf{1-30}$$

or, specializing it to the one-space-dimensional systems that we have been discussing,

$$(\Delta s)^2 = (c\Delta t)^2 - (\Delta x)^2 \qquad \textbf{1-31}$$

It may help to think of Equations 1-30 and 1-31 like this:

$$[\text{interval}]^2 = [\text{separation in time}]^2 - [\text{separation in space}]^2$$

The interval Δs is the only measurable quantity describing pairs of events in spacetime for which observers in all inertial frames will obtain the same numerical value. The negative sign in Equations 1-30 and 1-31 implies that $(\Delta s)^2$ may be positive, negative, or zero depending on the relative sizes of the time and space separations. With the sign of $(\Delta s)^2$, nature is telling us about the causal relation between the two events. Notice that whichever of the three possibilities characterizes a pair for one observer, it does so for all observers since Δs is invariant. The interval is called *timelike* if the time separation is the larger and *spacelike* if the space separation predominates. If the two terms are equal, so that $\Delta s = 0$, then it is called *lightlike*.

Timelike Interval Consider a material particle[15] or object, such as, the elephant in Figure 1-27, that moves relative to *S*. Since no material particle has ever been measured traveling faster than light, particles always travel less than 1 m of distance in 1 m of light travel time. We saw that to be the case in Example 1-8, where the time interval between launch and birth of the baby elephant was 31.7 months on the *S* clock, during which time the mother elephant had moved a distance of $23.8c \cdot$ months. Equation 1-31 then yields $(c\Delta t)^2 - (\Delta x)^2 = (31.7c)^2 - (23.8c)^2 = (21.0c)^2 = (\Delta s)^2$ and the interval in *S* is $\Delta s = 21.0c \cdot$ months. The time interval term being the larger, Δs is a timelike interval and we say that material particles have *timelike worldlines*. Such

in 1971 by Shapiro and coworkers using radar signals reflected from several planets. Two of these experimental tests of relativity's predictions, bending of light and gravitational redshift, are discussed in the Exploring sections that follow. The perihelion of Mercury's orbit and the delay of light are discussed in More sections on the web page. Many other predictions of general relativity are subjects of active current research. Two of these, black holes and gravity waves, are discussed briefly in the concluding paragraphs of this chapter.

EXPLORING

Deflection of Light in a Gravitational Field

With the advent of special relativity, several features of the Newtonian law of gravitation, $F_G = GMm/r^2$, became conceptually troublesome. One of these was the implication from the relativistic concept of mass-energy equivalence that even particles with zero rest mass should exhibit properties such as weight and inertia, thought of classically as masslike; classical theory does not include such particles. According to the equivalence principle, however, light, too, would experience the gravitational force. Indeed, the deflection of a light beam passing through the gravitational field near a large mass was one of the first consequences of the equivalence principle to be tested experimentally.

This relativistic effect results in gravitational lenses in the cosmos that focus light from extremely distant galaxies, greatly improving their visibility in telescopes, both on Earth and in orbit.

To see why a deflection of light would be expected, consider Figure 2-19, which shows a beam of light entering an accelerating compartment. Successive positions of the compartment are shown at equal time intervals. Because the compartment is accelerating, the distance it moves in each time interval increases with time. The path of the beam of light, as observed from inside the compartment, is therefore a parabola. But according to the equivalence principle, there is no way to distinguish between an accelerating compartment and one with uniform velocity in a uniform gravitational field. We conclude, therefore, that a beam of light will accelerate in a gravitational field as do objects with rest mass. For example, near the surface of Earth light will fall with acceleration 9.8 m/s^2. This is difficult to observe because of the enormous speed of light. For example, in a distance of 3000 km, which takes about 0.01 second to cover, a beam of light should fall about 0.5 mm. Einstein pointed out that the deflection of a light beam in a gravitational field might be observed when light from a distant star passes close to

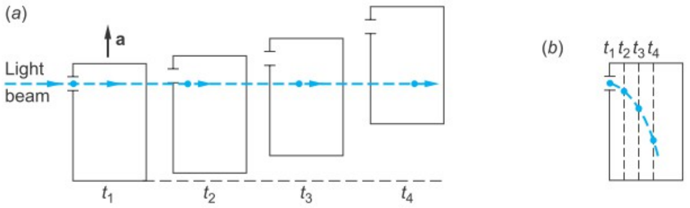

FIGURE 2-19 (*a*) Light beam moving in a straight line through a compartment that is undergoing uniform acceleration. The position of the light beam is shown at equally spaced times t_1, t_2, t_3, t_4. (*b*) In the reference frame of the compartment, the light travels in a parabolic path, as would a ball were it projected horizontally. Note that in both (*a*) and (*b*) the vertical displacements are greatly exaggerated for emphasis.

the Sun.[16] The deflection, or bending, is computed as follows. Rewriting the spacetime interval (Equation 2-42) in polar coordinates,

$$ds^2 = c^2\,dt^2 - (dr^2 + r^2\,d\theta^2 + r^2\sin^2\theta\,d\varphi^2) \tag{2-47}$$

Since the deflection of the light beam occurs in a plane, the two-dimensional version of Equation 2-47 is

$$ds^2 = c^2\,dt^2 - (dr^2 + r^2\,d\theta^2) \tag{2-48}$$

Einstein showed that Equation 2-48 is modified in the presence of a (spherical, nonrotating) mass M to become

$$ds^2 = \gamma(r)^2 c^2\,dt^2 - dr^2/\gamma(r)^2 - r^2\,d\theta^2 \tag{2-49}$$

where $\gamma(r) = (1 - 2GM/c^2r)^{1/2}$, with G = universal gravitational constant and r = distance from the center of mass M. The factor $\gamma(r)$ is roughly analogous to the γ of special relativity. In the following Exploring section on gravitational redshift, we will describe how $\gamma(r)$ arises. For now, $\gamma(r)$ can be thought of as correcting for *gravitational time dilation* (the first term on the right of Equation 2-49) and *gravitational length contraction* (the second term).

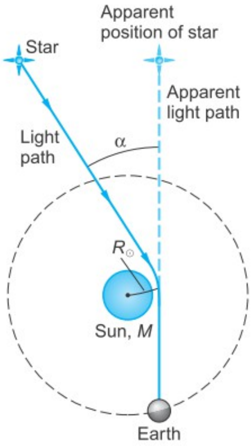

FIGURE 2-20 Deflection (greatly exaggerated) of a beam of starlight due to the gravitational attraction of the Sun.

This situation is illustrated in Figure 2-20, which shows the light from a distant star just grazing the edge of the Sun. The gravitational deflection of light (with mass $\gamma m = E/c^2$) can be treated as a refraction of the light. The speed of light is reduced to $\gamma(r)c$ in the vicinity of the mass M since $\gamma(r) < 1$ (see Equation 2-49), thus bending the wave fronts, and hence the beam, toward M. This is analogous to the deflection of starlight toward Earth's surface as a result of the changing density—hence index of refraction—of the atmosphere. By integrating Equation 2-49 over the entire trajectory of the light beam (recall that $ds = 0$ for light) as it passes by M, the total deflection α is found to be[17]

$$\alpha = 4GM/c^2R \tag{2-50}$$

where R = distance of closest approach of the beam to the center of M. For a beam just grazing the Sun, $R = R_\odot$ = solar radius = 6.96×10^8 m. Substituting the values for G and the solar mass ($M = 1.99 \times 10^{30}$ kg) yields $\alpha = 1.75$ arc second.[18]

Ordinarily, of course, the brightness of the Sun prevents astronomers (or anyone else) from seeing stars close to the limbs (edges) of the Sun, except during a total eclipse. Einstein completed the calculation of α in 1915, and in 1919 expeditions were organized by Eddington[19] at two points along the line of totality of a solar eclipse, both of which were successful in making measurements of α for several stars and testing the predicted $1/R_\odot$ dependence of α. The measured values of α for grazing beams at the two sites were

At Sobral (South America): $\alpha = 1.98 \pm 0.12$ arc seconds
At Principe Island (Africa): $\alpha = 1.61 \pm 0.30$ arc seconds

their average agreeing with the general relativistic prediction to within about 2 percent. Figure 2-21 illustrates the agreement of the $1/R_\odot$ dependence with Equation 2-50. (Einstein learned of the successful measurements via a telegram from H. A. Lorentz.) Since 1919, many measurements of α have been made during eclipses. Since the development of radio telescopes, which are not blinded by sunlight and hence don't require a total eclipse, many more measurements have been made. The latest data agree with the deflection predicted by general relativity to within about 0.1 percent.

The gravitational deflection of light is being put to use by modern astronomers via the phenomenon of *gravitational lensing* to help in the study of galaxies and other large masses in space. Light from very distant galaxies passing near or through other galaxies or clusters of galaxies between the source and Earth can be bent so as to reach Earth in much the same way that light from an object on a bench in the laboratory can be refracted by a glass lens and thus reach the eye of an observer. An intervening galaxy or cluster of galaxies can thus produce images of the distant source, even ones magnified and distorted, just as the glass lens can. Figure 2-22*a* will serve as a reminder of a refracting lens in the laboratory, while Figure 2-22*b* illustrates the corresponding action of a gravitational lens. The accompanying photograph shows the images of several distant galaxies drawn out into arcs by the lens effect of the cluster of galaxies in the center. The first confirmed discovery of images formed by a gravitational lens, the double image of the quasar QSO 0957, was made in 1979 by D. Walsh and his coworkers. Since then astronomers have found many such images. Their discovery and interpretation is currently an active area of research (see Chapter 13).

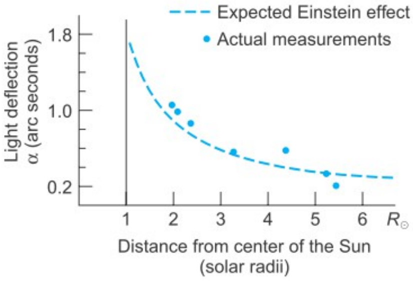

FIGURE 2-21 The deflection angle α depends on the distance of closest approach $R_\odot$ according to Equation 2-50. Shown here is a sample of the data for 7 of the 13 stars measured by the Eddington expeditions. The agreement with the relativistic prediction is apparent.

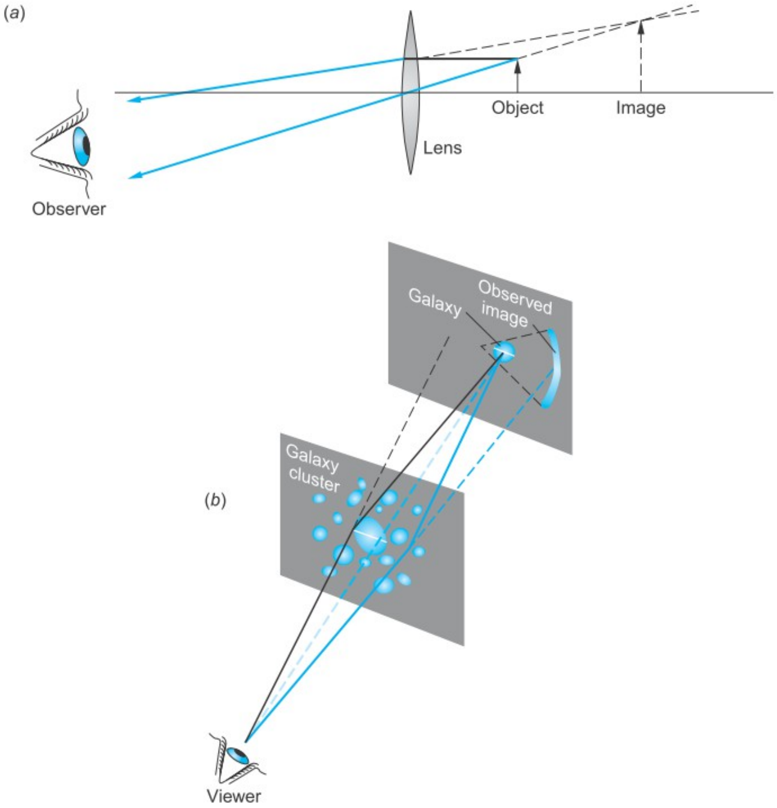

FIGURE 2-22 (*a*) Ordinary refracting lens bends light, causing many rays that would not otherwise have reached the observer's eye to do so. Their apparent origin is the image formed by the lens. Notice that the image is not the same size as the object (magnification) and, although not shown here, the shape of the lens can cause the image shape to be different from that of the object. (*b*) Gravitational lens has the same effects on the light from distant galaxies seen at Earth.

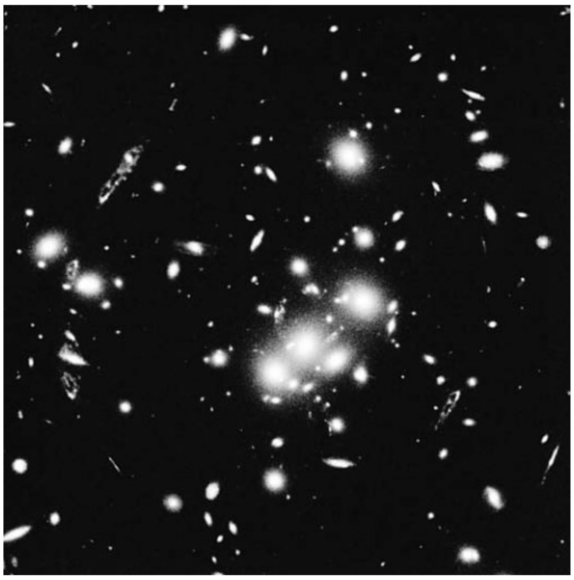

Images of distant galaxies are drawn out into arcs by the massive cluster of galaxies Abell 2218, whose enormous gravitational field acts as a lens to magnify, brighten, and distort the images. Abell 2218 is about 2 billion $c \cdot$ y from Earth. The arcs in this January 2000 Hubble Space Telescope photograph are images of galaxies 10 to 20 billion $c \cdot$ y away. [*NASA, A. Fruchter; ERO Team.*]

EXPLORING
Gravitational Redshift

A second prediction of general relativity concerns the rates of clocks and the frequencies of light in a gravitational field. As a specific case that illustrates the gravitational redshift as a direct consequence of the equivalence principle, suppose we consider two identical light sources (A and A') and detectors (B and B') located in identical spaceships (S and S') as illustrated in Figure 2-23. The spaceship S' in Figure 2-23*b* is located far from any mass. At time $t = 0$, S' begins to accelerate, and simultaneously an atom in the source A' emits a light pulse of its characteristic frequency f_0. During the time $t(= h/c)$ for the light to travel from A' to B', B' acquires a speed $v = at = gh/c$, and the detector B', receding from the original location of A', measures the frequency of the incoming light to be f *redshifted* by a fractional amount $(f_0 - f)/f_0 \approx \beta$ for $v = c$ (see Section 1-5). Thus,

$$(f_0 - f)/f_0 = \Delta f/f \approx \beta = v/c = gh/c^2 \qquad \textbf{2-51}$$

Notice that the right side of Equation 2-51 is equal to the gravitational potential (i.e., the gravitational potential energy per unit mass) $\Delta\phi = gh$ between A and B, divided by c^2. According to the equivalence principle, the detector at B in S must also measure the frequency of the arriving light to be f, even though S is at rest on the planet and, therefore, the shift cannot be due to the Doppler effect! Since the vibrating atom that produced the light pulse at A can be considered to be a clock, and since no "cycles" of the vibration

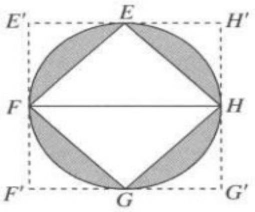
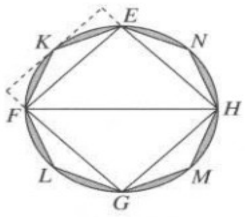
Area and Circumference

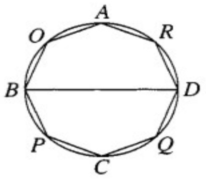
Any proof that relies on Lemma 6.2.2 is said to use the **method of exhaustion**. Eudoxus used this technique to prove many theorems. These include that the volumes of two spheres are to each other as the cubes of their radii, the volume of a pyramid equals one third the volume of a prism of the same base and the same height, and the volume of a cone is one third the volume of a cylinder with the same base and of the same height (Kline 1972, 50). He also used it to prove the next theorem.

■ **THEOREM 6.2.3 [*Elements* XII.2]**

The areas of two circles are to one another as the squares of their diameters.







PROOF

Take two circles and call them $\odot ABCD$ and $\odot EFGH$, where $\overline{BD}$ is a diameter of the first circle and $\overline{FH}$ is a diameter of the second. We need to show

$$\frac{\text{area}(\odot ABCD)}{\text{area}(\odot EFGH)} = \frac{BD^2}{FH^2}.$$

Suppose not, and let s be an area that is either less than or greater than the area of $\odot EFGH$, so that

$$\frac{\text{area}(\odot ABCD)}{s} = \frac{BD^2}{FH^2}. \qquad (6.8)$$

We will show that the first case leads to a contradiction and leave the second to Exercise 6. So assume that

$$s < \text{area}(\odot EFGH).$$

We will apply the procedure of Lemma 6.2.2 to the magnitudes

$$\text{area}(\odot EFGH)$$

and

$$\text{area}(\odot EFGH) - s.$$

To do this, first construct $\square EFGH$ inscribed within $\odot EFGH$ and $\square E'F'G'H'$ circumscribed about it. Then appealing to Exercise 5, we have

$$2\text{area}(\square EFGH) = \text{area}(\square E'F'G'H') > \text{area}(\odot EFGH), \qquad (6.9)$$

so

$$\text{area}(\square EFGH) > \frac{1}{2}\text{area}(\odot EFGH).$$

Take $\square EFGH$ and remove it from $\odot EFGH$, resulting in the shaded area in the first figure. We next construct isosceles $\triangle FKE$ with K on the circle. We observe that

$$\text{area}(\triangle FKE) = \frac{1}{2}\text{area}(\sqsubset FKE) > \frac{1}{2} \text{ the area enclosed by } \widehat{FKE}.$$

This is because if a tangent is drawn at K and a rectangle is constructed on the tangent with base $\overline{FE}$, the area of $\triangle EKF$ is half that of the rectangle. Repeat this with the isosceles $\triangle ENH$, $\triangle HMG$, and $\triangle GLF$. Letting a represent the sum of the areas of these four triangles, we conclude that

$$a > \frac{1}{2}\text{area(shading on the right)},$$

and we remove a from the shading in the first figure resulting in the shading of the second. We continue this process of constructing isosceles triangles so that at each step an area is removed that is more than half of the area that remains from the previous step. Lemma 6.2.2 tells us that eventually the remaining area will be less than the area of $\odot EFGH$ minus s. Suppose that the process stops as with the second diagram on page 186 so that

$$\text{area(shading on the right)} < \text{area}(\odot EFGH) - s.$$

Since the area of polygon $EKFLGMHNE$ is equal to the area of $\odot EFGH$ less the shading, we conclude that

$$\text{area}(EKFLGMHN) > s. \qquad (6.10)$$

We now need to include $\odot ABCD$ so that we can set up the ratio. Construct the polygon $AOBPCQDR$ so that it is similar to the polygon $EKFLGMHN$ and inscribed within $\odot ABCD$. This yields

$$\frac{BD^2}{FH^2} = \frac{\text{area}(AOBPCQDR)}{\text{area}(EKFLGMHN)} \qquad (6.11)$$

by Exercise 5, and then by Equation 6.8 we have

$$\frac{\text{area}(\odot ABCD)}{s} = \frac{\text{area}(AOBPCQDR)}{\text{area}(EKFLGMHN)}.$$

Since the area of $\odot ABCD$ is greater than the area of $AOBPCQDR$, s must be greater than the area of $EKFLGMHN$, a contradiction of Inequality 6.10. Therefore, s cannot be less than the area of $\odot EFGH$. This combined with Exercise 6 proves that $s = \text{area}(\odot EFGH)$. ■

The theorem can be used to derive the formula for the area of a circle. Let A be the area of a randomly selected circle and r its radius. The theorem shows that the ratio $A/4r^2$ is the same number no matter which circle is chosen. Call this number $\pi/4$ and write

$$\frac{A}{4r^2} = \frac{\pi}{4},$$

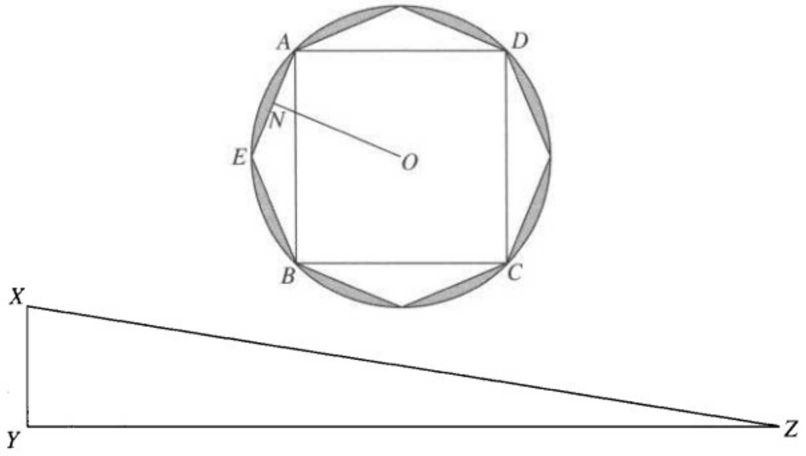
from which we quickly derive

$$A = \pi r^2. \tag{6.12}$$

Now to find the circumference. Archimedes provided the calculation in his work *Measurement of a Circle* (Archimedes 1897, 91–98).

■ **THEOREM 6.2.4** [***Measurement of a Circle* 1**]

The area of a circle is equal to the area of a right triangle in which the length of one leg equals the radius of the circle and the other leg equals the circumference of the circle.



PROOF

The proof uses the method of exhaustion. Let $\odot ABCD$ be the given circle and let $\triangle XYZ$ be such that XY equals the radius of the circle and YZ equals its circumference. To obtain a contradiction, first suppose that the area of the circle is greater than the area of the triangle. Inscribe $\square ABCD$ within $\odot ABCD$. Bisect the arcs cut by $\overline{AB}$, $\overline{BC}$, $\overline{CD}$, and $\overline{DA}$. Join the resulting midpoints to form a regular octagon. Continue this process until we find a regular polygon inscribed within the circle such that its area is a and

$$\text{area}(\odot ABCD) - a < \text{area}(\odot ABCD) - \text{area}(\triangle XYZ)$$

by Lemma 6.2.2. Thus, we have

$$a > \text{area}(\triangle XYZ).$$

Suppose that the polygon with area a is the polygon in the diagram. Let $\overline{AE}$ be a side of the polygon. Find N on $\overline{AE}$ such that $\overline{ON}$ is perpendicular to $\overline{AE}$. Then ON is less than the radius of $\odot ABCD$ and thus less than XY. Furthermore, the perimeter of the polygon is less than the circumference, so it is also less than YZ. Therefore, since the area of a regular polygon equals half the product of its apothem and its perimeter,

$$a < \text{area}(\triangle XYZ),$$

a contradiction. The case when the area of the circle is less than the area of the triangle is similarly brought to a contradiction by using circumscribed polygons (Exercise 7). ■

In modern notation the theorem states that if A is the area of a circle, C its circumference, and r is its radius,

$$A = \frac{Cr}{2}.$$

By Equation 6.12 we conclude that $\pi r^2 = Cr/2$. Hence,

$$C = 2\pi r,$$

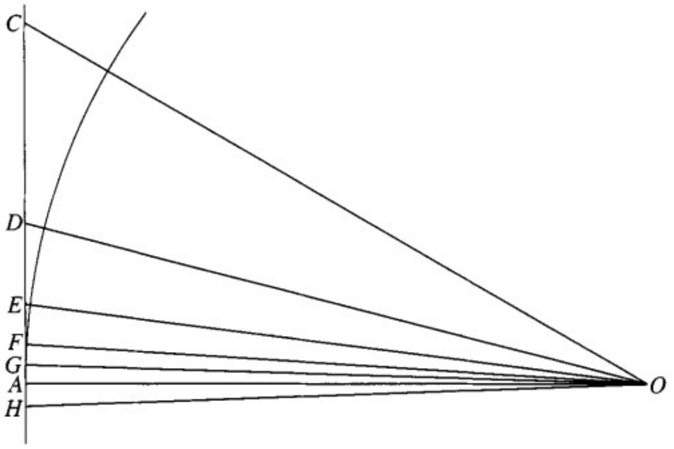
and we see further that π represents the ratio of a circle's circumference to its diameter.

Estimating Pi

Now that we have formulas for the area and circumference of a circle, it is natural to try to determine the value of π. Archimedes succeeded in finding an estimate in his *Measurement of a Circle*. His used the strategy found in the method of exhaustion.

■ **THEOREM 6.2.5** [*Measurement of a Circle* 3]

The circumference of a circle is greater than $3\frac{10}{71}$ times its diameter but less than $3\frac{1}{7}$ times its diameter.



PROOF

We are given $\odot O$ with radius $\overline{OA}$. The goal is to both inscribe and circumscribe a regular 96-gon about the circle and to use those polygons to estimate π. Find C so that $\overline{AC}$ is tangent to $\odot O$ and $\sphericalangle COA$ is a third of a right angle. We may view $\overline{AC}$ as half of one side of a regular dodecagon circumscribed about the circle. Now construct a sequence of angle bisectors:

- Bisect $\sphericalangle COA$ with $\overline{OD}$.
- Bisect $\sphericalangle DOA$ with $\overline{OE}$.
- Bisect $\sphericalangle EOA$ with $\overline{OF}$.
- Bisect $\sphericalangle FOA$ with $\overline{OG}$.

Assume that D, E, F, and G are on $\overline{AC}$. Therefore, $m\sphericalangle GOA$ is $1/48$ that of a right angle. Extend $\overline{GA}$ to H so that $\overline{GA} \cong \overline{AH}$ and $\sphericalangle GOA \cong \sphericalangle HOA$. We see that $m\sphericalangle GOH$ is $1/24$ that of a right angle, so $\overline{GH}$ can be considered one side of a regular 96-gon circumscribed about $\odot O$. Its perimeter is $96GH$. We therefore conclude that

$$\pi = \frac{\text{circumference of } \odot O}{\text{diameter of } \odot O} < \frac{96GH}{2OA} = \frac{96GA}{OA}. \tag{6.13}$$

We need to find an estimate for GA/OA. In order to accomplish this, begin by noticing that the angles constructed above yield a sequence of ratios,

$$\frac{OA}{CA}, \frac{OA}{DA}, \frac{OA}{EA}, \frac{OA}{FA}, \frac{OA}{GA},$$

where each numerator is the radius of the circle and each denominator is half the length of a side of a regular polygon that has been circumscribed about the circle. Note that since $\triangle COA$ is a 30-60-90 triangle,

$$\frac{OC}{CA} = 2 \text{ and } \frac{OA}{CA} = \sqrt{3}.$$

Hence,

$$\frac{OC}{CA} = \frac{306}{153} \tag{6.14}$$

and

$$\frac{OA}{CA} > \frac{265}{153}. \tag{6.15}$$

The fraction $265/153$ is chosen to approximate $\sqrt{3}$, and $306/153$ is chosen to have the same denominator as the first fraction, yet equal 2.

For the second ratio of our sequence, because $\overline{OD}$ bisects $\sphericalangle COA$, we may appeal to Exercise 19 of Section 5.4 and conclude that

$$\frac{OC}{OA} = \frac{CD}{DA}.$$

Therefore,

$$\frac{OC + OA}{OA} = \frac{CD + DA}{DA} = \frac{CA}{DA},$$

and we have *permutando*,

$$\frac{OA}{DA} = \frac{OC + OA}{CA} = \frac{OC}{CA} + \frac{OA}{CA} > \frac{306}{153} + \frac{265}{153}.$$

The last inequality follows from Equation 6.14 and Inequality 6.15. Therefore, we have

$$\frac{OA}{DA} > \frac{571}{153}$$

as a lower bound for the second term of the sequence. By the Pythagorean Theorem we know that $OD^2 = OA^2 + DA^2$. Hence,

$$\frac{OD^2}{DA^2} = \frac{OA^2 + DA^2}{DA^2} > \frac{571^2 + 153^2}{153^2} = \frac{349,450}{23,409},$$

so we have

$$\frac{OD}{DA} > \frac{591\frac{1}{8}}{153}.$$

This allows us to find a lower bound for the third term of the sequence because we may repeat the argument above to find that

$$\frac{OA}{EA} = \frac{OD}{DA} + \frac{OA}{DA},$$

and then

$$\frac{OA}{EA} > \frac{1162\frac{1}{8}}{153} \text{ and } \frac{OE}{EA} > \frac{1172\frac{1}{8}}{153}. \tag{6.16}$$

Similarly,

$$\frac{OA}{FA} > \frac{2334\frac{1}{4}}{153} \text{ and } \frac{OF}{FA} > \frac{2339\frac{1}{4}}{153}, \tag{6.17}$$

and finally,

$$\frac{OA}{GA} > \frac{4673\frac{1}{2}}{153}. \tag{6.18}$$

From Inequalities 6.13 and 6.18, we conclude that

$$\pi < \frac{96GA}{OA} < \frac{96 \cdot 153}{4673\frac{1}{2}} = 3 + \frac{667\frac{1}{2}}{4673\frac{1}{2}} < 3 + \frac{667\frac{1}{2}}{4672\frac{1}{2}} = 3\frac{1}{7} \tag{6.19}$$

A similar argument using inscribed polygons will yield the lower limit. ■

Without decimal notation, calculators, or computers, Archimedes found upper and lower bounds on π equivalent to

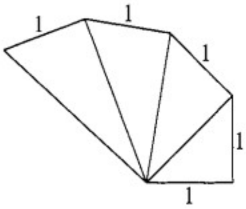
$$3.140845070 < \pi < 3.142857143.$$

Furthermore, the upper bound of π is the famous Archimedean approximation:

$$\pi \approx \frac{22}{7}.$$

Exercises

1. Theodorus showed that $\sqrt{n}$ is irrational when the radicand n is not a perfect square and $2 \leqslant n \leqslant 17$. Use the diagram below to make a conjecture on why Theodorus stopped at 17.



2. Use Antiphon's method of finding the area of a circle to estimate π accurate to five decimal places. What is the minimum number of sides of the inscribed polygon that is necessary to accomplish this?

3. Show that the proof of Lemma 6.2.2 still works if $\overline{DE}$ is divided into an even number of segments.

4. Identify the unstated assumptions in Lemma 6.2.2.

5. Prove Equations 6.9 and 6.11 of the proof of Theorem 6.2.3.

6. Prove that the assumption $s >$ area($\odot EFGH$) also leads to a contradiction in the proof of Theorem 6.2.3.

7. In Archimedes' proof of Theorem 6.2.4, prove that the case when the area of the circle is less than the area of the triangle yields a contradiction using circumscribed polygons.

8. Burton (1985, 126) observes that Archimedes used but never proved that

$$\frac{1351}{780} > \sqrt{3} > \frac{265}{153}, \tag{6.20}$$

and he conjectured that Archimedes would have demonstrated the left-hand inequality by relying on the following two inequalities. Show both.

(a) $26 - \frac{1}{52} = \sqrt{26^2 - 1 + \left(\frac{1}{52}\right)^2} > \sqrt{26^2 - 1}.$

(b) $\frac{1351}{780} = \frac{1}{15}\left(26 - \frac{1}{52}\right) > \frac{\sqrt{26^2 - 1}}{15} = \sqrt{3}.$

9. Prove the right-hand side of Inequality 6.20 by replacing $1/52$ with $1/51$ in the inequalities of Exercise 8.

10. Given a circle with unit radius:
    (a) Construct an octagon inscribed within the circle.
    (b) Construct an octagon circumscribed about the circle.
    (c) Use the two octagons to approximate the area of the circle and then use this result to approximate the value of π.
    (d) What size n-gon is required so that the difference between the estimate for π and its true value is less than 0.001?

11. Use calculus to prove that $A = \pi r^2$ and $C = 2\pi r$.

12. Check that Inequalities 6.16, 6.17, 6.18, and 6.19 on page 191 hold.

13. Show that the ratio of the area of a circle to the square of its diameter is approximately $11/14$ without a calculator.

14. The volume of a cone is one third the volume of a cylinder with the same base and of the same height.
    (a) Write an algebraic equation for this geometric expression.
    (b) Use calculus to prove it.

15. The volumes of two spheres are to one another as the cubes of their radii.
    (a) Write an algebraic equation for this geometric expression.
    (b) Use calculus to prove it.

6.3 THE METHOD

Take a two-by-four and place it across a sawhorse. What we have is a crude **lever** with the sawhorse as the **fulcrum**. Put a brick on one end of the two-by-four and three bricks at the other end. We know that for this to balance, we must move the lumber so that the distance from the fulcrum to the lone brick is longer than that to the three bricks. More precisely, if m_1 is the mass of the single brick and d_1 is its distance to the fulcrum, and if m_2 is the mass of the three bricks with d_2 the distance from the bricks to the fulcrum, then for the lever to balance we need

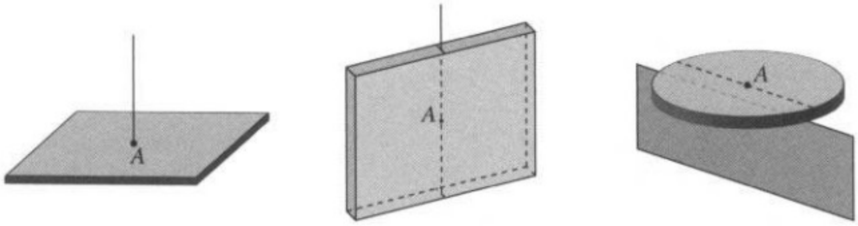
$$\frac{m_1}{m_2} = \frac{d_2}{d_1}. \tag{6.21}$$

Now make the situation abstract. Represent the two-by-four as a line segment and the sawhorse as a point on the segment. Treat the masses as if they are concentrated in a point. We say that this **system** is in **equilibrium** if the lever balances, and it will balance if and only if Equation 6.21 holds. This proposition is known as the **Law of the Lever**, and Archimedes gave a nearly complete proof of it in his *On the Equilibrium of Planes* (Archimedes 1897, 189–220).

The Law of the Lever was known before the time of Archimedes. The significance of *On the Equilibrium of Planes* was not the novelty of the concept but how it was presented. Archimedes was the first to derive the Law of the Lever from a set of postulates. Each of these assumptions was chosen by Archimedes because he considered each to be clearly true based on his own experience. In so doing, Archimedes became the first Greek to treat what happened on the earth mathematically. Plato viewed the universe as an imperfect representation of the realm of forms, and mathematics was the way to escape this world and learn about the true reality. Aristotle believed that one learns truth by observation, but although his *Physics* dealt with natural phenomena, it was based on nonmathematical intuition. Archimedes followed neither one. Instead, he believed that natural phenomena can be studied using the method of the *Elements*. From agreed upon and simple first principles that reflect nature, laws of the universe can be deduced mathematically because mathematics perfectly represents the world in which we live (Boyer and Merzbach 1991, 121–122).

Center of Gravity

The point at which we find the fulcrum of a system of weights that is in equilibrium is called the **center of gravity** of the system. We assume that the total weight of the system is concentrated at this point. We now generalize this concept of balance to other situations. We first deal with a single object. Take either a plane or solid figure. If it is only two-dimensional, view it as having a nearly infinitesimal thickness and uniform density. Such an object is called a **lamina**. The ancient Greeks knew of three possible interpretations for what it meant to balance such an object (Figure 6.7). The first two have the object being suspended in some way. The **horizontal suspension** point is the location where an object must be attached to a wire so that it is perfectly balanced in the horizontal direction. Now take the object and hang it vertically by



(a) Horizontal suspension. (b) Vertical suspension. (c) Balance.

Figure 6.7 Centers of gravity.

the wire. From the point connected to the wire draw a vertical line. Remove the object, rotate it a few degrees, and then hang again vertically so that it balances. When the second vertical line is drawn it will intersect the first in the **vertical suspension** point. Finally, imagine an extremely thin metal sheet standing upright. The intersection of all lines on which the object will balance on that sheet we call the **balance** point. Although experiment would confirm our guess, we assume that these three interpretations result in the same point that we define to be the center of gravity of the object (Stein 1999, 15–17). We also make the following two assumptions:

■ **POSTULATES 6.3.1 [*On the Equilibrium of Planes* I, Postulates]**

1. The centers of gravity of similar figures are in the same relative positions.
2. The center of gravity of a convex polygon must lie within the figure.

We now follow Archimedes to generalize the center of gravity to any number of weights. He began by proving the following special case. See Exercise 2.

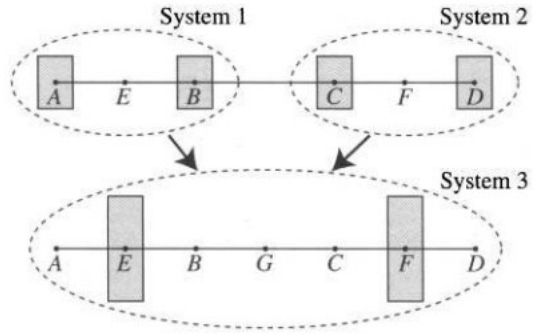
■ **THEOREM 6.3.2 [*On the Equilibrium of Planes* I.4, 5]**

- If the centers of gravity of two equal weights are not at the same point, the weights balance at the midpoint of the segment joining their centers of gravity.
- If three equal weights have their centers of gravity on a straight line at equal distances, the center of gravity of the system will coincide with the center of gravity of the middle weight.

Theorem 6.3.2 can be generalized to any number of weights. We deal with the even number case here and leave the odd case to Exercise 4. Since the two-weight result is the first part of Theorem 6.3.2, to prove the result for an even number of weights, we start with four.

■ **THEOREM 6.3.3 [*On the Equilibrium of Planes* I.5 Corollary]**

If an even number of equal weights have their centers of gravity on a straight line such that the distances between any pair of consecutive centers of gravity are the same, the midpoint of the segment joining the middle two centers of gravity is the center of gravity of the entire system.



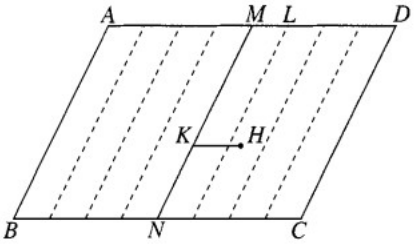
PROOF

Let weights of equal magnitude be placed on a line segment so that their centers of gravity are at points A, B, C, and D. Let E be the midpoint of $\overline{AB}$, and let F be the midpoint of $\overline{CD}$. By Theorem 6.3.2, the total mass of System 1 is concentrated at E, and the total mass of System 2 is at F. Now the lever can be viewed as in System 3, with G being the midpoint of $\overline{EF}$. Since the mass at E equals the mass at F, the system is in equilibrium with center of gravity G. Since $\overline{EB} \cong \overline{CF}$ and $\overline{EG} \cong \overline{GF}$, we have $\overline{BG} = \overline{GC}$. Hence, G is the midpoint of $\overline{BC}$. Generalize this procedure to complete the proof. ■

As an example of how Archimedes worked with centers of gravity, we shall find the center of gravity of a parallelogram.

■ **THEOREM 6.3.4 [*On the Equilibrium of Planes* I.9]**

The center of gravity of a parallelogram lies on the segment joining the midpoints of opposite sides.



PROOF

Let $ABCD$ be a parallelogram. Assume that M is the midpoint of $\overline{AD}$ and N is the midpoint of $\overline{BC}$. Join $\overline{MN}$. Designate the center of gravity of the parallelogram by H. We must prove that H is on $\overline{MN}$, so suppose it lies elsewhere inside the parallelogram (Postulate 6.3.1.2). Find K on $\overline{MN}$ so that $\overline{KH}$ is parallel to $\overline{AD}$. Find the midpoint of $\overline{MD}$. This divides the segment into two segments. Find the midpoint of one of these resulting segments and divide again. By continually finding midpoints in this fashion, we can locate L on $\overline{MD}$ such that $ML < KH$ (Lemma 6.2.2). Using this length, divide both $\overline{AM}$ and $\overline{MD}$ into consecutive congruent line segments of length ML. At the endpoints of each of these congruent segments, draw lines parallel to $\overline{MN}$. The resulting parallelograms are congruent. Therefore, their centers of gravity are in the same relative position (Postulate 6.3.1.1). This means that we have an even number of magnitudes of equal weight with collinear centers of gravity. Thus, by Theorem 6.3.3 the center of gravity of the system of parallelograms is on the midpoint of the line segment joining the centers of gravity of the middle two parallelograms, but this is impossible because H does not lie within either of these parallelograms. We are forced to conclude that H lies on $\overline{MN}$. ■

The last proposition quickly yields the next, so its proof is left to Exercise 5.

■ **THEOREM 6.3.5**

The center of gravity of a parallelogram lies at the intersection of its diagonals.

The Letter to Eratosthenes

Nearly all of the extant works of the ancient Greek mathematicians came down to us in their finished, polished form. By our own experience, work in mathematics does not flow directly from theorem to finished proof in one sitting. It may take hours, days, weeks, and in some cases years to write a proof. There are times of progress and times of stagnation. Often, a promising argument leads to a dead end, while an idea out of nowhere may be exactly what is needed. It would be fascinating and highly instructive if we could find a book of notes written by someone like Eudoxus that would illuminate the process by which he came by his results. In the case of Archimedes, *The Method* is that example. As with many of the works of Archimedes, *The Method* is actually a letter. It was written to his good friend Eratosthenes. More important, Archimedes knew that Eratosthenes was the perfect person to which to send this.

> Seeing moreover in you, as I say, an earnest student, a man of considerable eminence in philosophy, and an admirer [of mathematical inquiry], I thought fit to write out for you and explain in detail in the same book the peculiarity of a certain method, by which it will be possible for you to get a start to enable you to investigate some of the problems in mathematics by means of mechanics. (Archimedes 1897, *The Method*, Introduction, 13).

Eratosthenes was born in Cyrene around 284 B.C. Beside mathematics he studied philosophy and poetry. He combined his interests and wrote a summary of the mathematics needed for the study of Platonic philosophy. It included the tale of the Delians with their problem of doubling the volume of their altar (Section 4.3). His *On Means* was included in the *Treasury of Analysis* of Pappus. He studied geography and wrote *On the Measurement of the Earth*. Because of his expertise, he was invited to Egypt by Ptolemy Evergetes around the year 244 B.C. to tutor his son. He later became the librarian at Alexandria. Although he was expert in many fields, he was never viewed as the leading scholar in any of them. Mathematics is a case in point, where he was second to Archimedes. Because he always seemed to come in second, he gained the nickname *Beta* (Heath 1921b, 104–107).

Eratosthenes is famous for two main contributions that are still taught today. The first is in the field of number theory. The ancient Greeks did study numbers, including the prime numbers (page 47). Eratosthenes' contribution is an algorithm designed to identify the primes in a list of given numbers. It is known as the **sieve of Eratosthenes** (Figure 6.8). The sieve works like this. Make a list of consecutive numbers starting with 2 and ending with n. Circle 2 but cross out all other multiples of two. Next, circle 3 (the next number that is neither circled nor crossed-out) and cross out all other multiples of three. Repeat this process until the next available number is greater than $\sqrt{n}$. At his point, as seen in Figure 6.8, all circled and nonmarked numbers are prime.

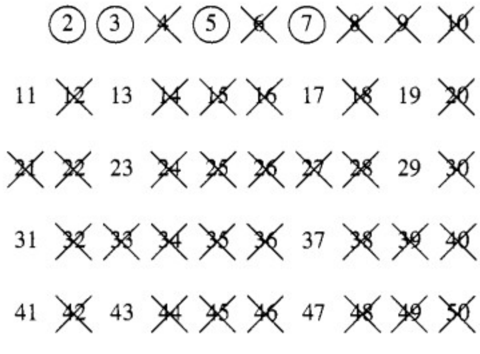


Figure 6.8 The sieve of Eratosthenes.

The second of Eratosthenes' contributions is usually taught in trigonometry or high school geometry courses. It was known that on the summer solstice the sun would be directly above Syene (now Aswan) in Egypt. This was confirmed by noting that the sun could be seen at the bottom of a well. Also on the summer solstice, at Alexandria the sun formed an angle equivalent to one fiftieth of a circle. This is the angle α in Figure 6.9. If we suppose that the rays of the sun form parallel lines, we may conclude that the measure of the arc between the two cities is also α. Estimate the distance between Syene and Alexandria to be 5000 stadia. This is based on how long it took a caravan with camels to travel between those two cities (Kline 1972, 160–161). Since the cities were approximately on the same longitudinal line and α represents one fiftieth of a circle, the circumference of the globe can be calculated to be approximately 250,000 stadia. Assuming that a stadia is equivalent to 517 feet, Eratosthenes' measurement equals 24,479 miles. The earth's true circumference is approximately 24,900 miles (24,902 miles at the equator and 24,860 miles pole to pole), so his measurement is off by 2%, the best among the ancient Greeks.

We see then that Eratosthenes had the intellectual résumé to appreciate and use the method that Archimedes was about to show him. Archimedes continues:

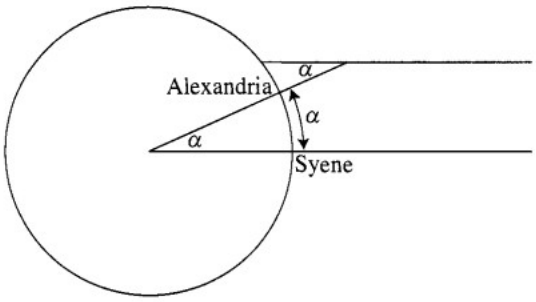

Figure 6.9 Eratosthenes and the circumference of the earth.

> This procedure, is I am persuaded, no less useful even for the proof of the theorems themselves; for certain things first became clear to me by a mechanical method, although they had to be demonstrated by geometry afterwards because their investigation by the said method did not furnish an actual demonstration. But it is of course easier, when we have previously acquired, by the method, some knowledge of the questions, to supply the proof than it is to find it without any previous knowledge. This is a reason why, in the case of the theorems the proof of which Eudoxus was the first to discover, namely that the cone is a third part of the cylinder, and the pyramid of the prism, having the same base and equal height, we should give no small share of the credit to Democritus, who was the first to make the assertion with regard to the said figure though he did not prove it. (Archimedes 1897, *The Method*, Introduction, 13)

Archimedes told Eratosthenes that the first theorem that he discovered using the method is the formula on page 177 for the area of a parabola. By repeating the method for different questions he convinced himself of the truth of many other results that he outlined for Eratosthenes. We will examine one of these by following Archimedes' line of thought as he uses his method to convince himself of the truth of his formula regarding the volume of a sphere, namely that

> the volume of a sphere is four times the volume of a cone with base area equal to that of a great circle of the sphere and height equal to its radius.

We start with the preliminary constructions. Let $\odot ABCD$ be a great circle of a sphere with perpendicular diameters $\overline{AC}$ and $\overline{BD}$ (Figure 6.10). Construct a circle with diameter $\overline{BD}$ and perpendicular to $\overline{AC}$. With this circle as its base, draw a cone with vertex A. Extend this cone to a new base that is a circle perpendicular to $\overline{AC}$ and with diameter $\overline{ECF}$. On this circle, construct a cylinder with height equal to AC. Finally, extend $\overline{AC}$ beyond A to H such that $\overline{HA} \cong \overline{AC}$. We shall view $\overline{HC}$ as a lever with fulcrum A.

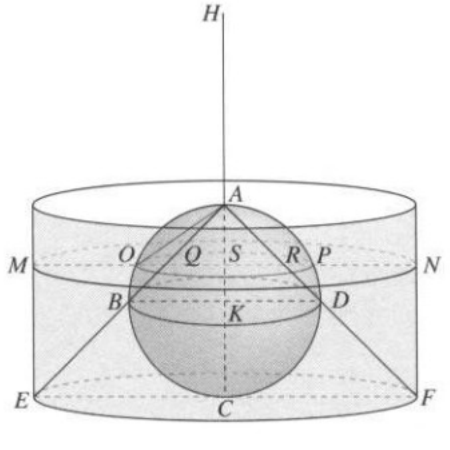

Figure 6.10 The sphere and its cone in a cylinder.

Next take a plane parallel to $\odot BD$ and intersect the cylinder. This forms a circle with diameter $\overline{MN}$. Call the points where $\overline{MN}$ intersects the sphere O and P. Further, $\overline{MN}$ intersects $\overline{AC}$ at S, $\overline{AE}$ at Q, and $\overline{AF}$ at R. Join $\overline{AO}$. This plane also intersects the sphere, forming a circle with diameter $\overline{OP}$, and it intersects the cone, forming a circle with diameter $\overline{QR}$.

Now that the setup is complete,

$$\overline{MS} \cong \overline{AC} \text{ and } \overline{QS} \cong \overline{AS}. \tag{6.22}$$

Therefore,

$$MS \cdot QS = AC \cdot AS = AO^2 = OS^2 + QS^2.$$

The last equality follows by the Pythagorean Theorem, and the second-to-last equality holds because $\triangle OAC \sim \triangle SAO$. Then, since $\overline{HA} \cong \overline{AC}$,

$$\frac{HA}{AS} = \frac{AC}{AS} = \frac{MS}{QS} = \frac{MS \cdot MS}{MS \cdot QS} = \frac{MS^2}{OS^2 + QS^2} = \frac{MN^2}{OP^2 + QR^2}.$$

Therefore,

$$\frac{HA}{AS} = \frac{\text{area(circle with diameter } \overline{MN})}{\text{area(circle with diameter } \overline{OP}) + \text{area(circle with diamter } \overline{QR})},$$

This means that if we take lever $\overline{HS}$ and place $\odot MN$ at S and both $\odot OP$ and $\odot QR$ at H, it balances at fulcrum A (Figure 6.11). The above can be repeated for any plane that cuts the cylinder parallel to its base. Archimedes now argues that since all of the slices of the cylinder at each S balance with the corresponding slices of the sphere and cone when placed at H with fulcrum A, the same lever will balance when the

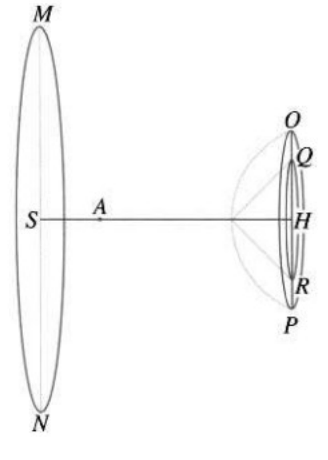

Figure 6.11 Circles formed by the plane in balance.

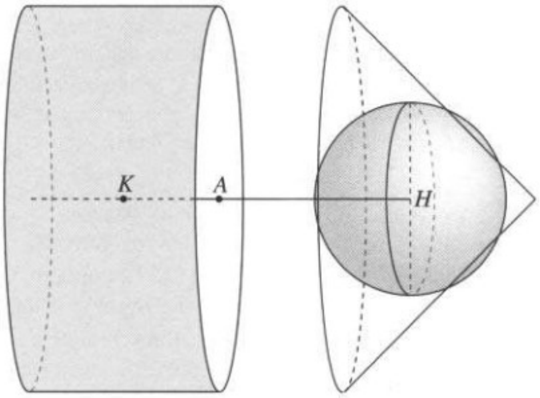

Figure 6.12 The cylinder balancing the sphere and cone.

entire cylinder is placed so that its center of gravity is at K while the sphere and cone are placed with their centers of gravity at H (Figure 6.12). By the Law of the Lever,

$$\frac{HA}{AK} = \frac{\text{volume(cylinder)}}{\text{volume(sphere)} + \text{volume(cone } AEF)}.$$

Since $HA = 2AK$,

$$\text{volume(cylinder)} = 2\text{volume(sphere)} + 2\text{volume(cone } AEF).$$

By Exercise 14 of Section 6.2,

$$\text{volume(cylinder)} = 3\text{volume(cone } AEF).$$

Thus,

$$\text{volume(cone } AEF) = 2\text{volume(sphere)},$$

but since $EF = 2BD$,

$$\text{volume(cone } AEF) = 8\text{volume(cone } ABD).$$

We may now conclude that

$$\text{volume(sphere)} = 4\text{volume(cone } ABD),$$

which is the formula.

At this point Archimedes observed that this method, which brought him to the formula for the volume of a sphere, also allowed him to derive the formula for the surface area of a sphere. He wrote:

> [f]rom this theorem, to the effect that a sphere is four times as great as the cone with a great circle of the sphere as base and with height equal to the radius of

> the sphere, I conceived the notion that the surface of any sphere is four times as great as a great circle in it; for, judging from the fact that any circle is equal to a triangle with base equal to the circumference and height equal to the radius of the circle, I apprehended that, in like manner, any sphere is equal to a cone with base equal to the surface of a sphere and height equal to its radius. (Archimedes 1897, *The Method*, 2, 20–21)

It seems that Archimedes' technique was quite productive.

The Method of Archimedes would have remained lost save by happy chance. In 1899, John L. Heiberg, a Danish scholar in ancient Greek mathematics and specialist on Archimedes, learned of a manuscript held at the library of the Holy Sepulchre at Jerusalem. The document was a **palimpsest**, a parchment manuscript that has had its original writing washed or scraped off and then reused for another purpose. In this case, the work was an Eastern Orthodox prayer book dating to about the thirteenth century. Fortunately, the original writing, dating to the tenth century, was not perfectly removed. Because of this, some of the original was translated and was seen to be a copy of a work of Archimedes. Hearing this, Heiberg had to see it, and he did in 1906 and 1908 at Constantinople. Heiberg translated what he could of the old text and discovered that the palimpsest contained copies of many Archimedean works. It includes *On the Sphere and Cylinder*, most of *On Spirals*, and parts of both *Measurement of a Circle* and *On the Equilibrium of Planes*, not to mention the only known Greek copy of *On Floating Bodies*. More important, it contains nearly all of *The Method*. This work of Archimedes had been cited by various writers, including some quotations, but the exact content had been unknown. The good fortune of the Heiberg discovery enables us to see some of the ideas behind Archimedes' great work. For further details see Netz and Noel (2007), Dijksterhuis (1987), and Archimedes (1897, The *Method* of Archimedes).

Exercises

1. Masses of a and b are placed at the ends of lever $\overline{AB}$ with fulcrum F.

   (a) If $a = 3$, $b = 7$, and $AF = 10$, what is FB?
   (b) If a is three times as massive as b when $AF = 20$, what is FB?
   (c) If the lever balances in its current configuration and then a mass b is added to the left-hand side, how far to the left must F be moved to make the lever balance?

2. Prove Theorem 6.3.2.

3. Rewrite the proof of Theorem 6.3.3 for the case of six equally spaced weights on a lever.

4. Prove that if five weights have their centers of gravity on a straight line such that the distances between any pair of consecutive centers of gravity are the same, the center of gravity of the middle segment is the center of gravity of the entire system.

5. Prove Theorem 6.3.5.

6. Show using any method that the center of gravity of:
   (a) a circle is its center.
   (b) a triangle is the intersection of two segments each joining a vertex with the midpoint of the opposite side.

7. Construct the center of gravity of a rectangle, a circle, and a triangle.

8. Use the sieve of Eratosthenes to find all prime numbers between 51 and 150.

9. The circumference of the earth's equator is 24,902 miles and the circumference of the great circle that has its diameter as the segment with its endpoints at the poles is 24,860 miles. Find the approximate volume of the earth in cubic miles.

10. Put a coordinate system on Figure 6.10 so that the center of the sphere K is the origin, D is $(0,\ a,\ 0)$, and A is $(0,\ 0,\ a)$. Find equations for:
   (a) $\overline{AF}$
   (b) $\odot OP$ where S is $(0,\ 0,\ s)$
   (c) $\odot QR$
   (d) $\odot MN$

11. Continue with Exercise 10.
   (a) Find the areas of $\odot OP$, $\odot QR$, and $\odot MN$
   (b) Show that HA/AS equals

$$\frac{\text{area(circle with diameter } \overline{MN})}{\text{area(circle with diameter } \overline{OP}) + \text{area(circle with diamter } \overline{QR})},$$

   (c) Compute the volume of the sphere $ABCD$, the cone AEF, and the cylinder with height AC and base $\odot EF$ by integration.
   (d) Use the volume just found to show that

$$\frac{HA}{AK} = \frac{\text{volume(cylinder)}}{\text{volume(sphere)} + \text{volume(cone } AEF)}.$$

12. Use Archimedes' method to show the following:
   (a) The volume of a cylinder with base equal to a great circle of a sphere and height equal to its diameter is $3/2$ times the volume of the sphere.
   (b) The volume of a right-angled conoid between its vertex and a plane perpendicular to its axis is $3/2$ times the volume of a cone that has the same base and the same height as the segment of the conoid.

13. Find the centers of gravity of the given solids using any method.
   (a) A right-angled conoid.
   (b) A hemisphere.
   (c) An obtuse-angled conoid.
   (d) A spheroid (oblong or flat).

7.2 THREE PROBLEMS

Viète made other contributions to mathematics besides his analytic art. In the field of geometry he worked issues related to the three famous Greek construction problems. The first is the Delian problem. The other two are known as **squaring the circle** and **trisecting an angle**. To square a circle means to find a square with the area of a given circle, while to trisect an angle means to divide an arbitrary angle into three congruent angles. These three problems cannot be constructed with a compass and straightedge alone, so they require other methods.

Square the Circle

Viète used his analysis to give the first equation for π involving an infinite sequence of algebraic operations. If he could find its value, he could square the circle by computing $\sqrt{\pi}$. Up to his day there were many estimates for π. Simply use Archimedes' method with regular polygons with more and more sides inscribed in and circumscribed about a circle. Viète's approach found this equation:

$$\frac{2}{\pi} = \sqrt{\frac{1}{2}}\sqrt{\frac{1}{2}+\frac{1}{2}\sqrt{\frac{1}{2}}}\sqrt{\frac{1}{2}+\frac{1}{2}\sqrt{\frac{1}{2}+\frac{1}{2}\sqrt{\frac{1}{2}}}}\cdots.$$

To represent this infinite product, Viète wrote the first four terms (without the square root sign but with an l for *latus*) and then noted, "*in infinitum observata uniformi methodo*" (Cajori 1928, vol. II, 78, 185). Boyer and Merzbach (1991, 321) note that this equation is closely linked to a curve called the **quadratrix**. The curve was discovered by Hippias around 475 B.C. Hippias was born in Elis in southern Greece, and he was a Sophist. Plato included him in two of his dialogues, but his portrayal was not very flattering (Plato 1961, *Hippias Major* and *Hippias Minor*).

The quadratrix was the first locus to be described by a Greek mathematician beyond the simple line and circle. It works like this: Take $\square ABCD$ and let $\overset{\frown}{BD}$ be the first quadrant of $\odot A$ with radius $\overline{AB}$. If $\overline{BC}$ moves uniformly to $\overline{AD}$ in the same amount of time as radius $\overline{AB}$ turns to $\overline{AD}$, the result is curve BHG in Figure 7.2. Letting HF represent the height of $\overline{BC}$ at a given point in time, due to the uniform motion, we see that

$$\frac{HF}{AB} = \frac{\theta}{\pi/2}.$$

Since $HF = AH\sin\theta$,

$$\frac{AH\sin\theta}{\theta} = \frac{2AB}{\pi}.$$

Letting $a = AB$ and $r = AH$, this becomes

$$r = \frac{2a\theta}{\pi\sin\theta} \tag{7.1}$$

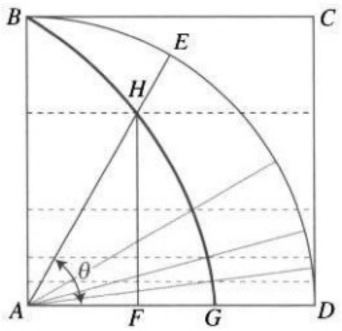

Figure 7.2 The quadratrix of Hippias.

in polar form. Therefore, because

$$\lim_{\theta \to 0^+} \frac{\theta}{\sin \theta} = 1,$$

there exists a point G on $\overline{AD}$ such that H lands on G when $\theta = 0$ and

$$AG = \frac{2a}{\pi}. \tag{7.2}$$

This equation means that the quadratrix has given us a segment that we can now use to construct a segment of length π with only a straightedge and compass. Namely,

$$\pi = \frac{2a}{AG},$$

and from this we can construct a segment of length $\sqrt{\pi}$. This is what we need to square the circle (Heath 1921a, 226–227).

Back to Viète's formula. Define the sequence r_n using Equation 7.1 with $a = 1$ and $\theta = \pi/2^n$,

$$r_n = \left(2^{n-1} \sin \frac{\pi}{2^n}\right)^{-1}$$

This equation amounts to taking a right angle, continually bisecting it, and finding the corresponding value on the quadratrix. Furthermore, observe that $r_1 = 1$ and by a double-angle formula,

$$\sin \frac{\pi}{2^{n-1}} = 2 \sin \frac{\pi}{2^n} \cos \frac{\pi}{2^n}.$$

This gives

$$\left(2 \sin \frac{\pi}{2^n}\right)^{-1} \left(\sin \frac{\pi}{2^{n-1}}\right) = \cos \frac{\pi}{2^n}.$$

Therefore,

$$\frac{r_n}{r_{n-1}} = \left(2^{n-1}\sin\frac{\pi}{2^n}\right)^{-1}\left(2^{n-2}\sin\frac{\pi}{2^{n-1}}\right) = \cos\frac{\pi}{2^n}. \tag{7.3}$$

We now proceed by examining the infinite product:

$$\frac{r_2}{r_1}\cdot\frac{r_3}{r_2}\cdot\frac{r_4}{r_3}\cdots = \lim_{n\to\infty}\left(r_2\cdot\frac{r_3}{r_2}\cdot\frac{r_4}{r_3}\cdots\frac{r_n}{r_{n-1}}\right) = \lim_{n\to\infty} r_n = \frac{2}{\pi}.$$

The last equality holds due to the limit implied by Equation 7.2. Substituting with Equation 7.3 gives

$$\cos\frac{\pi}{4}\cdot\cos\frac{\pi}{8}\cdot\cos\frac{\pi}{16}\cdots = \frac{2}{\pi},$$

and we then arrive at Viète's formula because

$$\begin{aligned}
\cos\frac{\pi}{4} &= \sqrt{\frac{1+\cos\pi/2}{2}} = \sqrt{\frac{1}{2}} \\
\cos\frac{\pi}{8} &= \sqrt{\frac{1+\cos\pi/4}{2}} = \sqrt{\frac{1}{2}+\frac{1}{2}\sqrt{\frac{1}{2}}} \\
\cos\frac{\pi}{16} &= \sqrt{\frac{1+\cos\pi/8}{2}} = \sqrt{\frac{1}{2}+\frac{1}{2}\sqrt{\frac{1}{2}+\frac{1}{2}\sqrt{\frac{1}{2}}}} \\
&\vdots
\end{aligned}$$

Duplicate the Cube

Viète solved the problem of duplicating the cube by again finding inspiration from the seventh book of the *Mathematical Collection* of Pappus. There he found problems that dealt with ***neusis***, a term that means "verging" or "inclination." According to Pappus, if a line passes through a point when produced, the line makes a neusis on that point. The general problem is that given two lines, place between them a segment of a given magnitude so that the segment intersects a particular point. The *neusis* often assumed that the segment had to be shifted from some other position so that it would include the desired point. Many Greek geometers used a *neusis* without explicitly stating it as a postulate or proving it as a theorem. For example, Archimedes did this in his work *On Spirals* (Pappus 1986, *Mathematical Collection*, Introduction, 112; Boyer 1956, 143; Archimedes 1897, c-ci).

To solve a *neusis* problem, one needs a tool besides a straightedge and compass. The ancient Greek geometer Nicomedes, who lived around 200 B.C., provided such a tool. Start with a horizontal **ruler** labeled $\overline{AB}$ (Figure 7.3). At its midpoint F attach another ruler perpendicular to the first. Call it $\overline{FE}$. On this second ruler fix a small peg at point C called the **pole**, and on C attach a third ruler that itself has a peg at D and at the other end a slot in which the peg at C can run. The peg of the third

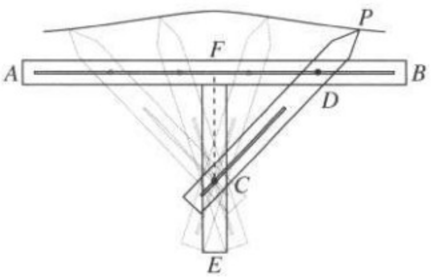

Figure 7.3 The first conchoid of Nicomedes.

ruler slides in a groove in ruler $\overline{AB}$. As the peg D slides along $\overline{AB}$, the endpoint P of the third ruler describes a locus of points that is known as the **first conchoid** of Nicomedes. If we let $DP = a$ (the **distance**) and $FC = b$ (Figure 7.4), then using polar coordinates the curve is given by the equation

$$r = a + b\csc\theta. \tag{7.4}$$

The derivation is left for Exercise 7. Proclus noted that there were other conchoids, but the details of the work of Nicomedes are no longer extant (Heath 1921a, 238–240).

Related to the conchoid is a curve known as a **cissoid**. The credit of the discovery of this curve is due to Diocles, who around 100 B.C. wrote *On Burning-glasses* in which he gave a solution to the duplication of the cube problem using this curve. The details of his solution are left to Exercise 11. To define the curve, take a circle with radius $\overline{AB}$ and construct $\overline{CD}$ to be the perpendicular bisector of the diameter (Figure 7.5). Find G and H on $\overline{AB}$ so that $\overline{GC} \cong \overline{CH}$ and erect perpendiculars at G and H that meet the circumference of the circle at E and F, respectively. Join $\overline{EB}$ and let P be the intersection of $\overline{EB}$ with $\overline{HF}$. The locus of all points P formed in this manner as different points G and H are found on $\overline{AB}$ with $\overline{GC} \cong \overline{CH}$ is the cissoid (Heath 1921a, 264–265).

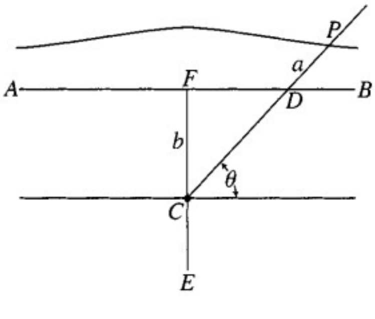

Figure 7.4 Deriving the polar equation for the first conchoid.

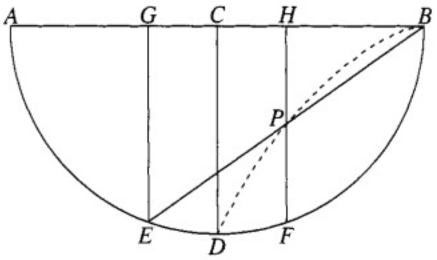

Figure 7.5 The cissoid of Diocles.

When the cissoid of Diocles is generalized, we see the the conchoid is a type of cissoid in this new sense. Let c and c' be two curves and fix a point B that we will call the **pole**. Take any point E on c and find the line l that joins B and E. Let E' be the intersection of l and c' and take P on l such that $BP = EE'$. The locus of all points P is the **generalized cissoid** (Figure 7.6). If c is a circle, B is a point on c, and c' is the tangent line to c that is opposite B, the resulting curve is the cissoid of Diocles. The conchoid of Nicomedes is a generalized cissoid when c is a line, c' a circle, and B the center of the circle. See Exercise 12.

Inspired by the *neusis* problems, Viète took what he learned from Pappus and expanded Euclid's postulate set to include the following three propositions. These and the proofs that follow are from Viète's *A Supplement to Geometry* (Viète 1983, 388–398).

■ POSTULATE 7.2.1

Through a point not on two given lines, there exists a third line that intersects the first two lines, forming a segment of any possible length.

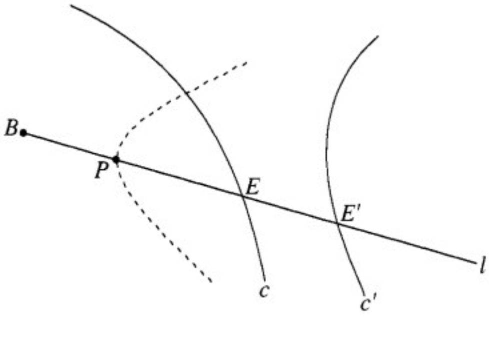

Figure 7.6 The generalized cissoid.

POSTULATE 7.2.2

Given a point on the exterior of an angle such that there exists lines through the point intersecting both sides of the angle, there exists a line through the point that intersects both sides of the angle, forming a segment of any possible length.

POSTULATE 7.2.3

There exists a line from any given point within or on a circle to any line that intersects the circle, forming a segment of any possible length.

The conchoid provided justification for Viète that these postulates were reasonable. For example, we can use it to confirm Postulate 7.2.1. Let the pole C be the given point and the distance a the given length. Suppose that one of the lines is $\overline{AB}$ and the other line l intersects the generated conchoid. If we move the ruler so that P is at the intersection of the conchoid and l, the line formed by the ruler is the desired line that passes through C and intersects the two lines forming a segment of length a.

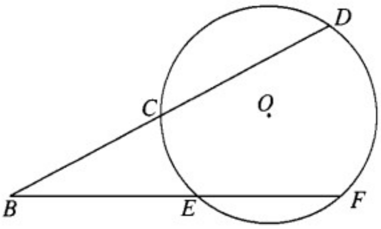
Nicomedes used his curve to duplicate the cube and trisect an angle (Exercises 9 and 10). Viète used his *neusis* postulates to do the same. First, he duplicated the cube by finding two mean proportionals. We start with a lemma.

LEMMA 7.2.4 [*A Supplement to Geometry*, IV]

Let B be on the exterior of $\odot O$. If $\overline{BD}$ intersects $\odot O$ at C and D and $\overline{BF}$ intersects $\odot O$ at E and F such that

$$BC \cdot BE = CD \cdot EF,$$

$\overline{BC}$ and $\overline{BE}$ will be two continued mean proportionals between $\overline{CD}$ and $\overline{EF}$.



PROOF

Let $\overline{BD}$ intersect $\odot O$ at C and D and $\overline{BF}$ intersect the circle at E and F. By hypothesis we have

$$\frac{CD}{BE} = \frac{BC}{EF}.$$

Since $BC = BD - CD$ and $EF = BF - BE$, we have

$$\frac{CD}{BE} = \frac{BD}{BF}.$$

By the Secant Theorem (5.5.4),

$$\frac{BD}{BF} = \frac{BE}{BC}.$$

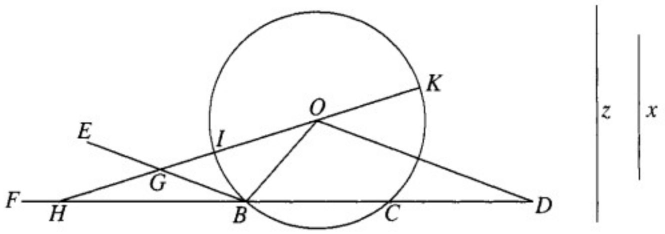
Hence,

$$\frac{CD}{BE} = \frac{BE}{BC} = \frac{BC}{EF}. \blacksquare$$

Viète uses the lemma to prove that one can construct (using his additional postulates) two mean proportionals between two given magnitudes, and thus one can duplicate the cube.

■ **CONSTRUCTION 7.2.5 [*A Supplement to Geometry*, V]**

Find the two mean continued proportionals between two given magnitudes.



PROOF

We are given line segments of length x and z. Draw $\odot O$ with radius $\overline{OB}$ such that $OB = z/2$. Next draw chord $\overline{BC}$ such that $BC = x$ by Postulate 7.2.3. Extend $\overline{BC}$ to D so that C is the midpoint of $\overline{BD}$. Join $\overline{OD}$. Let $\overline{BE}$ be parallel to $\overline{OD}$ and extend $\overline{BD}$ indefinitely to F beyond B. By Postulate 7.2.2, find H on $\overline{BF}$ such that $\overline{OH}$ meets $\overline{BE}$ at G with $\overline{HG} \cong \overline{OB}$. Finally, let $\overline{OH}$ be extended to meet $\odot O$ at K and let I be the intersection of $\overline{OH}$ with $\odot O$. Notice that we have

$$\frac{HG}{HB} = \frac{OG}{BD} \tag{7.5}$$

since $\overline{OD}$ is parallel to $\overline{BG}$ (Exercise 6), and because $HG = OB$ we have

$$\frac{HG}{IK} = \frac{BC}{BD}. \tag{7.6}$$

Because of Equations 7.5 and 7.6, we see that

$$HB \cdot OG = IK \cdot BC.$$

Because $HG = OI$, we have $OG = HI$. Hence,

$$HB \cdot HI = IK \cdot BC.$$

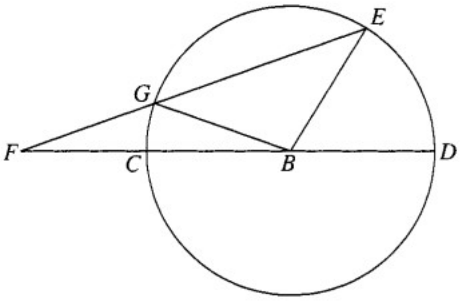
By the last equation we see that the conditions to Lemma 7.2.4 are satisfied. Therefore, HB and HI are the two mean continued proportionals desired because $IK = z$ and $BC = x$. ■

Trisect an Angle

The third postulate allows Viète to trisect an arbitrary angle. The proof of this theorem is similar to that of Archimedes (1897, *Book of Lemmas*, Proposition 8, 309).

■ **CONSTRUCTION 7.2.6 [*A Supplement to Geometry*, IX]**

Trisect a given angle.



PROOF

Let $\measuredangle A$ be the given angle. If $\measuredangle A$ is a right angle, it is a theorem of Euclid's geometry that $\measuredangle A$ can be trisected. Suppose, then, that $\measuredangle A$ is acute. The obtuse case will be similar to what follows.

Construct $\odot B$ with diameter $\overline{CD}$. Find E on the circumference such that $\measuredangle EBD \cong \measuredangle A$. Find F on an extension of $\overline{CD}$ beyond C so that $\overline{EF}$ intersects the circle at G and $\overline{FG} \cong \overline{BC}$ (Postulate 7.2.3). To trisect $\measuredangle EBD$, first join $\overline{BG}$. This yields the isosceles $\triangle FGB$. The details that follow are left unstated by Viète. They are due to Witmer (Viète 1983, 398). Now $\measuredangle BGE$ is an exterior angle of $\triangle BGF$. Hence,

$$\mathrm{m}\measuredangle BGE = \mathrm{m}\measuredangle BFG + \mathrm{m}\measuredangle GBF = 2\mathrm{m}\measuredangle GBF$$

since the base angles are congruent. However, $\measuredangle BGE \cong \measuredangle BEG$ because $\triangle BEG$ is isosceles. This gives

$$\begin{aligned}\mathrm{m}\measuredangle GBE &= \text{two right angles} - \mathrm{m}\measuredangle BGE - \mathrm{m}\measuredangle BEG\\ &= \text{two right angles} - 4\mathrm{m}\measuredangle GBF.\end{aligned}$$

Furthermore,

$$\mathrm{m}\measuredangle GBD = \text{two right angles} - \mathrm{m}\measuredangle GBF.$$

Thus,

$$\begin{aligned}\mathrm{m}\measuredangle EBD &= \text{two right angles} - \mathrm{m}\measuredangle GBE - \mathrm{m}\measuredangle GBF\\ &= \text{two right angles} - (\text{two right angles} - 4\mathrm{m}\measuredangle GBF) - \mathrm{m}\measuredangle GBF\\ &= 3\mathrm{m}\measuredangle GBF.\end{aligned}$$

Hence, $\measuredangle A$ is trisected. ■

Exercises

1. Suppose that for all circles, there exists a rectangle with area equal to the circle. From this prove that every circle can be squared.

2. Use the spiral of Archimedes to square the circle and trisect an angle.

3. Find the equation in rectangular coordinates for the quadratrix and graph it.

4. The quadratrix can be used to trisect an angle. Take $\sphericalangle GAH$ and let H lie on the quadratrix. Find M on $\overline{BA}$ and N on $\overline{CD}$ such that $\overline{MN}$ is parallel to $\overline{AD}$. Trisect both $\overline{MA}$ at points M' and M''. Do the same for $\overline{ND}$ at N' and N''. Let H' be the intersection of the quadratrix with $\overline{M'N'}$ and H'' be the intersection between the quadratrix and $\overline{M''N''}$.

   (a) Prove that $\sphericalangle GAH'' \cong \sphericalangle H''AH' \cong \sphericalangle H'AH$.
   (b) Perform the construction to trisect a randomly selected acute angle.

5. Use the quadratrix to divide an angle that measures half a right angle into five congruent angles.

6. Confirm Equation 7.5 in the proof for Construction 7.2.5.

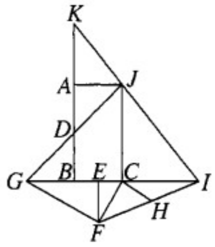
7. Derive Equation 7.4. This is illustrated in Figure 7.4.

8. The conchoid of Nicomedes can be described by the equation

$$(x^2 + y^2)(x - b)^2 - a^2x^2 = 0.$$

   (a) Show how this equation is derived from Equation 7.4.
   (b) Graph this equation.
   (c) Find the area of the loop when $b/a = 1/2$.
   (d) Generalize the argument on page 239 to generate the loop.

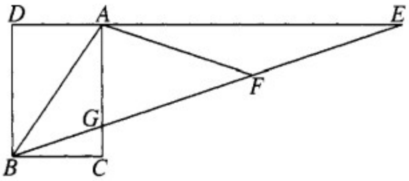
9. Nicomedes used the conchoid to duplicate the cube (Heath 1921a, 260–262). To do this it suffices to find two continued mean proportional between two segments $\overline{AB}$ and $\overline{BC}$. Draw them at right angles. Find J so that $AJCB$ is a rectangle. Let D be the midpoint of $\overline{AB}$ and E the midpoint of $\overline{BC}$. Join $\overline{DJ}$ and produce it beyond D to meet $\overline{BC}$ produced at G. Construct $\overline{EF}$ such that $\overline{FC} \cong \overline{AD}$. Join $\overline{GF}$. Construct $\overline{CH}$ parallel to $\overline{GF}$.



(a) Draw $\overline{FI}$ and assume that H is on it so that I is on $\overline{BC}$ produced and $\overline{HI} \cong \overline{FC}$. An appropriate conchoid will enable us to find I. Give the pole, ruler, and distance of this conchoid.

(b) Join $\overline{JI}$ and extend it to meet $\overline{AB}$ produced at K. Prove that CI and AK are two continued mean proportionals between AB and BC.

10. The conchoid can be used to trisect an angle (Heath 1921a, 236, 238). Given $\measuredangle ABC$, draw $\overline{AC}$ perpendicular to $\overline{BC}$. Find D so that $DACB$ is a rectangle. Let E be on $\overline{DA}$ produced. To find the exact location of E, draw the conchoid with pole B, ruler $\overline{AC}$, and distance $2AB$. Join $\overline{BE}$ and let G be the intersection of $\overline{BE}$ with $\overline{AC}$. Let F be the midpoint of $\overline{DE}$. Prove that $m\measuredangle ABC = 3m\measuredangle GBC$.



11. The cissoid of Diocles is illustrated in Figure 7.5. The point P is a point on the curve. Let $r = PB$, $\theta = m\measuredangle ABP$, and $AB = 1$.

(a) Show that the equation in polar coordinates for the cissoid of Diocles is $r = \sec\theta - \cos\theta$.

(b) Prove that the equation in part (a) is equivalent to $r = \tan\theta \sec\theta$.

(c) Show that the equation for this cissoid is $x(x^2 + y^2) - y^2 = 0$.

(d) Solve the Delian problem using the cissoid by showing that HF and HB are two continued mean proportionals between AH and HP.

12. Show that both the conchoid of Nicomedes and the cissoid of Diocles are generalized cissoids.

13. Given a right triangle, find another right triangle with the same height such that the product of the difference between their bases and the difference between their hypotenuses is equal to the area of a given rectangle.

14. If there exists an isosceles triangle and a line from an endpoint of the base to the opposite leg of length equal to that leg, prove that the exterior angle formed by the base and the line has measure equal to three times one of the base angles.

which has been proved in Cowling–Haagerup [6] (see also [5]). Here $\mathcal{L}_s$ is the conformally invariant fractional power of the sublaplacian which is defined by the relation $\widehat{\mathcal{L}_s f}(\lambda) = \hat{f}(\lambda) M_s(\lambda)$ where $M_s(\lambda)$ is the same family of operators used in the definition of G_s and $\hat{f}$ stands for the operator valued group Fourier transform of f on $\mathbb{H}^n$. From (9) we obtain

$$\pi(\Phi_{-s,\rho}) G_s f(\xi, w) = (2\pi)^{2s} \rho^{2s} \pi(\Phi_{s,\rho}) f(\xi, w) = (2\pi)^{2s} u(\xi, w, \rho). \qquad (10)$$

In [14] the authors have calculated that $-\rho^{1-2s}\partial_\rho \varphi_{-s,\rho} = \rho^{-2n-2}\psi_{s,1}(\rho^{-1}z, \rho^{-2}w)$ for an explicit function $\psi_{s,1}$ and constant $C_2(n,s)$, where $\varphi_{s,\rho}(z,w) = ((\rho^2 + |z|^2)^2 + 16w^2)^{-\frac{n+s+1}{2}}$. Thus differentiating both sides of (10) by ρ and multiplying by $-\rho^{1-2s}$, we obtain

$$C_1(n, -s)\pi(\psi_{s,p}) G_s f(\xi, w) = -(2\pi)^{2s} \rho^{1-2s} \partial_\rho u(\xi, w, \rho).$$

This proves our claim with $C_{n,s} = (2\pi)^{-2s} C_1(n, -s) = 2^{n-3s-1}\pi^{-n-s-2}\Gamma(\frac{n+1-s}{2})^2$. Finally we calculate B_s using the value of $C_2(n,s)$ calculated in [14]:

$$B_s = \left(2^{n-3s-1}\pi^{-n-s-2}\Gamma(\frac{n+1-s}{2})^2\right) \times \left(2^{-n+s}\pi^{n+1}\Gamma(1-s)/\Gamma(\frac{n+1-s}{2})^2\right)$$
$$= 2^{-1-2s}\pi^{-1-s}\Gamma(1-s).$$

The proof is complete. □

5 Trace Hardy and Hardy Inequalities

Consider the vector fields $X_j = \xi_j \frac{\partial}{\partial w}$, $Y_j = \frac{\partial}{\partial \xi_j}$ and $T = \frac{1}{2}\rho\frac{\partial}{\partial w}$ on $\mathbb{R}^{n+1} \times \mathbb{R}^+$. Let X be one of these vector fields. For real valued functions u, v defined on $\mathbb{R}^{n+1} \times \mathbb{R}^+$ consider

$$\int_0^\infty \int_{\mathbb{R}^{n+1}} \left(Xu - \frac{u}{v}Xv\right)^2 \rho^{1-2s}\, d\xi\, dw d\rho.$$

Using integration by parts and assuming that u and v are such that $\frac{u^2}{v}Xv$ vanishes at infinity, we have

$$\int_{\mathbb{R}^{n+1}} \frac{u}{v} Xu\, Xv\, d\xi dw = -\int_{\mathbb{R}^{n+1}} \frac{u}{v} Xu\, Xv\, d\xi dw - \int_{\mathbb{R}^{n+1}} u^2 X(\frac{1}{v}Xv)\, d\xi dw.$$

Simplifying, we get

$$\int_{\mathbb{R}^{n+1}} \frac{u^2}{v^2}(Xv)^2\, d\xi - 2\int_{\mathbb{R}^{n+1}} \frac{u}{v} Xu\, Xv\, d\xi = \int_{\mathbb{R}^{n+1}} \frac{u^2}{v} X^2 v\, d\xi. \tag{11}$$

Consequently,

$$\begin{aligned}&\int_0^\infty \int_{\mathbb{R}^{n+1}} \Big(Xu - \frac{u}{v}Xv\Big)^2 \rho^{1-2s}\, d\xi\, dw d\rho \\ &\quad = \int_0^\infty \int_{\mathbb{R}^{n+1}} (Xu)^2 \rho^{1-2s}\, d\xi\, dw d\rho + \int_0^\infty \int_{\mathbb{R}^{n+1}} \frac{u^2}{v}(X^2 v)\rho^{1-2s}\, d\xi\, dw d\rho.\end{aligned}$$

In a similar way, using integration by parts, we can check that

$$\begin{aligned}&\int_0^\infty \frac{u^2}{v^2}(\partial_\rho v)^2 \rho^{1-2s}\, d\rho - 2\int_0^\infty \frac{u}{v}\partial_\rho u\, \partial_\rho v\, \rho^{1-2s}\, d\rho \\ &\quad = \int_0^\infty \frac{u^2}{v}\partial_\rho(\rho^{1-2s}\partial_\rho v)\, d\rho + \lim_{\rho\to 0}\left(\frac{u^2}{v}\rho^{1-2s}\partial_\rho v\right)\end{aligned}$$

which leads to the equation

$$\begin{aligned}&\int_0^\infty \int_{\mathbb{R}^{n+1}} \Big(\partial_\rho u - \frac{u}{v}\partial_\rho v\Big)^2 \rho^{1-2s}\, d\xi\, d\rho \\ &\quad = \int_0^\infty \int_{\mathbb{R}^{n+1}} (\partial_\rho u)^2 \rho^{1-2s}\, d\xi\, d\rho + \int_0^\infty \int_{\mathbb{R}^{n+1}} \frac{u^2}{v}\partial_\rho(\rho^{1-2s}\partial_\rho v)\rho^{1-2s}\, d\xi\, d\rho \\ &\qquad + \int_{\mathbb{R}^{n+1}} \frac{u^2(\xi,0)}{v(\xi,0)} \lim_{\rho\to 0}(\rho^{1-2s}\partial_\rho v)(\xi,\rho)\, d\xi.\end{aligned}$$

Let us now consider the gradient

$$\nabla u = (X_1 u, \cdots, X_n u, Y_1 u, \cdots, Y_n u, \frac{1}{2}\rho\, \partial_w u, \partial_\rho u). \tag{12}$$

Adding the above equations we obtain the identity

$$\begin{aligned}&\int_0^\infty \int_{\mathbb{R}^{n+1}} |\nabla u - \frac{u}{v}\nabla v|^2 \rho^{1-2s}\, d\xi\, dw d\rho = \int_0^\infty \int_{\mathbb{R}^{n+1}} |\nabla u|^2 \rho^{1-2s}\, d\xi\, dw d\rho \\ &\qquad + \int_{\mathbb{R}^{n+1}} \frac{u^2(\xi,0)}{v(\xi,0)} \lim_{\rho\to 0}(\rho^{1-2s}\partial_\rho v)(\xi,\rho)\, d\xi\, dw d\rho \\ &\qquad\quad + \int_0^\infty \int_{\mathbb{R}^{n+1}} \frac{u^2}{v}(-G + \frac{1}{4}\rho^2\partial_w^2 + \partial_\rho)(\rho^{1-2s}\partial_\rho v) d\xi\, dw d\rho.\end{aligned}$$

If v solves the extension problem

$$\left(-G+\partial_\rho^2+\frac{1-2s}{\rho}\partial_\rho+\frac{1}{4}\rho^2\partial_w^2\right)v(\xi,\rho)=0,$$

then the last term in the above vanishes. As the left hand side is non-negative, this leads to the following inequality known as trace Hardy inequality in the literature.

Proposition 7 *Let u be a real valued compactly supported continuous function on $\mathbb{R}^{n+1}\times[0,\infty)$ which is smooth for $\rho>0$. Let v be a real valued function which solves the extension problem for the Grushin operator. Then*

$$\int_0^\infty\int_{\mathbb{R}^{n+1}}|\nabla u(\xi,w,\rho)|^2\rho^{1-2s}\,d\xi\,dwd\rho \geqslant -\int_{\mathbb{R}^{n+1}}\frac{u^2(\xi,w,0)}{v(\xi,w,0)}\lim_{\rho\to 0}(\rho^{1-2s}\partial_\rho v)(\xi,w,\rho)\,d\xi dw.$$

When v is the solution of the extension problem for the Grushin operator G with initial condition $\varphi\in L^2(\mathbb{R}^{n+1})$ defined by (6) then we have proved that $\lim_{\rho\to 0}\rho^{1-2s}\partial_\rho v=-B_sG_s\varphi$ where B_s is given in Theorem 4.1. Thus the inequality in the above proposition takes the form

$$\int_0^\infty\int_{\mathbb{R}^{n+1}}|\nabla u(\xi,w,\rho)|^2\rho^{1-2s}\,d\xi\,dwd\rho\geqslant c_s\int_{\mathbb{R}^{n+1}}\frac{u^2(\xi,w,0)}{\varphi(\xi,w)}G_s\varphi(\xi,w,\rho)\,d\xi dw$$

where $c_s=2^{1-2s}\frac{\Gamma(1-s)}{\Gamma(s)}$. In the case of the sublaplacian on H-type groups, there are explicit functions $\varphi_{s,\delta}$ such that $\mathcal{L}_s\varphi_{-s,\delta}=\delta^sC_{n,s}\varphi_{s,\delta}$ with explicit constant $C_{n,s}$ which have allowed the authors in [14] to simplify the quotient $\frac{\mathcal{L}_s\varphi_{-s,\delta}}{\varphi_{-s,\delta}}$ to get a sharp trace Hardy inequality. Unfortunately in our context, though we can find analogues of $\varphi_{s,\delta}$ the quotient $\frac{G_s\varphi_{-s,\delta}}{\varphi_{-s,\delta}}$ does not seem to simplify. But things are not so bad if we slightly modify the definition of the fractional power G_s.

Recall that G_s is defined in terms of the multiplier

$$M_s(\lambda)=(2|\lambda|)^s\sum_{k=0}^\infty\frac{\Gamma(\frac{2k+n+1+s}{2})}{\Gamma(\frac{2k+n+1-s}{2})}P_k(\lambda).$$

Instead of this we use the slightly different multiplier

$$\tilde{M}_s(\lambda)=(2|\lambda|)^s\sum_{k=0}^\infty\frac{\Gamma(\frac{2k+n+2+2s}{4})}{\Gamma(\frac{2k+n+2-2s}{4})}P_k(\lambda)$$

in defining the modified fractional power $\tilde{G}_s$. Note that $\tilde{G}_s$ is nothing but $(\frac{1}{2}G)_s$. The operators G_s and $\tilde{G}_s$ are comparable. For $0<s<1$ let $C_1(s)$ and $C_2(s)$ be defined by

$$C_1(s) = \inf_k \frac{\Gamma(\frac{2k+n+1+s}{2})}{\Gamma(\frac{2k+n+1-s}{2})} \frac{\Gamma(\frac{2k+n+2-2s}{4})}{\Gamma(\frac{2k+n+2+2s}{4})}, \; C_2(s)^{-1} = \inf_k \frac{\Gamma(\frac{2k+n+1-s}{2})}{\Gamma(\frac{2k+n+1+s}{2})} \frac{\Gamma(\frac{2k+n+2+2s}{4})}{\Gamma(\frac{2k+n+2-2s}{4})}.$$

In view of Stirling's formula for the gamma function, these constants are positive and finite. Then it follows that

$$C_1(s)\langle \tilde{G}_s f, f\rangle \leq \langle G_s f, f\rangle \leq C_2(s)\langle \tilde{G}_s f, f\rangle. \tag{13}$$

The operator $\tilde{G}_s$ is better behaved as we can see from the following proposition.

For any $s \in \mathbb{R}$ and $\delta > 0$ let $u_{s,\delta}(x, w) = ((\delta + |\xi|^2)^2 + w^2)^{-\frac{n+2+2s}{4}}$ defined on $\mathbb{R}^{n+1}$. We have an explicit expression for the action of $\tilde{G}_s$ on $u_{-s,\delta}$.

Proposition 8 *For any $\delta > 0$ and $0 < s < 1$, we have $\tilde{G}_s u_{-s,\delta}(\xi, w) = C_{n,s}\delta^s u_{s,\delta}(\xi, w)$, where $C_{n,s} = \frac{2^{2s}\Gamma(\frac{n+2+2s}{4})^2}{\Gamma(\frac{n+2-2s}{4})^2}$.*

Proof Since $u_{-s,\delta}$ is radial in ξ the action of G on $u_{-s,\delta}$ is the same as that of the generalised sublaplacian $\mathcal{L}(n/2-1) = -\partial_r^2 - \frac{(n-1)}{r}\partial_r - r^2\partial_w^2$. Therefore, the result follows from Theorem 3.11 in [5]. This can be proved by expanding the function $u^{\lambda}_{-s,\delta}(r)$ in terms of Laguerre functions of type $(n/2 - 1)$. We leave the details to the reader. □

Using the above proposition it is easy to prove a Hardy inequality for the modified fractional power $\tilde{G}_s$. If we let T_s to stand for the operator

$$T_s f(\xi, w) = ((\delta + |\xi|^2)^2 + w^2)^{\frac{n+2}{4}} \tilde{G}_s\big(((\delta + |\xi|^2)^2 + w^2)^{-\frac{n+2}{4}} f\big)(\xi, w),$$

then it follows that

$$T_s((\delta + |\xi|^2)^2 + w^2)^{\frac{s}{2}} = C_{n,s}\delta^s((\delta + |\xi|^2)^2 + w^2)^{-\frac{s}{2}}.$$

Therefore, using Schur test we can prove the following inequality (see Section 5.1 in [13]).

Theorem 9 *Let $f \in L^2(\mathbb{R}^{n+1})$ be real valued and assume that $G_s f \in L^2(\mathbb{R}^{n+1})$. Then for any $\delta > 0$ we have the inequality*

$$\langle \tilde{G}_s f, f\rangle \geqslant A_1(n, s)\delta^s \int_{\mathbb{R}^{n+1}} \frac{(f(\xi, w))^2}{((\delta + |\xi|^2)^2 + w^2)^s}\, d\xi\, dw$$

where $A_1(n, s) = 4^s \frac{\Gamma(\frac{n+2+2s}{4})^2}{\Gamma(\frac{n+2-2s}{4})^2}$. The inequality is sharp and equality holds when $f = u_{-s,\delta}$.

Remark 10 In view of (13) we also have the Hardy inequality for G_s, namely

$$\langle G_s f, f\rangle \geqslant C_1(s)A_1(n,s)\delta^s \int_{\mathbb{R}^{n+1}} \frac{(f(\xi,w))^2}{((\delta+|\xi|^2)^2+w^2)^s}\,d\xi\,dw.$$

Finally, using the above Hardy inequality we can prove the following trace Hardy inequality for the Grushin operator G.

Theorem 11 *Let $\delta > 0$ and $0 < s < 1$. For any real valued compactly supported continuous function u on $\mathbb{R}^{n+1} \times [0,\infty)$ which is smooth for $\rho > 0$, we have the inequality*

$$\int_0^\infty \int_{\mathbb{R}^{n+1}} |\nabla u(\xi,w,\rho)|^2 \rho^{1-2s}\,d\xi\,dw d\rho$$
$$\geqslant C_1(s)B_s A_1(n,s)\delta^s \int_{\mathbb{R}^{n+1}} \frac{u(\xi,w,0)^2}{((\delta+|\xi|^2)^2+w^2)^s}\,d\xi\,dw.$$

In view of Hardy's inequality for G_s all we have to do is to prove the following energy estimate for the Grushin operator. The following result is the analogue of Theorem 1.2 in [8] proved in the context of Heisenberg groups.

Theorem 12 *Let $\delta > 0$ and $0 < s < 1$. For any real valued compactly supported continuous function u on $\mathbb{R}^{n+1} \times [0,\infty)$ which is smooth for $\rho > 0$, we have the inequality*

$$\int_0^\infty \int_{\mathbb{R}^{n+1}} |\nabla u(\xi,w,\rho)|^2 \rho^{1-2s}\,d\xi\,dw d\rho \geqslant B_s\langle G_s f, f\rangle$$

where $f(\xi,w) = u(\xi,w,0)$ and $B_s = 2^{-1-2s}\pi^{-1-s}\Gamma(1-s)$.

Proof In proving this theorem we closely follow the proof of Theorem 1.2 in [8]. We therefore give only a sketch of the proof referring to [8] for details. In what follows we assume that u is smooth. The general case can be dealt with using an approximation argument.

Let $H^s(\mathbb{R}^{n+1})$ be the completion of $C_0^\infty(\mathbb{R}^{n+1})$ with respect to the norm $\|f\|_{(s)}^2 = \langle G_s f, f\rangle$. It can be verified that the dual of $H^s(\mathbb{R}^{n+1})$ is $H^{-s}(\mathbb{R}^{n+1})$. If $g \in H^{-s}(\mathbb{R}^{n+1})$, it follows that $h = G_s^{-1}g = G_{-s}g \in H^s(\mathbb{R}^{n+1})$. Let $H(\xi,w,\rho)$ be the solution of extension problem with initial condition h defined as in (6). In view of Theorem 2 and Theorem 6, $H(\xi,w,\rho)$ converges to $C_s h$ with $C_s = \frac{1}{4}\Gamma(s)\pi^{-s-1}$ and $-\rho^{1-2s}\partial_\rho H(\xi,w,\rho)$ converges to $B_s G_s h$ with $B_s = 2^{-1-2s}\pi^{-1-s}\Gamma(1-s)$. If we let $W(\xi,w,q) = H(2^{-1/2}\xi, 2^{-1}w,\rho)$ with $q = \rho^2/2$, then W satisfies the equation

$$2\big(q\partial_q^2 + (1-s)\partial_q + q\partial_w^2 - G\big)W(\xi,w,q) = 0. \tag{14}$$

Moreover, as $q \to 0$, we have $W(\xi, w, q) \to C_s h(\xi, w)$ in $H^s(\mathbb{R}^{n+1})$ and $-q^{1-s}\partial_q W(\xi, w, q) \to 2^{s-1}B_s G_s h(\xi, w)$ in $H^{-s}(\mathbb{R}^{n+1})$. We define $U(\xi, w, q) = u(\xi, w, \rho)$ with $q = \rho^2/2$ and proceed as in the proof of Theorem 1.2 in [8]. We leave the details to the reader. □

6 An Isometry Property of the Solution Operator Associated to the Extension Problem

In this section we will prove an isometry property of the solution operator associated to the extension problem for the Grushin operator. Such a property has been already proved in the context of $\mathbb{R}^n$ and $\mathbb{H}^n$ in [11], see also [14]. Let $u(\xi, w, \rho)$ be the solution of the extension problem given by (6). For $s > 0$, for which G_s makes sense (e.g. $0 < s < (n+1)$), recall that the Sobolev space $H^s(\mathbb{R}^{n+1})$ is defined as the completion of $C_0^\infty(\mathbb{R}^{n+1})$ under the norm

$$\|f\|_{(s)}^2 = \langle G_s f, f\rangle = \|G_s^{1/2} f\|_{L^2(\mathbb{R}^{n+1})}^2.$$

Let $\Phi_\alpha^\lambda,\ \alpha \in \mathbb{N}^n$ be the scaled Hermite functions which are eigenfunctions of scaled Hermite operator $H(\lambda) = -\Delta + \lambda^2|\xi|^2$. In view of the spectral decomposition of G_s we have that

$$\|f\|_{(s)}^2 = (2\pi)^{-1}\int_{-\infty}^{\infty}(2|\lambda|)^s\left(\sum_{\alpha\in\mathbb{N}^n}\frac{\Gamma(\frac{2|\alpha|+n+1+s}{2})}{\Gamma(\frac{2|\alpha|+n+1-s}{2})}|\langle f^\lambda, \Phi_\alpha^\lambda\rangle|^2\right)d\lambda.$$

We think of the solution $u(\xi, w, \rho)$ as a function on $\mathbb{R}^{n+3}$ which is radial in the third variable. Thus $U(\xi, w, \zeta) = u(\xi, w, |\zeta|)$ is a function on $\mathbb{R}^{n+3}$. For $(\alpha, \beta) \in \mathbb{N}^n \times \mathbb{N}^2$, let $\Phi_{\alpha,\beta}^\lambda(\xi, \zeta) = \Phi_\alpha^\lambda(\xi)\Phi_\beta^{\lambda/2}(\zeta)$, where $\Phi_\alpha^\lambda(\xi)$ and $\Phi_\beta^{\lambda/2}(\zeta)$ are Hermite functions on $\mathbb{R}^n$ and $\mathbb{R}^2$ respectively. Now we define the Sobolev space $\widetilde{H}^{s+1}(\mathbb{R}^{n+3})$ in terms of $\Phi_{\alpha,\beta}^\lambda(\xi, \zeta)$ as the space of all functions $U \in L^2(\mathbb{R}^{n+3})$ for which the following norm is finite.

$$\begin{aligned}&\|U\|_{\widetilde{H}^{s+1}(\mathbb{R}^{n+3})}^2\\ &= (2\pi)^{-1}\int_{-\infty}^{\infty}(2|\lambda|)^{s+1}\left(\sum_{(\alpha,\beta)\in\mathbb{N}^n\times\mathbb{N}^2}\frac{\Gamma(\frac{2|\alpha|+|\beta|+n+1+1+s+1}{2})}{\Gamma(\frac{2|\alpha|+|\beta|+n+1+1-s-1}{2})}|\langle U^\lambda, \Phi_{\alpha,\beta}^\lambda\rangle|^2\right)d\lambda\end{aligned}$$

where U^λ is defined as usual by

$$U^\lambda(\xi;\zeta) = \int_{-\infty}^{\infty} U(\xi, w, \zeta)e^{i\lambda w}d\lambda.$$

Chapter 7

Angular momentum of light

7.1 Introduction

Electromagnetic waves carry energy and momentum. The energy flux is given by the Poynting vector $\vec{S}$ and the momentum density is given by $\vec{\mathscr{P}} = \epsilon_0\mu_0\vec{S}$. Johannes Kepler used the concept of radiation pressure way back in the seventeenth century, to explain why the tail of a comet around the Sun's orbit always points away from the Sun. This radiation pressure is due to the momentum carried by light and it can exert a pressure on any object exposed to light. Maxwell published a paper on radiation pressure in 1862 and it was experimentally demonstrated by Lebedev in 1900.

7.2 Linear momentum

The linear momentum carried by electromagnetic waves is given by $\vec{p} = \hbar\vec{k} = \frac{E}{c}\hat{k}$ for a linearly polarized light. This is the momentum per photon. Here E is the energy per photon, c speed of light and $\vec{k}$ is the propagation vector. The linear momentum density $\vec{\mathscr{P}}$ averaged over a cycle, of a light beam can be calculated from its electric and magnetic fields

$$\vec{\mathscr{P}} = \epsilon_0\langle\vec{E} \times \vec{B}\rangle \tag{7.1}$$

where $\vec{E}$ and $\vec{B}$ are electric and magnetic fields respectively and ϵ_0 is the permittivity of free space.

Consider a monochromatic plane wave traveling in the z direction. The electric and magnetic fields of the wave are

$$\begin{aligned}\vec{E} &= E_0\cos(kz - \omega t)\hat{x}\\ \vec{B} &= \frac{E_0}{c}\cos(kz - \omega t)\hat{y}\end{aligned} \tag{7.2}$$

doi:10.1088/978-0-7503-1698-9ch7

© IOP Publishing Ltd 2018

Hence the momentum density is given by

$$\overrightarrow{\mathscr{P}} = \frac{1}{c}\epsilon_0 {E_0}^2 \cos^2(kz - \omega t)\hat{z} = \frac{1}{c}\epsilon_0 E^2 \hat{z} \tag{7.3}$$

The energy per unit volume $\mathscr{E}$ stored in EM fields is

$$\frac{1}{2}\left(\epsilon_0 E^2 + \frac{1}{\mu_0}B^2\right) = \epsilon_0 E^2 = \mathscr{E} \tag{7.4}$$

7.3 Angular momentum

Poynting using the analogy with the wave motion predicted that the circularly polarized photons carry $\hbar$ units of angular momentum [1]. A circularly polarized light passing through a half wave plate can transfer its angular momentum to the plate to become a circularly polarized light with opposite handedness and this momentum transfer was detected by Beth in his experiments with suspended quarter wave plate [2]. This angular momentum carried by circularly polarized light is called spin angular momentum (SAM) of light. Apart from that, the angular momentum carried by the phase of the light is called orbital angular momentum (OAM).

In 1992, Allen *et al* recognized that light beams with an azimuthal phase dependence of $\exp(il\phi)$ carry an orbital angular momentum (OAM) that can be many times greater than the spin angular momentum, where ϕ is the azimuthal coordinate in the beam's cross section, and l can take any integer value, positive or negative [3, 4]. The magnitude of orbital angular momentum carried by the beam is related to the topological charge of the beam and is $\pm l\hbar$ per photon. The key point was that this OAM was a natural property of all helically phased beams, and hence could be readily realizable in the laboratory. There is also great interest in these types of beams with OAM due to diverse possible applications [5–9]. Orbital angular momentum arises whenever a beam's phase fronts are not perpendicular to the general propagation direction and hence transverse components of propagation vectors are present. Termed as internal flows, the angular momentum and internal energy carried by such beams were described in chapter 5. The most common form of helically phased beam is the so-called Laguerre–Gaussian (LG) laser hybrid mode. Other beams with helical wavefronts such as Bessel beams [10], Mathieu beams [11], and Ince–Gaussian beams [12] can also carry orbital angular momentum. In chapter 9, it is shown that plane wavefronts with characteristic inhomogeneous polarization distribution can also carry orbital angular momentum. In the same way that the suspended half-wave plate acquires an angular momentum of $2\hbar$ when a right circularly polarized photon passes through it (figure 7.1), the cylindrical mode converter can acquire an angular momentum of $2l\hbar$ when a photon with orbital angular momentum $l\hbar$ passes through it.

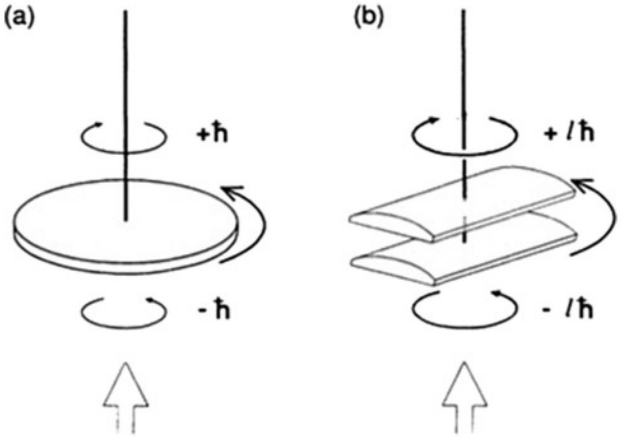

Figure 7.1. (a) A suspended half-wave plate undergoes torque in transforming right-handed into left-handed circularly polarized light, Beth's experiment. (b) Suspended cylindrical lenses undergo torque in transforming a Laguerre–Gaussian mode of orbital angular momentum $-l\hbar$ per photon, into one with $+l\hbar$ per photon [3]. Reprinted with permission from [3]. Copyright (1992) by the American Physical Society.

The local wavefront normal indicates the direction of energy and momentum flow in the fields. Since the vortex beam has helical shaped wavefronts the local normal to the wavefront also spirals as the beam advances. This gives rise to transverse components of propagation vector distribution which has non-zero curl. This suggests that the singular beam carries OAM. The photon trajectories for a Bessel beam with $l = 2$ are shown in figure 7.2. These trajectories are reconstructed from measurements of the transverse Poynting-vector distribution, with a constant longitudinal component added.

The angular momentum density, $\vec{\mathscr{J}}$, of a light beam can be calculated from

$$\vec{\mathscr{J}} = \epsilon_0(\vec{r} \times \langle \vec{E} \times \vec{B} \rangle) = \vec{r} \times \vec{\mathscr{P}} \tag{7.5}$$

This equation encompasses both the spin and orbital angular momentum density of a light beam. The local value of the linear momentum density [16] under paraxial approximation is given by

$$\vec{\mathscr{P}} = i\omega\frac{\epsilon_0}{2}(u^*\nabla u - u\nabla u^*) + \omega k\epsilon_0|u|^2\hat{z} + \omega\sigma\frac{\epsilon_0}{2}\frac{\partial|u|^2}{\partial r}\hat{\phi} \tag{7.6}$$

where $u = u(r, \phi, z)$ is the complex scalar function describing the distribution of the field amplitude. Here σ describes the degree of polarization of the light; $\sigma = \pm 1$ for right- and left-hand circularly polarized light, respectively, and $\sigma = 0$ for linearly polarized light. The cross product of this linear momentum density with the radius vector $\vec{r}(r, 0, z)$ yields an angular momentum density. The angular momentum density in the z direction can come from the first or the third term of the linear momentum density equation (7.6). As one can see, the first term depends on the phase gradient of the complex field and the third term depends on the polarization of

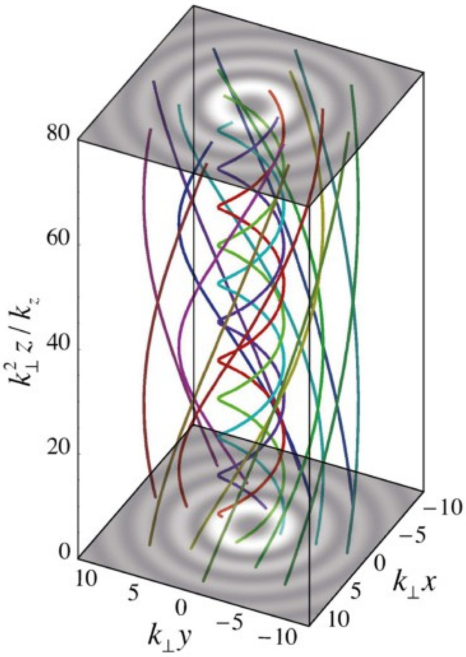

Figure 7.2. Photon trajectories are helical in a Bessel beam with a vortex of charge 2. This suggests that photon momentum is helical and hence singular beam carries OAM. Reproduced from [18] © IOP Publishing Ltd and Deutsche Physikalische Gesellschaft. CC BY-NC-SA 3.0.

the complex field. The angular momentum arising from the cross product of radius vector $\overrightarrow{r}$ with the phase gradient term is called the orbital angular momentum and the cross product with the third term is called the spin angular momentum of light.

7.4 Orbital and spin angular momentum of light

7.4.1 Angular momentum due to circular polarization

The spin angular momentum arising due to polarization of light is given by $\sigma_z\hbar$ per photon with $-1 \leqslant \sigma_z \leqslant 1$, where the extrema $\sigma_z = \pm 1$ corresponds to pure circular polarization.

From the azimuthal part of the linear momentum density given in equation (7.6), the z-component of the angular momentum density is given by

$$\mathscr{J}_z = |\overrightarrow{r} \times \overrightarrow{\mathscr{P}_\phi}| = r\mathscr{P}_\phi = r\omega\sigma\frac{\epsilon_0}{2}\frac{\partial |u|^2}{\partial r} \tag{7.7}$$

The angular momentum density in equation (7.7) integrated over the beam, gives spin angular momentum (SAM) and is given by $\sigma\hbar$.

7.4.2 Angular momentum due to azimuthal phase dependence in the beam

The z-component of the angular momentum density arising from the phase gradient terms in equation (7.6) is given by

$$\mathscr{J}_z = \overrightarrow{r} \times \left\{ i\omega\frac{\epsilon_0}{2}(u^*\nabla u - u\nabla u^*) \right\} \tag{7.8}$$

The angular momentum density in equation (7.8) integrated over the beam gives OAM and is given by $l\hbar$. Note that in chapter 5, we have seen that the optical current in terms of phase gradient is given by

$$\frac{i}{2}(u^*\nabla u - u\nabla u^*) = Im(u^*\nabla u) = I\nabla\phi \tag{7.9}$$

The orbital angular momentum is due to the azimuthal phase dependence in the beam and is equivalent to $l\hbar$ per photon. The analogy between paraxial wave equation with the Schrodinger wave equation suggests the identification of an orbital angular momentum for light beams [13]. The operator corresponding to the z-component of orbital angular momentum is $L_z = -i\hbar\frac{\partial}{\partial\phi}$ and applying this to beams having azimuthal phase dependence like $\exp\{il\phi\}$ gives an orbital angular momentum component to phase singular beams. This analogy between paraxial optics and quantum mechanics has been exploited to introduce an eigenfunction description of laser beams, and quantum harmonic oscillator modes [14]. Laguerre–Gaussian modes are the laser mode analog of the angular momentum eigenstates of the isotropic two-dimensional harmonic oscillator.

In the case of speckle patterns, the overall OAM is zero as there is an equal number of positive and negative charge optical vortices. The angular momentum density $\overrightarrow{\mathscr{J}}$, is related to the linear momentum density $\overrightarrow{\mathscr{P}} = \epsilon_0\langle\overrightarrow{E} \times \overrightarrow{B}\rangle$ by the relation $\overrightarrow{\mathscr{J}} = \overrightarrow{r} \times \overrightarrow{\mathscr{P}}$ where ϵ_0 is the free space permittivity and $\overrightarrow{E}$ and $\overrightarrow{B}$ are the electric and magnetic fields, respectively. From this relation, for any angular momentum component directed along the z direction, there must be a transverse component of linear momentum, i.e. in the xy-plane. This means that to have a z-component of angular momentum there must be a transverse component, i.e. a z-component of the electric and/or magnetic field. Further, such a transverse component of momentum should be circulating. The center of the vortex beam corresponds to the position of zero intensity and hence it carries neither linear nor angular momentum. Indeed, the angular momentum is associated with regions of high intensity, which is a bright annular ring for a donut vortex beam. The azimuthal component of the Poynting vector is parallel to that of the transverse linear momentum density in a helical phase front [7]. Spin angular momentum (SAM) has only two independent states corresponding to left- and right-handed circular polarization, while orbital angular momentum has an unlimited number of possible states, corresponding to all integer values of l.

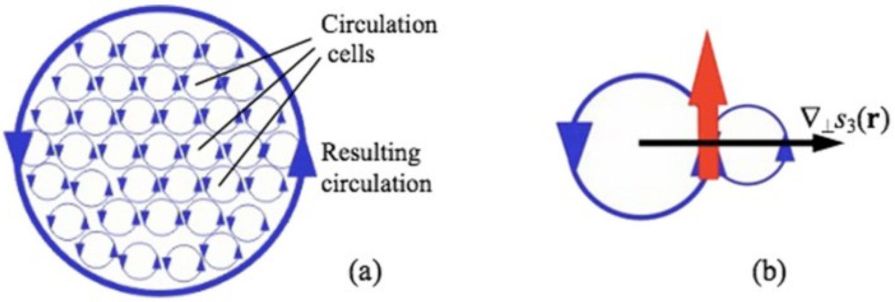

Figure 7.3. Orbital angular momentum due to spatially varying spin angular momentum. (a) In a uniform distribution of spin angular momentum according to Stokes theorem, the internal circulations cancel out and only circulation at the boundary remains. (b) In an non-uniform distribution of spin angular momentum, there can be a volume spin current, as there is incomplete internal cancellations of circulations. Reproduced with permission from the corresponding author [15]. © IOP Publishing. Reproduced with permission. All rights reserved.

7.4.3 Angular momentum due to spatially varying circular polarization

There is a possibility that a spatially varying circular polarization can result in orbital angular momentum. This can result in optical current flow across the beam cross section. Consider the fundamental theorem of curls which states that

$$\int\int(\nabla \times \vec{A}) \cdot \vec{da} = \oint \vec{A} \cdot \vec{dl} \tag{7.10}$$

All the elementary circulations, which are of the same magnitude, can result in a single large circulation around the boundary enclosing the region. This is due to the cancellation of circulating components between adjacent circulating cells. This is explained in figure 7.3(a). But when there is a spatially varying spin angular momentum distribution, there can be a volume spin current due to incomplete cancellation of circulations. As a result any larger circulation arising due to the spatially varying circular polarization is not origin-dependent as it arises due to individual spins which are origin-independent. In figure 7.3(b), the spin current arising between two unequal adjacent circular polarization components is depicted. The gradient of Stokes' S_3 parameter in the figure indicates spatially varying circular polarization. The Stokes' parameter $S_3 = \pm 1$ for circular states. Any state of polarization can be decomposed into right and left circularly polarized components and ∇S_3 in the figure represents spatial variation of SAM component.

7.5 Intrinsic and extrinsic angular momenta

There are three forms of angular momenta namely intrinsic spin angular momentum, intrinsic orbital angular momentum and extrinsic orbital angular momentum [16] abbreviated as EOAM. The angular momentum that is independent of the choice of the axis is intrinsic. The spin angular momentum is therefore intrinsic and the orbital angular momentum carried by phase singularity with its core along the optical axis of the system is intrinsic. Any vortex which is situated away from the center of the beam axis gives rise to extrinsic orbital angular momentum.

These three forms of the AM of light beams correspond to different degrees of freedom of light and to different structural constituents. In free space propagation these different forms of AM are conserved. Any transverse shift of the field centroid (trajectory), leads to the conversion from intrinsic OAM to the extrinsic OAM.

The angular momentum which arises for any light beam from the product of the z-component of linear momentum about a radius vector, may be said to be extrinsic because its value depends upon the choice of calculation axis.

Berry showed [17] that the orbital angular momentum of a light (J) beam does not depend upon the lateral position of the axis and can therefore also be said to be intrinsic, provided the direction of the axis is chosen so that the transverse momentum is zero. When integrated over the whole beam the angular momentum in the z direction is

$$\vec{J_z} = \epsilon_0 \int \int dxdy(\vec{r} \times \langle \vec{E} \times \vec{B} \rangle) \tag{7.11}$$

If the axis is laterally displaced by $\vec{r_0}(r_{0x}, r_{0y})$ it is easy to show that the change in the z-component of angular momentum is given by

$$\begin{aligned} \Delta J_z &= (r_{0x} \times P_y) + (r_{0y} \times P_x) \\ &= r_{0x}\epsilon_0 \int \int dxdy\langle \vec{E} \times \vec{B} \rangle_y + r_{0y}\epsilon_0 \int \int dxdy\langle \vec{E} \times \vec{B} \rangle_x \end{aligned} \tag{7.12}$$

The angular momentum is intrinsic only if ΔJ_z equals zero. Any beam with a helical phase front apertured symmetrically about the beam axis has zero ΔJ_z and, consequently, an orbital angular momentum of $l\hbar$ per photon, independent of the axis of calculation [16]. The orbital angular momentum of the light beam may therefore be described as intrinsic. However, when the beam is passed through an off-axis aperture, its transverse momentum is non-zero and the orbital angular momentum depends upon the choice of calculation axis and so must be described as extrinsic.

The OAM is intrinsic only if the vortex core coincides with the beam axis. In this case the OAM will turn out to be independent of the choice of the calculation axis. For apertured beams even if the vortex is positioned at the center of the aperture and the beam axis does not coincide with the center of the aperture, the computed OAM will yield different results and is dependent on the choice of the coordinate system used. Therefore, the OAM in this case is extrinsic. This means that vortices positioned away from the beam axis (also called the centroid of the beam) have extrinsic OAM. Therefore, it does not follow that the angular momentum of the apertured beam is intrinsic as the result does depend upon the choice of calculation axis. Figure 7.4 depicts the numerically calculated local spin and orbital angular momentum densities in the direction of propagation for a circularly polarized LG beam. It shows how (1) the axis of the beam, (2) the position about which angular momentum is calculated and (3) aperturing, affect the calculated OAM. Further,

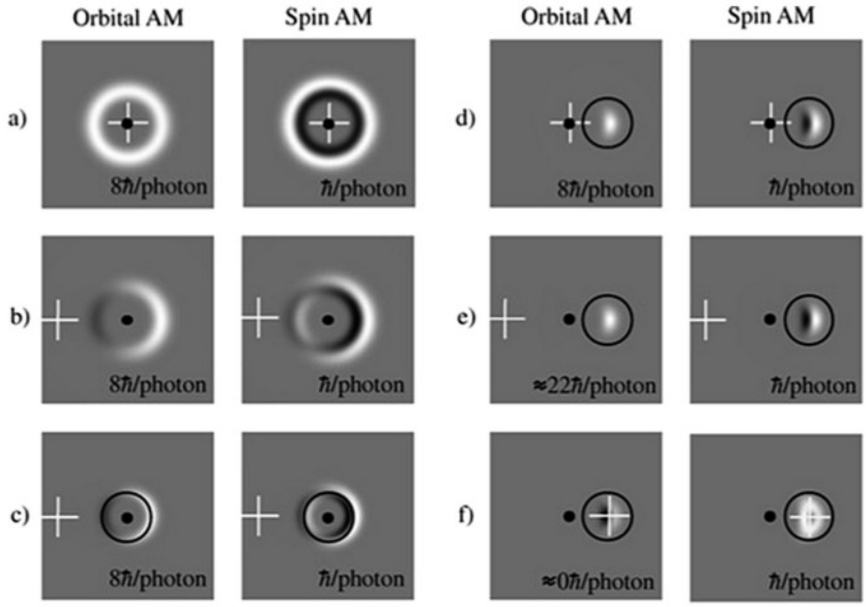

Figure 7.4. Numerically calculated local spin and orbital angular momentum densities in the direction of propagation for a $l = 8$ and $\sigma = 1$ Laguerre–Gaussian mode [16]. In the gray scale, white represents the positive and black the negative contributions. The axis of the beam is marked by a black spot while the axis about which the angular momenta are calculated is shown by a white cross. The black circle marks the position of a soft edged aperture. Note that the spin angular momentum is equivalent to $\sigma\hbar$ per photon irrespective of the choice of aperture or calculation axis, whereas the orbital angular momentum is only $l\hbar$ per photon if the aperture or calculation axis coincide with the axis of the original beam. Reprinted with permission from [16], Copyright (2002) by the American Physical Society.

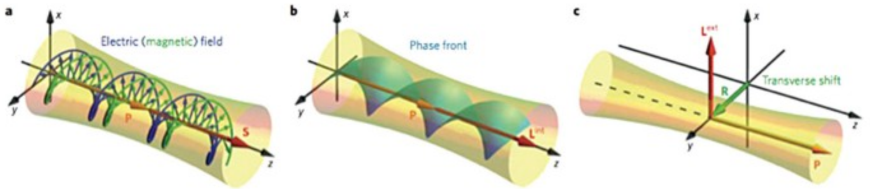

Figure 7.5. Angular momenta of paraxial optical beams [19]. (a) SAM for a right-hand circularly polarized beam with $\sigma = 1$. The instantaneous electric and magnetic field vectors are shown. (b) IOAM in a vortex beam with $l = 2$. The instantaneous surface of a constant phase is shown. (c) EOAM due to the propagation of the beam at a distance R from the coordinate origin. Chapter 10

Fine Structure of the Hydrogen Atom

Now that we have covered the two revolutionary theorems of quantum physics and relativity, we can start to think about how they mesh together. After all, a complete description of the universe should encompass both theories. We will study relativistic quantum mechanics in detail in Chapter 11 but, for now, consider the case of the hydrogen atom, which is an ideal system for starting to understand the connection. One of the reasons for this is that the speed of an electron in the ground state of the hydrogen atom is (see (2.49)) $v = \alpha c$, i.e. about $c/137$. This is significantly smaller than the speed of light, so relativistic effects normally can be ignored. However, in the very precise realm of atomic spectroscopy, these effects are measurable and need to be accounted for. The good news is that, since the corrections are small, we can use perturbation theory to study them and so do not need a fully relativistic quantum theory just yet.

10.1. Relativistic correction to the kinetic energy

When we considered the spectrum of the hydrogen atom in Section 5.4, we calculated the energy levels by using the nonrelativistic Hamiltonian. This was found by adding the kinetic energy and Coulomb potential energy of the electron, and converting this total energy to an operator by use of the correspondence principle. However, the form of the kinetic energy is different if we take into account special relativity. In this section, we will see how this effect changes the energy levels of hydrogen.

The relativistic form of the kinetic energy can be written as

$$T = \sqrt{p^2c^2 + M^2c^4} - Mc^2, \tag{10.1}$$

where the first term is the total relativistic energy and the second term is the rest energy of the electron. Expanding the square-root, we get[1]

$$\begin{aligned} T &= Mc^2 \left[\sqrt{1 + \frac{p^2}{M^2c^2}} - 1 \right] \\ &= Mc^2 \left[-1 + 1 + \frac{1}{2}\left(\frac{p^2}{M^2c^2}\right) - \frac{1}{8}\left(\frac{p^2}{M^2c^2}\right)^2 + \cdots \right] \\ &\approx \frac{p^2}{2M} - \frac{p^4}{8M^3c^2}. \end{aligned} \tag{10.2}$$

We can truncate the expansion since $p \ll Mc$. The first term in (10.2) is just the nonrelativistic kinetic energy and so the second term is the first-order correction to the kinetic energy due to relativistic effects. If the total Hamiltonian is $H = H_0 + H_1$, where H_0 is the nonrelativistic Hamiltonian, the perturbation term is

$$H_1 = -\frac{p^4}{8M^3c^2} = -\frac{E_k^2}{2Mc^2},$$

where $E_k = p^2/(2M)$ is the nonrelativistic form of the kinetic energy. Using perturbation theory, the first-order correction to a general (unperturbed) state Ψ_{nlm} of the hydrogen atom is, therefore,

$$\begin{aligned} \Delta E_1 &= -\frac{1}{2Mc^2}\langle \Psi_{nlm}|E_k^2|\Psi_{nlm}\rangle \\ &= -\frac{1}{2Mc^2}\langle (E_n - V(r))^2 \rangle \\ &= -\frac{1}{2Mc^2}\left(\langle E_n^2\rangle - 2\langle E_n\, V(r)\rangle + \langle V^2(r)\rangle\right). \end{aligned} \tag{10.3}$$

In the second line, we have used $E_k = E_n - V(r)$, where $E_n \approx -13.6\,\mathrm{eV}/n^2$ is the total energy, $V(r) = -e^2/(4\pi\epsilon_0 r)$ is the potential energy, and we have

---

[1] Using Newton's generalised binomial theorem:

$$(x+y)^r = x^r + rx^{r-1}y + \frac{r(r-1)}{2!}x^{r-2}y^2 + \cdots.$$

dropped the state we are averaging over for notational simplicity. Now, since the wave functions ψ_{nlm} are eigenfunctions of E_n, we have

$$\begin{aligned}\Delta E_1 &= -\frac{1}{2Mc^2}\left(E_n^2 - 2E_n\langle V\rangle + \langle V^2\rangle\right) \\ &= -\frac{1}{2Mc^2}\left(E_n^2 - 2E_n\langle\frac{-e^2}{4\pi\epsilon_0 r}\rangle + \langle\frac{e^4}{(4\pi\epsilon_0)^2 r^2}\rangle\right). \qquad (10.4)\end{aligned}$$

As an example, let's calculate the energy shift for the 1s state of hydrogen. We know from Section 5.4 that the wave function for this state is

$$\Psi_{100} = \frac{1}{\sqrt{\pi a_0^3}}\,\mathrm{e}^{-r/a_0}, \qquad (10.5)$$

and $E_1 = -\alpha^2 Mc^2/2$ (see (2.52)), where α is the fine-structure constant as given in (2.50). We can now evaluate $\langle V\rangle$ and $\langle V^2\rangle$ directly,[2]

$$\begin{aligned}\langle V\rangle &= 4\pi\int_0^\infty r^2\left(\frac{-e^2}{4\pi\epsilon_0 r}\right)\frac{1}{\pi a_0^3}\,\mathrm{e}^{-2r/a_0}\,dr \\ &= \frac{-e^2}{4\pi\epsilon_0 a_0} = -\alpha^2 Mc^2 \qquad (10.6) \\ \langle V^2\rangle &= 4\pi\int_0^\infty r^2\left(\frac{-e^2}{4\pi\epsilon_0 r}\right)^2\frac{1}{\pi a_0^3}\,\mathrm{e}^{-2r/a_0}\,dr \\ &= 2\left(\frac{e^2}{4\pi\epsilon_0 a_0}\right)^2 = 2\alpha^4 M^2 c^4. \qquad (10.7)\end{aligned}$$

Substituting these results into (10.4), we obtain

$$\Delta E_1 = -\frac{5}{8}Mc^2\alpha^4, \qquad (10.8)$$

which is the first-order relativistic correction for the ground state of hydrogen. You can probably see now why α is called the fine-structure constant.

---

[2] Using the integral identity

$$\int_0^\infty r^n\,\mathrm{e}^{-\beta r}\,dr = n!\,\beta^{-(n+1)}.$$

A more general calculation[3] gives

$$\Delta E_1 = -\frac{1}{2}Mc^2\frac{(Z\alpha)^4}{n^4}\left(\frac{n}{l+1/2}-\frac{3}{4}\right). \tag{10.9}$$

We see that the energy now depends on l as well as n, i.e. the $2s$ and $2p$ states will have different energies. This is significant as it is the first departure we have seen from Bohr's theory, which says that the energy levels depend only on the quantum number n.

10.2. Addition of angular momenta

In an atom, there are different angular momenta associated with the particles, such as the orbit of the electrons and the spin of the electron or the nucleus. It is therefore important that we understand how to combine angular momenta in this setting. In classical physics, it is straightforward. Angular momentum is a continuous vector quantity and thus, to find the total angular momentum we just vectorially sum all the contributions

$$\vec{L} = \sum_i \vec{L}_i. \tag{10.10}$$

In quantum physics, things are more complicated since angular momentum is quantised not just in the values it can take, but also in the directions that it can point in. So the question is: how do we combine angular momenta in quantum physics? Let's start by considering the addition of two angular momenta since, once we know how to add two, we can add any number by applying the rules sequentially. Suppose we have two angular momenta $\vec{L}_1$ and $\vec{L}_2$ with corresponding quantum numbers l_1 and l_2. We know that the magnitude of the two vectors will be

$$|\vec{L}_1| = \hbar\sqrt{l_1(l_1+1)} \quad \text{and} \quad |\vec{L}_2| = \hbar\sqrt{l_2(l_2+1)} \tag{10.11}$$

and their components along the z axis will be $L_{1z} = m_1\hbar$ and $L_{2z} = m_2\hbar$, where m_1 and m_2 are given by $-l_1 \leq m_1 \leq l_1$ and $-l_2 \leq m_2 \leq l_2$. The two vectors will be able to add up in different (quantised) ways — as shown in Fig. 10.1 — that we want to understand. Firstly, it is clear that the component of the overall vector, $\vec{L} = \vec{L}_1 + \vec{L}_2$ in the z-direction, will simply

---

[3] Given as a exercise (with solution) at the end of the chapter.

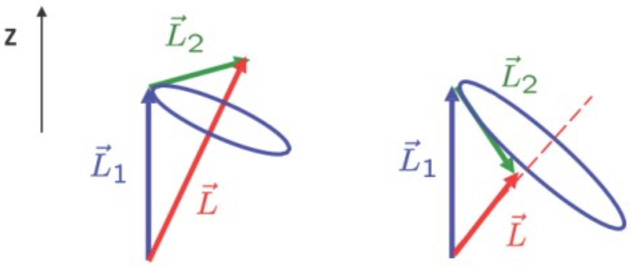

Figure 10.1: Addition of angular momenta. Two vectors $\vec{L}_1$ and $\vec{L}_2$ with fixed magitude are added and, owing to the different projections they can have on the z axis, result in different vectors $\vec{L}$. The allowed magnitudes of the resulting vector are given by (10.14). As described in the text, the good quantum numbers can be visualised by considering rotations about the $\vec{L}$ direction.

be the sum of the z-components of the other vectors, i.e.

$$L_z = m\hbar = L_{1z} + L_{2z} = m_1\hbar + m_2\hbar. \tag{10.12}$$

So we have $m = m_1 + m_2$. Since the overall vector is an angular momentum, we know that its length can be written in terms of a quantum number l in the usual form

$$|\vec{L}| = \hbar\sqrt{l(l+1)}. \tag{10.13}$$

The rule for finding l in terms of l_1 and l_2 is

$$|l_1 - l_2| \leq l \leq l_1 + l_2, \tag{10.14}$$

where l increases in integer steps. This is an important and general rule for adding angular momenta in quantum mechanics.

We can know the lengths of $\vec{L}$, $\vec{L}_1$ and $\vec{L}_2$ simultaneously; their operators all commute and so they are compatible observables. Their corresponding quantum numbers are all good quantum numbers, that is, they can all be specified simultaneously. As we have seen above, the z-component of $\vec{L}$ is also compatible with the other observables. However, m_1 and m_2 are not good quantum numbers. While their sum $m = m_1 + m_2$ is well-defined, we cannot specify m_1 and m_2 separately. A good way of visualising this is with Fig. 10.1. If we imagine that everything is rotating about the vector $\vec{L}$, then we can see that $\vec{L}$ has a fixed length and direction (i.e. l and m can be specified). We also see that $\vec{L}_1$ and $\vec{L}_2$ have fixed lengths, meaning that l_1 and l_2 can be specified. However, the projections of $\vec{L}_1$ and $\vec{L}_2$ onto the z axis change with time, meaning that m_1 and m_2 are not good quantum numbers.

Let's conclude this section with an example of how to apply the angular momentum addition rule given by (10.14). Suppose we have two particles, each with quantum numbers $l_1 = l_2 = 1$, e.g two electrons in a p subshell. The possible combined values of l are

$$0 \leq l \leq 2, \tag{10.15}$$

i.e. $l = 0, 1, 2$. This is an odd number of values and it is worth noting that we always get an odd number of possible l values whenever the individual values that are combined (l_1 and l_2 in this case), are integers. For each value of l, the possible values of m are given by the usual rule, $-l \leq m \leq l$. So for $l = 2$, we would have $m = -2, -1, 0, 1, 2$.

10.3. Spin-orbit coupling

In the early days of spectroscopy, scientists were puzzled by the appearance of closely spaced lines, called doublets, in the spectra of alkali metals such as lithium, sodium and potassium.[4] The lines were too close together to be able to be explained by Bohr's theory, where the energies depend only on n. However, as we saw in Section 10.1, relativistic effects mean that atomic spectra depend on l as well as n, so perhaps the doublet could be explained in terms of the addition on orbital angular momenta. Unfortunately, this was not so. Since the quantum numbers l can only take integer values, we have seen that they combine to always give an odd number of different values, so we should expect to see an odd number of closely spaced lines rather than the two we see in a doublet. This is all reminiscent of the Stern-Gerlach experiment that we saw in Section 6.1 and the resolution is, of course, the same — that the electron has a spin value of one-half. The precise details of the doublet can be explained in terms of coupling between the electron's orbital angular momentum and its spin — the so-called spin-orbit coupling. In order to understand spin-orbit coupling, it is helpful to first have an operator for magnetic moment.

We can find the magnetic moment operator by using classical physics and then applying the correspondence principle. Consider the classical

---

[4] The reader may be familiar with the sodium doublet from the orange street lamps often seen in cities. The light that these emit are from the two sodium doublet lines at around 589 nm. These lamps are particularly useful where light pollution is an issue, such as near astronomical observatories, since they emit light at two dominant frequencies and so have minimal interference with the other frequencies that we may be interested in seeing.

Figure 5.5 A microstrip trace. The cross-sectional view of a microstrip trace.

Solution: Using (5.5) where $l = 1$ cm $= 0.01$ m, $\sigma = 5.8 \times 10^7$ S-m^{-1}, and $A = wt = 3.43 \times 10^{-5} w$ m^2:

(a) For $w_1 = 2.5 \times 10^{-4}$ m, we have $R_1 \simeq 20.1$ mΩ-cm^{-1}, and
(b) for $w_2 = 2w_1 = 5 \times 10^{-4}$ m, we have $R_2 = R_1/2 \simeq 10.05$ mΩ-cm^{-1}.

Example 5.3: Curved bar. The resistance of a rectangular block of metal was discussed in this section and found to be given by $R = l/(\sigma A)$, where σ is the conductivity, l is the length, and A is the cross-sectional area. As a more complicated geometry, consider the resistor in the form of a curved bar, which is made of the rectangular block bent to form the arc of a circle, with the two end surfaces remaining flat, as shown in Figure 5.6a. The edges are coated with perfectly conducting material so that they constitute electrodes at uniform potential. Find the resistance R between the electrodes.

Solution: This problem has a cylindrical symmetry with respect to the O-O′ axis, as shown. The equipotential surfaces are the intersections of the curved rectangular bar and the planes

Figure 5.6 A curved-bar resistor. (a) A rectangular bar bent into a circular arc of rectangular cross section. (b) A differential angular element along the arc. (c) A flat washer is equivalent to a curved bar of arc length $\phi_0 \simeq 2\pi$. (d) The flat washer can be viewed as a parallel combination of elemental resistances of radial width Δr, as shown.

passing through the O-O′ axis. The current flow lines **J** are circular arcs centered on the O-O′ axis (i.e., **J** is in the $\hat{\boldsymbol{\phi}}$ direction). We may suppose from symmetry that the **E** vector is the same at all points inside the bar that are equidistant from the O-O′ axis. However, the electric field must vary with radial distance from the axis (r) across the curved bar, since the inward portions of the end faces are closer to each other than the outward portions are (i.e., **E** must be a function of r, or $\mathbf{E} = \mathbf{J}/\sigma = \hat{\boldsymbol{\phi}} E_\phi(r)$). To determine how the electric field varies with radial distance, we can use the fact that $\oint_C \mathbf{E} \cdot d\mathbf{l} = 0$ (equation (4.20)). Consider a closed contour ABCD, as shown in Figure 5.6b. We have

$$\oint_C \mathbf{E} \cdot d\mathbf{l} = \left(E_\phi + \frac{dE_\phi}{dr} \Delta r \right) (r + \Delta r) \Delta\phi - E_\phi r \Delta\phi = 0$$

where the first term is the contribution from path segment AB and the second term is that from path segment CD. We thus have

$$E_\phi \Delta r + r \frac{dE_\phi}{dr} \Delta r + \frac{dE_\phi}{dr} (\Delta r)^2 = 0 \qquad \rightarrow \qquad \frac{dE_\phi}{E_\phi} = -\frac{dr}{r}$$

where the last term drops out as $\Delta r \to 0$. Therefore

$$\ln E_\phi = -\ln r + K_1 \qquad \rightarrow \qquad E_\phi = \frac{K}{r}$$

where K_1 and K are constants. The functional form of E_ϕ is thus determined. Note that we could alternatively have found $\Phi(r)$ using Laplace's equation, namely $\nabla^2 \Phi = 0$, and subsequently determined **E** from $\mathbf{E} = -\nabla \Phi$. The voltage between the end faces is thus

$$\Phi_{12} = -\int_1^2 \mathbf{E} \cdot d\mathbf{l} = -\int_{\phi_0}^{0} \frac{K}{r} \hat{\boldsymbol{\phi}} \cdot \hat{\boldsymbol{\phi}} r \, d\phi = \int_0^{\phi_0} \frac{K}{r} r \, d\phi = K\phi_0 = \frac{Kl}{a}$$

where we have implicitly assumed the end face at the lower potential to be at $\phi = \phi_0$, so that $\mathbf{E} = \hat{\boldsymbol{\phi}}(K/r)$. The total current between the end faces is given by

$$I = \int_S \mathbf{J} \cdot d\mathbf{s} = \int_S \sigma \mathbf{E} \cdot d\mathbf{s} = \sigma w K \ln \frac{b}{a}$$

Hence the resistance is given by

$$R = \frac{\Phi_{12}}{I} = \frac{l}{\sigma w a \ln(b/a)}$$

Note that the preceding expression for R applies for any arc length l of the curved bar. For example, consider the flat washer shown in Figure 5.6c, with resistance between the edges of a saw-cut through the radius of the washer (i.e., the shaded surface and the one facing it). In this case, and assuming the arc length of the cut region is very small ($\ll 2\pi a$), we simply replace the length l in the previous expression with $l \simeq 2\pi a$. Note from Figure 5.6d that the resistance of the flat washer between the indicated faces can also be thought of as being the parallel combination of elemental flat washer resistances, each of radial thickness Δr.

Provenzale (1989)). On the other hand, there are deterministic dynamical systems for which time series appear stochastic, for instance when the noise level is high. A further consideration with regard to reliable estimation of the correlation dimension is the length of the embedded time series. Ding *et al.* (1993) showed that the estimated correlation dimension for rather short series falls systematically below that for longer series. The estimation of invariants is a somewhat sensitive matter – indeed, it has been said that *'[it] is often as much an art as it is a science'* (Diks, 1999).

To conclude this discussion of the estimation of invariants, we wish to draw attention to the problem of 'error bars'. For instance, suppose that we have measured a time series and, in the reconstructed space, estimated the MCLE as $\hat{\lambda} = 0.072$. May we believe that we have a chaotic system? This depends on how precise our estimate is. If the standard error were, say, 0.8, it would actually be difficult to be confident about the chaotic nature of the system – hence the need to assign measures of precision to estimates. In an imaginary world of Oz, if we had a measured series with one million observations, then we could divide this series into, say, 100 subseries, each 10 000 observations long, and estimate the MCLE and the correlation dimension in each of them. From this sample, it should be straightforward to derive the estimates of the whole original series and the confidence intervals. In our actual world, something similar can be done, even with only a single available series of reasonable length. Suppose that we have measured a series of length, say, 10 000 observations. Then, by means of so-called ***bootstrap methods*** (see Appendix C), we can generate 100 new series, each 10 000 observations long, since these are in all respects like 100 new measurements of the same process. We have shown that on the basis of such techniques, we can assign the standard deviation and confidence intervals to estimation of the MCLE and of the correlation dimension; the reader is referred to Giannerini *et al.* (2007*b*) and Borovkova *et al.* (2011), respectively. Incidentally, the estimate $\hat{\lambda} = 0.072$ refers to the Rössler attractor, introduced by Rössler (1976) in his studies on chemical kinetics, and its standard error is calculated in Giannerini and Rosa (2002) to be 0.006.

4.5 Poincaré Map

Imagine that the phase space is something real and so is the representative point. Suppose that the representative point follows the trajectory sketched in Figure 4.15a, namely a periodic orbit. Imagine now putting a piece of paper P parallel to the plane (x, z). The representative point intersecting the paper cuts a 'hole' in it. If the orbit has period 1, there is only one 'hole', A (Figure 4.15a). At every period, the representative point passes through the hole A. If the orbit is doubly periodic, there are two 'holes', A and B (Figure 4.15b), so the representative point passes through A and B alternately. The 'piece of paper' is the ***Poincaré section***, and the 'holes' form the ***Poincaré map***, also known as *first-return map*. In Figure 4.15, the 'holes' in the Poincaré section are mathematically points, but are enlarged for the sake of clarity, as will done also in the following. The process at the basis of the Poincaré section construction consists in converting the trajectory of a continuous dynamical system in an N-dimensional phase space into a discrete trajectory (i.e. a map) in an $(N-1)$-dimensional phase space. We can look at this geometrical construction as a 'stroboscopic' representation

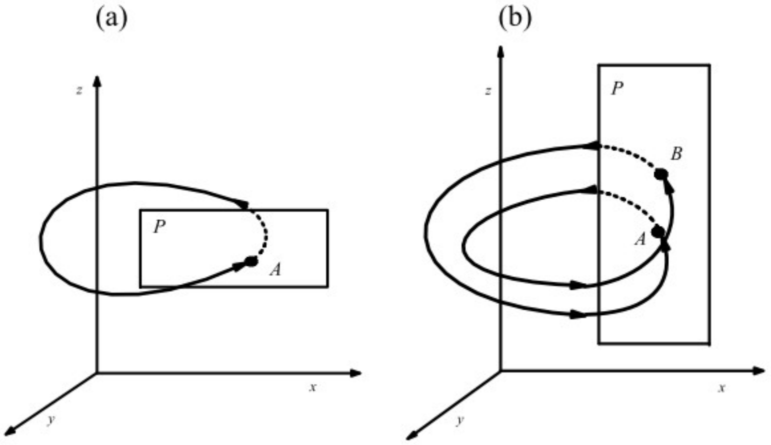

Fig. 4.15 Poincaré map for (a) a period-1 cycle and (b) a period-2 cycle.

of the dynamics of a system. We have seen that for a period-1 cycle, the Poincaré map consists of only one point in the Poincaré section; that is, at every period, the points are plotted upon each other. For a period-2 cycle, the Poincaré map consists of two points; for a period-n cycle, there are n points in the Poincaré section. Note that the intersection points that are considered are only those produced by trajectories in a specified direction, for instance those that cross the plane from the same side.

In the following, we will exploit the Poincaré map to show the dynamics of the *damped driven pendulum*. This pendulum derives from the ideal pendulum already discussed, but now it is more 'realistic', since, in addition to the force of gravity, two further forces acting on it are considered: the damping force and the driving force. The damping force takes into account possible friction with the suspension point and air resistance. The amplitude of oscillation will diminish gradually with time until eventually the system stops. However, an external force acts on the bob, supplying energy to the system, which can continue to oscillate. The interaction between the damping and driving forces makes the system exhibit an extraordinary variety of behaviour, including chaotic behaviour, as shown in Baker and Gollub (1996).

The damping force and the driving force are chosen with very simple forms: the former as being linearly dependent on the velocity of the bobs and the latter as periodic. The the equation of motion of the pendulum, in dimensionless form, is then

$$\frac{d^2x}{dt^2} + \gamma\frac{dx}{dt} + \sin x = F\cos(wt) \tag{4.9}$$

where γ is the *damping constant* (or damping coefficient). In the literature, the quantity $Q = 1/\gamma$, called the *quality factor*, or Q-factor, is also introduced Note that the small-angle approximation, $\sin x \approx x$, is *not* assumed. The parameters F and w are the amplitude and angular frequency of the periodic driving force. Do not confuse

w with ω in eqn (3.2) – the latter is the 'natural' angular frequency, that is, the pendulum frequency without the damping and driving forces. Note that ω does not appear explicitly in eqn (4.9), since it is taken equal to 1, so the driving angular frequency w is a multiple of ω.

Equation (4.9) can be rewritten as a system of three first-order differential equations:

$$\begin{cases} \dfrac{dx}{dt} = y \\ \dfrac{dy}{dt} = -\gamma y - \sin x + F \cos z \\ \dfrac{dz}{dt} = w \end{cases} \tag{4.10}$$

where $z = wt$ is the phase of the driving force. The phase space has three coordinate axes (x, y, z); recall that physically x is the angle $\theta(t)$ and y is the angular velocity $d\theta(t)/dt$ (see Figure 3.1). This system is clearly nonlinear owing to the presence of the terms $\sin x$ and $\cos z$.

For the system (4.10), the solutions depends on γ and ω (in our particular case, ω is fixed to be 1). Let $\gamma > 0$ and $\gamma^2 < 4\omega^2$. The solution is then a sine curve modulated by an exponential; in phase space, the orbits are spirals converging to the asymptotically stable fixed point, the origin $(x(0), y(0)) = (0, 0)$, which is an attractor, called the *focus* (see Figure 6.3b). The basin of attraction is the entire (x, y) plane. Recall that the term *basin of attraction* describes the set of initial points from which the trajectories start and will converge on the attractor at long times. The basin of attraction can be a region of phase space or the whole phase space. There are also trajectories that are not attracted by attractors and are called *separatrices* (singular *separatrix*). They separate regions of phase space inside which the trajectories have different qualitative and quantitative behaviours. In the chaotic regime, the basins of attraction have fractal boundaries.

Mathematically, we can consider also $\gamma < 0$. In this case, the origin $(0, 0)$ becomes an unstable focus, that is, a repeller. If $\gamma^2 < 4\omega^2$, with $\gamma > 0$, the attractor is a *node* and the trajectories approach it monotonically, without spiralling. We are in the presence of *overdamped* motion. See the discussion in Section 5.2. We can solve the system (4.10) by means of Code 4.4 `p_damp_driv_1.R`, which follows the same logic as `pend_id_s_o.R`, but now with three difference equations. As in Baker and Gollub (1996), the parameters γ (`gamma`) and w (`w`) are fixed ($\gamma = \frac{1}{2}$ and $w = \frac{2}{3}$), while F (`F`) assumes different values.

```

The period T_D of one driving cycle is $T_D = 2\pi/w$, and the driving angular frequency w is taken equal to $\frac{2}{3}$. The time step (`step`) is $3\pi/100 \approx 0.09425$, so in 100 iterations the system makes one complete phase orbit.

With $F = 0.9$, the trajectory in the three-dimensional phase space starts from the point $(5, 4, 0)$ and, after a brief transient, the motion becomes periodic and we see the trajectory spiral along the z axis, which represents the flow of time, as shown in Figure 4.16a. For clarity, the three-dimensional trajectory is projected onto the (x, y) plane (as we will also do in the following) in Figure 4.16b (full circles), with a further trajectory (open circles) starting from the point $(13, 0, 0)$ also being shown. After some steps the two trajectories, independently of the initial conditions, converge on a unique closed curve, which is an attractor called the *limit cycle*, more specifically, the period-1 limit cycle. Physically, the pendulum, after the initial transient is extinguished, oscillates at a single frequency, exactly the driving angular frequency w.

Two improvements are introduced in the code. The angle x (i.e. θ) is restricted to the interval $[-\pi, \pi]$, so that if the trajectory exits at the right edge ($> \pi$), it is reported at the left edge, and vice versa. The second improvement concerns the Poincaré map. The `R` package `nonlinearTseries` contains the function **poincareMap** to compute the Poincaré map. So Code 4.4 becomes Code 4.5 `p_damp_driv_2.R`, which is run for $F = 0.9$ and $F = 1.07$.

```
#Code 4.5     Damped driven pendulum (p_damp_driv_2.R)
# Angle x restricted in [-pi, pi], nonperiodic transient discarded.
#Poincare map computed
```

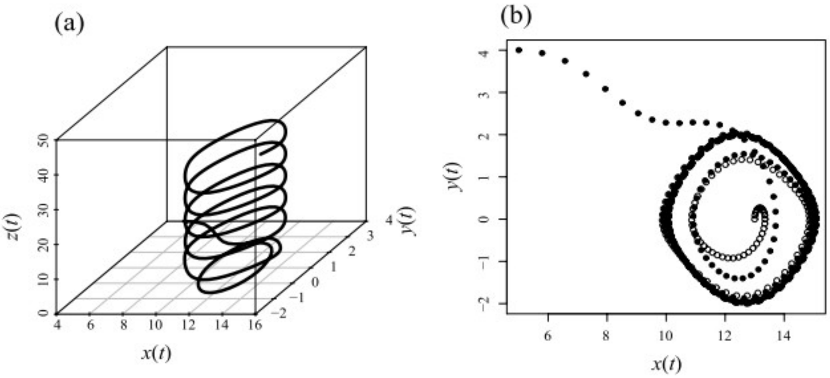

Fig. 4.16 (a) Trajectory in the three-dimensional phase space of the damped driven pendulum with parameters $\gamma = \frac{1}{2}$ and $w = \frac{2}{3}$ and $F = 0.9$ and with initial conditions $(5, 4, 0)$. (b) The same trajectory, but projected onto the (x, y) plane (full circles); a further trajectory starting from $(13, 0, 0)$ is also shown (open circles).

```

axis.y<-xyz[itrans:nstep,3]

for(i in 1:length(axis.x)){
```

```
if(axis.x[i]< -pi)    {             #  the trajectory is lesser than -pi ntimes
ntimes<-trunc(axis.x[i]/pi)
axis.x[i]<- axis.x[i]%%pi
if(ntimes%%2!=0)axis.x[i]<- axis.x[i]+pi
                      }
}

for(i in 1:length(axis.x)){
if(axis.x[i]> +pi)    {             #  the trajectory is greater than +pi ntimes
ntimes<-trunc(axis.x[i]/pi)
axis.x[i]<- axis.x[i]%%pi
if(ntimes%%2!=0)axis.x[i]<- axis.x[i]-pi
                      }
}
par(mai=c(1.02,1.,0.82,0.42)+0.1)
plot(axis.x,axis.y,type="p",pch=20,cex=0.3,xlab="x(t)",ylab="y(t)",
cex.lab=1.5,cex.axis=1.2,lwd=3,lty=1,xlim=c(-pi,pi),ylim=c(-pi,pi))

require(nonlinearTseries)
# compute poincare sections
takens=cbind(axis.x,axis.y)
pm=poincareMap(takens=takens,normal.hiperplane.vector=c(0,1),hiperplane.point=c(0,0))
points(pm$pm.pos,col="black",pch=19,cex=2.8,lwd=2.5)
```

To consider only the trajectory on the limit cycle, the nonperiodic transient is discarded. The line `takens=cbind(axis.x,axis.y)` means that the Takens vectors are known – that is, the real phase space, instead of the reconstructed phase space, is known to the user. If necessary, the embedding procedure can be performed with, for example, the instruction

```
pm=poincareMap(time.series=my.series, embedding.dim=3, time.lag=1,
takens=NULL, normal.hiperplane.vector=c(0,0,1), hiperplane.point=c(0,0,0))
```

The parameters `normal.hiperplane.vector=c(0,1)` and `hiperplane.point=c(0,0)` are used to select the Poincaré section. With `pm$pm.pos`, only intersection points produced by trajectories in the positive direction are considered. The result is shown in Figure 4.17 for $F = 0.9$ (a) and 1.07 (b).

Figure 4.17a shows the limit cycle in Figure 4.16b (initial condition $(5, 4, 0)$), but translated in $[-\pi, \pi]$. The result of the computer code is that the limit cycle in Figure 4.16b is inside $[10.06367, 15.07358]$. The right-hand limit is greater than $4 \times \pi$, so $x(t) = 15.07358$ has to be translated as $(15.07358 - 4 \times \pi = 2.507209)$. The Poincaré section is a plane perpendicular to the (x, y) plane and passing through the $y = 0$ axis. The Poincaré map appears as a single point – actually, single points are plotted in the same location on top of each other, at each integer multiple of T_D. When $F = 1.07$ (Figure 4.17b), the period doubles, $T_D = 6\pi$, so the Poincaré map consists of two points plotted within 3π of each other, signifying that the motion of the pendulum is characterized by two different periodic oscillations. Note that the small patch of trajectory on the right is due to the translation in $[-\pi, \pi]$ from left to right of the patch of trajectory less than $-\pi$.

Lastly, let us see what happens when $F = 1.15$. Figure 4.18a shows two trajectories starting from two very close points $A = (5, 5, 0)$ (continuous line) and $B = (5.001, 5.001, 0)$ (dashed line). Here the motion of the pendulum is chaotic: we see that, after a few steps, the trajectories separate themselves at an exponential rate and

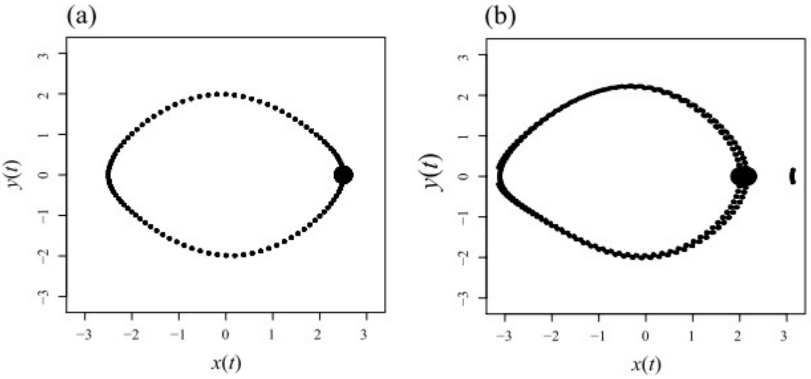

Fig. 4.17 Trajectory in the (x, y) plane of the damped driven pendulum with parameters $\gamma = \frac{1}{2}$ and $w = \frac{2}{3}$ and with initial conditions $(5, 4, 0)$. The trajectory is restricted to the interval $[-\pi, \pi]$ and the transient is discarded. The Poincaré map is also shown as full circles. (a) $F = 0.9$, (b) $F = 1.07$.

we again find a sensitivity to initial conditions, owing to the stretching and folding mechanism. Note that sometimes the single trajectory seems to intersect, although this is not possible for a deterministic system – actually, this impression is due to the projection of the trajectory onto the (x, y) plane. In Figure 4.18b, the trajectory starting from $(5, 5, 0)$ is 10 times longer and is translated in $[-\pi, \pi]$. The figure shows manifestly the 'strange' structure of the attractor, which can be seen in greater detail in the Poincaré map in Figure 4.19. There is no evidence of periodic behaviour, every cycle is different to every other and every point of phase space is visited by the system only once.

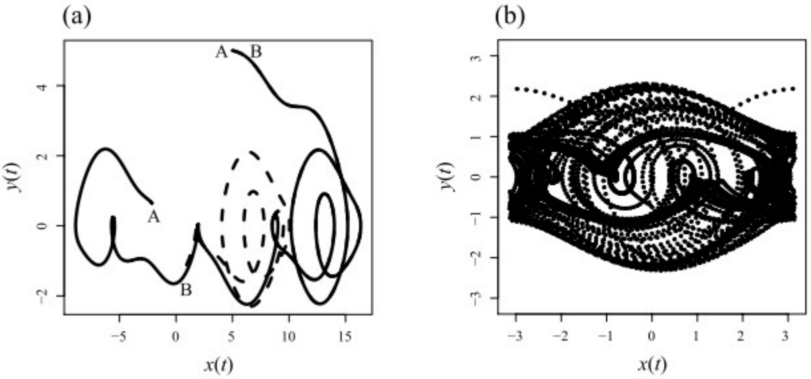

Fig. 4.18 (a) Trajectories in the (x, y) plane of the damped driven pendulum with parameters $\gamma = \frac{1}{2}$, $w = \frac{2}{3}$ and $F = 1.15$ and with initial conditions $A = (5, 5, 0)$ (continuous line) and $B = (5.001, 5.001, 0)$ (dashed line). (b) The trajectory starting from $A = (5, 5, 0)$ is restricted to the interval $[-\pi, \pi]$ and the transient is discarded. Compared with the trajectories in (a), the length of the trajectory here is 10 times greater.

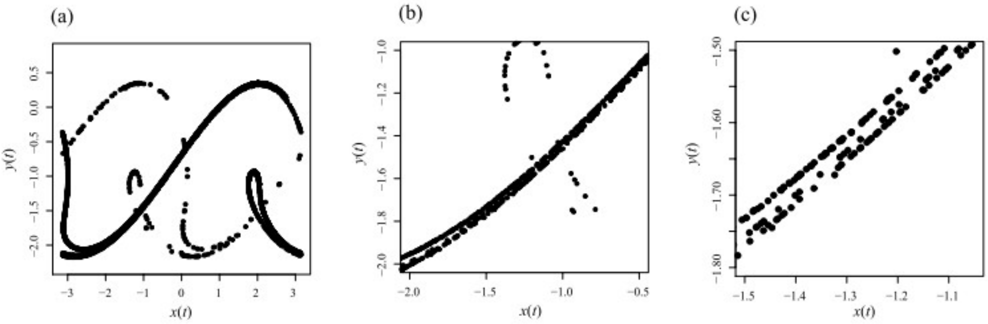

Fig. 4.19 (a) Poincaré map of the damped driven pendulum with parameters $\gamma = \frac{1}{2}$, $w = \frac{2}{3}$ and $F = 1.15$, and with initial conditions $(5, 5, 0)$, as in Figure 4.18b. (b, c) Zooming in on the Poincaré map highlights its fractal structure.

To compute the Poincaré map in this case, a 'stroboscopic picture' of the trajectory in Figure 4.18b is taken at every period of the driving force T_D. Figure 4.19a shows that the Poincaré map is no longer composed either of single points or of random points, but of a set of points with involute structure. If a 'line' on which the points are located is magnified, a group of similar lines emerges (Figure 4.19b, c; note the scales on the axes). Thus, the Poincaré map can be seen as an attractor having a fractal dimension. Looking at Figure 4.17, the cycle in (a), with $F = 0.9$, is symmetric with respect to the x and y axes, while cycle in (b), with $F = 1.07$, is asymmetric with respect to the x axis. If F is increased further, a period doubling occurs up to $F = 1.15$, when the system becomes chaotic. We will see such a route to chaos in Section 4.5.1.

4.5.1 Symmetry breaking

As we did for the logistic map, we construct a bifurcation diagram by computing the angular value $x(t)$ as a function of F, after the transient has been discarded, as shown in Figure 4.20. We have a cascade of bifurcations up to $F \approx 1.10$, even though only the first of these is clearly distinguishable. As F increases, a segment of period 3 becomes visible, around $F \approx 1.12$. For $F \approx 1.15$, a chaotic region begins, and, for $F \approx 1.30$, a period-1 window is born, which doubles for $F \approx 1.45$ and doubles again with a small increase in F. Around $F \approx 1.50$, the chaotic region reappears.

Let us examine in greater detail the first bifurcation occurring when F is very close to 1.066, as shown in Figure 4.21a and already seen in Figure 4.17b. It appears also that the period doubles again for $F \approx 1.08$. For Figure 4.21a, the initial conditions are $(5, 5, 0)$, but if the trajectory starts from $(5, 7, 0)$, we obtain Figure 4.21b. We can see that the arm between $F \approx 1.025$ and $F \approx 1.060$ is the same as that in Figure 4.21a, but as if it has been specularly 'reflected'.

To better understand what has happened, let us examine Figure 4.22a. It is immediately clear that the two innermost cycles are symmetric with respect to the x and y axes, while for the outermost cycles the symmetry with respect to the y axis is no longer apparent, as we have already seen in Figure 4.17. The orbit depicted by circles,

*D 3 3D !.

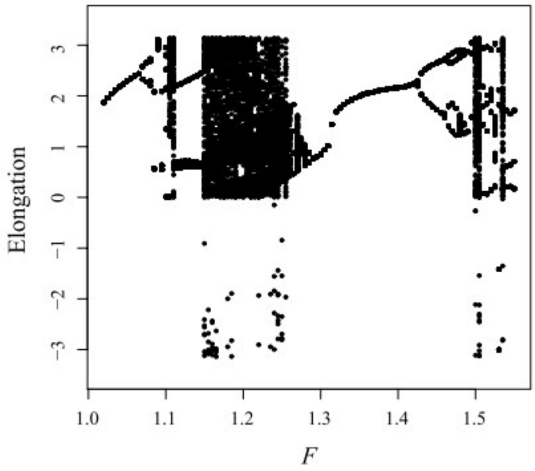

Fig. 4.20 Bifurcation diagram of the damped driven pendulum with parameters $\gamma = \frac{1}{2}$, $w = \frac{2}{3}$ and $F \in [1.020, 1.550]$.

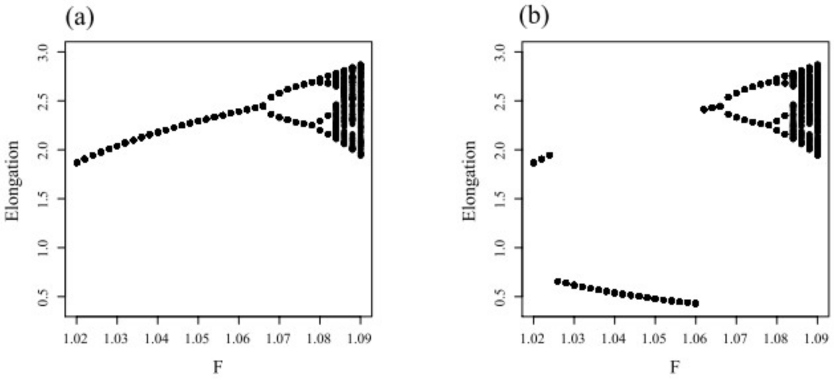

Fig. 4.21 Bifurcation diagram of the damped driven pendulum with parameters $\gamma = \frac{1}{2}$, $w = \frac{2}{3}$ and $F \in [1.020, 1.090]$, with initial conditions $(5, 5, 0)$ (a) and $(5, 7, 0)$ (b).

with initial conditions $(5, 7, 0)$, spends more time in the region with $x(t) < 0$; that is, the region to the left of the vertical line is visited more frequently than the region to the right. Specular behaviour occurs for the orbit depicted by open squares, with initial conditions $(5, 5, 0)$. Up to a value of $F \approx 1.024$, the trajectories converge on symmetric limit cycles, regardless of the initial conditions, but when F goes beyond this critical value, convergence occurs on two possible asymmetric limit cycles, each being the reflected image of the other. In other words, the trajectory may converge on a limit cycle or on its specular reflection, with both solutions being correct from a physical point of view and depending only on the initial conditions but not on the physical parameters. The existence of specular limit cycles explains the appearance of

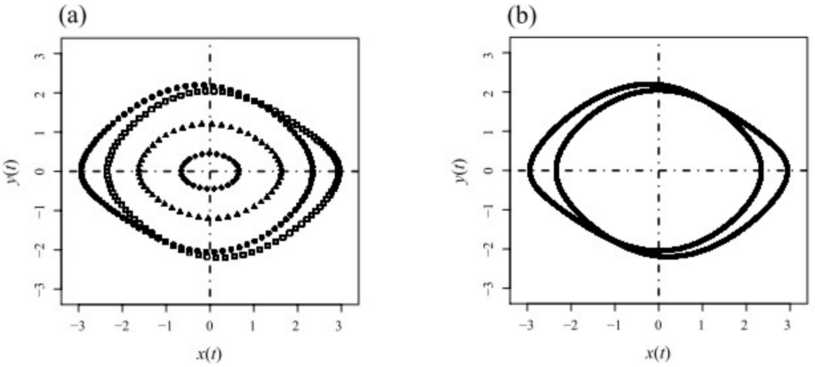

Fig. 4.22 Evolution in phase space of the damped driven pendulum with parameters $\gamma = \frac{1}{2}$ and $w = \frac{2}{3}$. (a) For the two innermost cycles, $F = 0.4$ (diamonds) and $F = 0.7$ (triangles), with initial conditions $(5, 7, 0)$. For the two outermost cycles, $F = 1.025$, with initial conditions $(5, 7, 0)$ (circles) and $(5, 5, 0)$ (open squares). (b) Only the two outermost cycles are plotted, with lines connecting the points.

the bifurcation plots in Figure 4.21, since the points on the specular arms are the coordinates x of the possible specular attractors. For instance, when $F = 1.026$, we find $x(t) = 0.657$ with initial conditions $(5, 7, 0)$ and $x(t) = 1.977$ with initial conditions $(5, 5, 0)$.

Nothing in the equations of the damped driven pendulum can reveal that the region to the right of the vertical line is more preferred than that on the left, or vice versa. This type of phenomenon is called *symmetry breaking*. Such symmetry breaking does not occur if the system evolution is described by linear equations, but is intimately connected with the nonlinear behaviour of the system. Note, however, that symmetry breaking of a single limit cycle leads to the emergence of a new symmetry if we imagine joining together the two specular attractors. We thereby obtain two limit cycles that are symmetric with respect to the vertical line. Figure 4.22b shows the two outermost cycles in Figure 4.22a, with the points now connected with a line, and the impression is of two symmetric limit cycles one inside the other.

The interconnected concepts of symmetry, symmetry breaking, conservation laws and degeneracy play a central role in the physical sciences (see e.g. Brading and Castellani (2013) and references therein). It is common knowledge that symmetry principles (or invariance principles) can be invoked to explain conservation laws. Examples from classical mechanics are energy conservation (related to invariance of the Hamiltonian under time translation) and momentum and angular momentum conservation (related to invariance of the Hamiltonian under spatial translation and rotation, respectively). In quantum mechanics, symmetry principles are even more powerful – recall, for instance, that so-called quantum statistics are related to a new kind of symmetry, the interchange of identical particles. A further consequence of symmetry is degeneracy of energy levels: greater symmetry in the Hamiltonian leads to more degeneracy in the energy spectrum. A further concept connected to symmetry is that of *symmetry breaking*. As David Gross (1996) writes: ‘The secret of nature is symmetry, but much of the texture of the world is due to mechanisms of symmetry breaking.' As we have seen, the laws of mechanics describing the dynamics of the pendulum are symmetric, but when F is greater than a critical value, the states visited by the system are no longer symmetric in phase space.

4.6 Summary

The strangeness of strange attractors is exhibited in the dynamics of trajectories and in the fractal warp woven by the system in (reconstructed) phase space. One of the main features of deterministic chaotic systems is their well-known sensitive dependence on initial conditions. Recall here that historically von Mises, as far back as 1939, recognized sensitivity to initial conditions as the primary source of randomness even in stochastic systems.

The maximal characteristic Lyapunov exponent (MCLE) is an important measure of stability and one of the indicators of the presence of chaos. There are two classes of estimators for the MCLE. The first measures the exponential divergence of trajectories that are initially close through estimation of the Jacobian matrix along the trajectories. The second directly measures the evolution in time of the distance between initially close points. We have focused in this chapter on the performance of the estimator of the MCLE implemented in `tseriesChaos`, which belongs to the second class. For this type of estimator, computation is easy compared with that of Jacobian estimators, and they can also detect whether a system is non-chaotic. The presence of a sharp linear region in the plot of the evolution of the logarithm of the mean distance between points is a strong signal of chaos. For stochastic systems, in contrast, the linear region tends to become flatter with increasing embedding dimension. However, there are situations (the presence of a dynamic noise component and/or series of moderate size) in which these estimators can produce a linear scaling region giving a positive estimate of the MCLE even for non-chaotic systems.

The 'strangeness' of an attractor's geometry is measured by its fractal dimension. There are a number of definitions of fractal dimension, one of which is the correlation dimension D_2. This is estimated via the so-called correlation integral, which is the proportion of all pairs of reconstruction vectors closer than a given distance ϵ in some norm. In the Grassberger–Procaccia correlation integral, if a point is less than a threshold ϵ, it counts as 1; otherwise it counts as 0. In the Gaussian correlation integral, two points that are a small distances apart are weighted (using a Gaussian weighting) more than those separated by large distances. An estimate of the correlation dimension is given by the slope of the log–log plot of the correlation integral versus ϵ. If this estimate is repeated for increasing embedding dimensions m, for chaotic systems, it initially increases with m, but eventually – at least theoretically – it asymptotically reaches a plateau. The value m^* at which this plateau begins is the next integer above D_2. For instance, if the estimated correlation dimension is 2.056, as for the Lorenz attractor, then the minimum number of variables required to describe the system is 3. Other techniques exist to estimate D_2. In Chapter 7, the entire procedure to estimate D_2 for the Lorenz attractor will be repeated, except that, finally, it will be derived through a maximum likelihood procedure (the Takens estimator).

Jules Henri Poincaré makes two appearances this chapter: in *Poincaré's recurrence theorem* and in the *Poincaré section*. He introduced the concept of recurrence, namely that systems, under certain conditions and after a sufficiently long but finite time, will return to a state as close as you like to the initial state. A graphical analysis of the recurrence states of a dynamical system can be executed through recurrence plots (RPs), which can be quantified using recurrence quantification analysis (RQA). In this chapter, we have applied RPs to the logistic map and the Lorenz attractor. It is important to note that methods based on RPs allow trajectories in the m-dimensional phase space of a system to be analysed in terms of a two-dimensional representation of the system's recurrences.

For the study of the *damped driven pendulum*, we have exploited the Poincaré section. This is constructed by converting the trajectory of a continuous dynamical system in an N-dimensional phase space into a discrete trajectory (i.e. a map) in an $(N-1)$-dimensional phase space. We can view this geometric construction as a 'stroboscopic' representation of the dynamics of the system. The damped driven pendulum is the ideal pendulum, introduced in Chapter 3, made more realistic by the inclusion, in addition to the force of gravity, of two further forces acting on it: a damping force and a driving force. The damping force takes into account possible friction with the suspension point and air resistance. The driving force is an external force acting on the bob and supplying energy to the system. A wide variety of behaviours, including chaotic ones, are shown by the damped driven pendulum. Here, we have studied the bifurcation diagram, as for the logistic map, and the particular phenomenon called *symmetry breaking*.

Up to this stage, the solution to Eq. (6.76) is expected to be represented in a series form of

$$V=\sum_{n=0}^{\infty}\mathcal{P}_n(r)\Theta_n(\theta)=\frac{1}{\sqrt{r}}\sum_{n=0}^{\infty}C_n\mathrm{J}_{n+\frac{1}{2}}(kr)\mathrm{P}_n(\cos\theta) \tag{6.83}$$

with the coefficients C_n to be determined.

Inserting the boundary condition of $V|_{r=1}=1-\cos^2\theta$ into Eq. (6.83) suggests

$$1-\cos^2\theta=\sum_{n=0}^{\infty}C_n\mathrm{J}_{n+\frac{1}{2}}(k)\mathrm{P}_n(\cos\theta). \tag{6.84}$$

For simplicity, we introduce $x=\cos\theta$, and Eq. (6.84) then becomes

$$1-x^2=\sum_{n=0}^{\infty}C_n\mathrm{J}_{n+\frac{1}{2}}(k)\mathrm{P}_n(x). \tag{6.85}$$

For determining C_n in Eq. (6.85), we note that the left side of Eq. (6.85) is a degree 2 polynomial. Thus $C_n=0$ for $n>2$. Besides, since $1-x^2$, the left side of Eq. (6.85), is an even function, $C_1=0$ as $\mathrm{P}_1(x)$ is an odd function. Equation (6.85) is further simplified to be

$$1-x^2=C_0\mathrm{J}_{\frac{1}{2}}(k)\mathrm{P}_0(x)+C_2\mathrm{J}_{\frac{5}{2}}(k)\mathrm{P}_2(x). \tag{6.86}$$

Incorporating it with Eq. (6.46) sets up a linear equation system for C_0 and C_2, and we obtain $C_0=2/(3J_{1/2}(k))$ and $C_2=-2/(3J_{5/2}(k))$. Inserting them back into Eq. (6.83), we finally express the solution to problem (6.78) by

$$\begin{aligned}V(r,\theta)&=\frac{1}{\sqrt{r}}\left(\frac{2}{3J_{\frac{1}{2}}(k)}\cdot\mathrm{J}_{\frac{1}{2}}(kr)\mathrm{P}_0(\cos\theta)-\frac{2}{3J_{\frac{5}{2}}(k)}\cdot\mathrm{J}_{\frac{5}{2}}(kr)\mathrm{P}_2(\cos\theta)\right)\\&=\frac{1}{\sqrt{r}}\left(\frac{2}{3J_{\frac{1}{2}}(k)}\cdot\mathrm{J}_{\frac{1}{2}}(kr)-\frac{1}{3J_{\frac{5}{2}}(k)}\cdot\mathrm{J}_{\frac{5}{2}}(kr)\left(3\cos^2\theta-1\right)\right).\end{aligned} \tag{6.87}$$

6.4.2 *Legendre–Gauss Quadrature*

The concept of the Legendre–Gauss quadrature has been intensively used for evaluating definite integrals. First, we derive the rule of the Legendre–Gauss quadrature. Then the idea is extended to general orthogonal polynomials, and the rule of general Gauss quadrature is presented.

To this end, we start with evaluating $\int_{-1}^{1} f(x)\,\mathrm{d}x$, where $f(x)$ is a polynomial of degree no greater than $2n-1$. Suppose that the roots of $\mathrm{P}_n(x)$ are denoted by $-1 < \zeta_1^{(n)} < \cdots < \zeta_n^{(n)} < 1$, i.e.

$$\mathrm{P}_n(x) = (x - \zeta_1^{(n)}) \cdots (x - \zeta_n^{(n)}). \tag{6.88}$$

Now we construct a function $F(x)$ through the Lagrange interpolation as

$$F(x) = \sum_{k=1}^{n} f(\zeta_k^{(n)}) \cdot \frac{\mathrm{P}_n(x)}{\mathrm{P}_n'(\zeta_k^{(n)})(x - \zeta_k^{(n)})}, \tag{6.89}$$

where P_n' denotes the first derivative of P_n. It can be checked that $F(x)$ is a polynomial of degree $n-1$ and

$$F(\zeta_k^{(n)}) = \lim_{x \to \zeta_k^{(n)}} F(x) = f(\zeta_k^{(n)}) \tag{6.90}$$

for $k = 1, \ldots, n$.

This implies that the function $F - f$ is essentially a polynomial of degree no greater than $2n-1$, and $\zeta_1^{(n)}, \ldots, \zeta_n^{(n)}$ are all its roots. In other words, the polynomial $F - f$ can be factorised by

$$F(x) - f(x) = (x - \zeta_1^{(n)})(x - \zeta_2^{(n)}) \cdots (x - \zeta_n^{(n)}) r(x) = \mathrm{P}_n(x) r(x), \tag{6.91}$$

where $r(x)$ is another polynomial of degree $\leq n-1$, and Eq. (6.88) is employed to derive the second identity.

Replacing $F(x)$ in Eq. (6.91) by Eq. (6.89) and rearranging the result, we get

$$f(x) = \sum_{k=1}^{n} f(\zeta_k^{(n)}) \cdot \frac{\mathrm{P}_n(x)}{\mathrm{P}_n'(\zeta_k^{(n)})(x - \zeta_k^{(n)})} - r(x)\mathrm{P}_n(x). \tag{6.92}$$

Integrating both sides on $(-1, 1)$ gives

$$\int_{-1}^{1} f(x)\,\mathrm{d}x = \sum_{k=1}^{n} \omega_k^{(n)} f(\zeta_k^{(n)}) - \int_{-1}^{1} r(x)\mathrm{P}_n(x)\,\mathrm{d}x, \tag{6.93}$$

where $w_k^{(n)}$ are sometimes termed as the *Christoffel numbers* defined by

$$w_k^{(n)} = \frac{1}{\mathrm{P}_n'(\zeta_k^{(n)})} \cdot \int_{-1}^{1} \frac{\mathrm{P}_n(x)\,\mathrm{d}x}{x - \zeta_k^{(n)}}. \tag{6.94}$$

Table 6.2 Roots of the Legendre polynomials and the Christoffel numbers defined by Eq. (6.94) up to degree 5

P_n	$\zeta_k^{(n)}$	$w_k^{(n)}$
$n=2$	$\pm\frac{1}{\sqrt{3}}$	1
$n=3$	0 $\pm\sqrt{\frac{3}{5}}$	$\frac{8}{9}$ $\frac{5}{9}$
$n=4$	$\pm\sqrt{\frac{15-2\sqrt{30}}{35}}$ $\pm\sqrt{\frac{15+2\sqrt{30}}{35}}$	$\frac{1}{36}\left(18+\sqrt{30}\right)$ $\frac{1}{36}\left(18-\sqrt{30}\right)$
$n=5$	0 $\pm\frac{1}{21}\sqrt{245-14\sqrt{70}}$ $\pm\frac{1}{21}\sqrt{245+14\sqrt{70}}$	$\frac{128}{225}$ $\frac{1}{900}\left(322+13\sqrt{70}\right)$ $\frac{1}{900}\left(322-13\sqrt{70}\right)$

With reference to Eq. (6.66), the integral on the right side of Eq. (6.93) should vanish. Hence, the *rule of the Legendre–Gauss quadrature* is derived to be

$$\int_{-1}^{1} f(x)\,\mathrm{d}x = \sum_{k=1}^{n} w_k^{(n)} f(\zeta_k^{(n)}). \tag{6.95}$$

Several properties shown by the rule of the Legendre–Gauss quadrature make it particularly attractive. Firstly, the integral about a polynomial of degree $2n-1$ is simply calculated by a summation of n terms. Secondly, the Christoffel numbers $w_k^{(n)}$ do not depend on the actual form of $f(x)$, but only on the roots of P_n. Thus, they can be computed beforehand during an "offline" stage as these roots are applied for all cases of $f(x)$. During the "online" stage when the target function $f(x)$ is specified, one can directly add together the n terms on the right side of Eq. (6.95), so as to calculate the integral $\int_{-1}^{1} f(x)\,\mathrm{d}x$.

Table 6.2 lists the roots of the Legendre polynomials and the corresponding Christoffel numbers up to $n=5$. Note that the roots that are symmetric to each other about $x=0$ share a same Christoffel number, and $\sum_{k=1}^{n} w_k^{(n)} = 2$ which is just the length of the domain of integration. Thus, the Christoffel numbers actually correspond to a partition of the domain $(-1, 1)$, and $f(\zeta_k^n)$ can be treated as a representative function value in the kth subinterval.

Equation (6.95) is exact for $f(x)$ being a polynomial of degree $2n-1$. When $f(x)$ is an arbitrary bounded function on $(-1, 1)$, it becomes an approximation. Rigorous analysis can be made to give an upper bound for the approximating error. However, we have seen from Eq. (6.64) that $f(x)$ can be approximated by a linear combination of Legendre polynomials, as shown in demonstrative Fig. 6.4. Therefore, the approximating error is expected to diminish quickly as n is relatively large.

Table 6.3 Calculation of the integral of $\int_{-1}^{1} \mathrm{e}^{2x}\,\mathrm{d}x$ using the rule of the Legendre–Gauss quadrature by Eq. (6.95) and the corresponding relative errors

	Exact	$n = 2$	$n = 3$	$n = 4$	$n = 5$
Value	3.6269	3.4882	3.6223	3.6268	3.6269
Rel. err.	–	0.0382	0.0013	2.26×10^{-5}	1.87×10^{-7}

In Table 6.3, the computed values for $\int_{-1}^{1} \mathrm{e}^{2x}\,\mathrm{d}x$ using the rule of the Legendre–Gauss quadrature are given for various n. It is observed that the approximating accuracy on using Eq. (6.95) is up to six decimal digits as n is as small as 5. From this example, we see that the rule of the Legendre–Gauss quadrature offers an effective algorithm for evaluating definite integrals.

Finally, the derivation for Eq. (6.95) is generalisable to cope with other types of classical orthogonal polynomials. The key difference then is one needs to multiply the corresponding weighted function $\rho(x)$ when integrating Eq. (6.92). And this gives rise to the *general rule of Gauss quadrature*:

$$\int_I \rho(x) f(x)\,\mathrm{d}x = \sum_{k=1}^{n} w_k^{(n)} f(\eta_k^{(n)}), \tag{6.96}$$

where I is the domain of the orthogonal polynomial $p_n(x)$ in consideration and $\eta_k^{(n)}$ denotes the kth root of $p_n(x)$. And the Christoffel numbers then become

$$w_k^{(n)} = \frac{1}{\mathrm{P}_n'(\eta_k^{(n)})} \cdot \int_{-1}^{1} \frac{\rho(x) p_n(x)\,\mathrm{d}x}{x - \eta_k^{(n)}}. \tag{6.97}$$

6.5 The Associated Legendre Functions

In this section, we further consider the solutions to the associated Legendre equation (6.19), that is,

$$(1 - x^2)\frac{\mathrm{d}^2 y}{\mathrm{d}x^2} - 2x\frac{\mathrm{d}y}{\mathrm{d}x} + \left(n(n+1) - \frac{m^2}{1 - x^2}\right) y = 0. \tag{6.98}$$

As discussed in Sect. 6.1, the cases when n and m are both non-negative integers are of particular importance for implementing the method of separation of variables. So the discussion in this section is confined to such situations. Since the present section is aimed to disseminate basic concepts, most of the related proofs are skipped in the main texts.

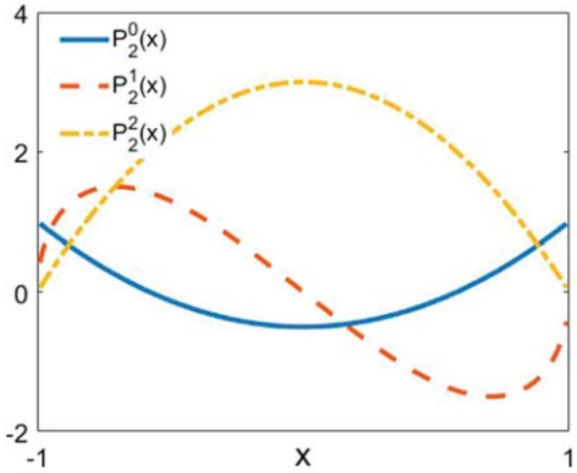

Fig. 6.5 Profiles of the associated Legendre function of the first kind $P_2^m(x)$, with $m = 0$, 1 and 2

We have demonstrated in Sect. 6.2.1 that a fundamental system of solutions to the Legendre equation (6.21) can be formed by the Legendre polynomial $P_n(x)$ given by Eq. (6.40) and the Legendre function of the second kind $Q_n(x)$ given by Eq. (6.44). Actually, the solutions to Eq. (6.98) can be induced from $P_n(x)$ and $Q_n(x)$.

For this purpose, we introduce

$$P_n^m(x) = (-1)^m \left(1 - x^2\right)^{\frac{m}{2}} \frac{d^m}{dx^m} P_n(x), \quad x \in (-1, 1) \tag{6.99}$$

and

$$Q_n^m(x) = (-1)^m \left(1 - x^2\right)^{\frac{m}{2}} \frac{d^m}{dx^m} Q_n(x), \quad x \in (-1, 1). \tag{6.100}$$

It can be checked that Eqs. (6.99) and (6.100) are both solutions to the associated Legendre equation (6.98). Here $P_n^m(x)$ is called the *associated Legendre function of the first kind*, and $Q_n^m(x)$ is called the *associated Legendre function of the second kind*. Here the integer coefficient n is termed as its *degree* and m as its *order*. Note that the term "degree" is inherited from that of Legendre polynomials, although P_n^m is not necessarily a polynomial.

From its definition (6.99), we see that $P_n^m(x)$ is uniformly zero if $n < m$. Thus, we require $n \geq m$ when defining $P_n^m(x)$. Besides, $P_n^0(x)$ is simply the Legendre polynomial of degree n. This coincides with the fact that Eq. (6.98) becomes the Legendre equation when $m = 0$.

In Fig. 6.5, the profiles of $P_2^m(x)$ up to order 2 are shown.

Some of the properties of the associated Legendre functions can be deduced straight forward from that of Legendre functions. For instance, the symmetry of $P_n^m(x)$ about $x = 0$ depends on the value of $n - m$. When $n - m$ is an odd number, $P_n^m(x)$ is an odd function. Moreover, $P_n^m(x)$ are bounded on $x \in (-1, 1)$, but $Q_n^m(x)$ are unbounded on $x \in (-1, 1)$.

Zeros

As for the zeros of $\mathrm{P}_n^m(x)$, we conclude

- $\mathrm{P}_n^m(x)$ has $(n-m)$ simple zeros within the interval $(-1, 1)$.
- The zeros of $\mathrm{P}_n^m(x)$ and $\mathrm{P}_{n+1}^m(x)$ alternate on $(-1, 1)$.
- $\mathrm{P}_n^m(x)$ and $\mathrm{P}_{n+1}^m(x)$ do not have common zeros.
- The zeros of $\mathrm{P}_n^m(x)$ are symmetric about $x = 0$.

Orthogonal systems

If replacing $n(n+1)$ in Eq. (6.98) by λ and rearranging it, we obtain an eigenvalue problem induced by a second-order linear ODE formulated by

$$\frac{\mathrm{d}}{\mathrm{d}x}\left((1-x^2)\frac{\mathrm{d}y}{\mathrm{d}x}\right) - \frac{m^2}{1-x^2}\cdot y + \lambda y = 0, \quad x \in (-1, 1). \tag{6.101}$$

A comparison of Eq. (6.101) with Eq. (2.76) $[k(x) = 1 - x^2 > 0, q = \frac{m^2}{1-x^2} \geq 0$ and $\rho(x) = 1]$ suggests that Eq. (6.101) is a Sturm–Liouville equation. Besides, since $k(\pm 1) = 0$, only natural boundary conditions are needed.

In comparison with Eq. (6.98), the eigenvalues for Eq. (6.101) should be

$$\lambda_n = n(n+1), \quad n \geq m. \tag{6.102}$$

Since only bounded solutions are considered, the corresponding eigenfunctions are

$$y_n(x) = \mathrm{P}_n^m(x), \quad n \geq m. \tag{6.103}$$

Hence, $\{\mathrm{P}_n^m(x)\}_{n=m}^{\infty}$ should form a complete set of orthogonal functions, and the following conclusions are naturally drawn.

For a bounded function $f(x)$ defined on $x \in (-1, 1)$, it can be expressed as a series expansion of the associated Legendre polynomials of order m

$$f(x) = \sum_{n=m}^{\infty} a_n \mathrm{P}_n^m(x), \tag{6.104}$$

where the coefficient a_n is given by

$$a_n = \frac{1}{M_n^m}\int_{-1}^{1} f(x)\mathrm{P}_n^m(x)\,\mathrm{d}x \tag{6.105}$$

with the modulus M_n^m given by

$$M_n^m = \int_{-1}^{1} (\mathrm{P}_n^m(x))^2\,\mathrm{d}x = \frac{2}{2n+1}\frac{(n+m)!}{(n-m)!}. \tag{6.106}$$

It is noted that when an orthogonal system is formed, we have already fixed the order m, and the summation is made over n, with n starting from m.

The aforementioned knowledge should enable us to access the solutions to the Helmholz equation defined within a sphere for more generally imposed boundary conditions.

Exercise

1. Verify that $\mathcal{P}_\alpha(r)$ given by Eq. (6.15) solves Eq. (6.11a).
2. Take the following steps to show that $\mathcal{P}(r) = \frac{1}{\sqrt{r}} J_{\alpha+\frac{1}{2}}(kr)$ is a solution to the Cauchy–Euler equation of Eq. (6.11a), when $k \neq 0$.
   (a) Suppose $\mathcal{P}(r) = F(kr)$, and derive the governing differential equation for $y = F(x)$.
   (b) Assume a series form of $F(x) = \sum_{m=0} a_m x^{m+c}$ and show that $c = \alpha$ if the series solves Eq. (6.11a).
   (c) Carry on to determine all the coefficients a_m in the series, and finalise the proof.
3. Verify that $\Theta(\theta) = F(\cos\theta)$ solves Eq. (6.17b), where $F(\cdot)$ is a solution to the associated Legendre equation (6.19).
4. Solve the Legendre equation [Eq. (6.21)] using the following series form:

$$y = \sum_{k=1}^{\infty} a_k x^k,$$

   and show that the resulting solution is effectively y_2 given by Eq. (6.31b).
5. Verify that Q_0 and Q_n defined by Eqs. (6.43) and (6.44), respectively, solve correspondingly the Legendre equation of degree 0 and of degree n.
6. Use the Rodrigues formula (6.45) to show that $P_n(1) = 1$, $P_n(-1) = (-1)^n$.
7. Based on Eq. (6.46) and recurrence relation (6.47) to express the Legendre polynomials of degrees 6, 7 and 8.
8. Verify the orthogonality condition of Eq. (6.55) for Legendre polynomials with the use of Rodrigues formula (6.45).
9. Write down the orthogonality condition, in comparison with Eq. (6.55), for other types of orthogonal polynomials listed in Table 6.1.
10. Consider the Helmholtz equation $\Delta u + k^2 u = 0$ in $\mathbb{R}^3$.
    (a) Derive the general form of its radial solution, that is, $u = u(\sqrt{x^2+y^2+z^2})$;
    (b) Find one of its fundamental solution following the strategy detailed in Sect. 3.4.
11. Consider the following problem governed by Laplace's equation:

$$\begin{cases} \Delta u = 0, \text{ in } \Omega = \left\{(x, y, z) | \sqrt{x^2+y^2+z^2} < R\right\}; \\ u|_{\partial\Omega} = 1 - z^2. \end{cases}$$

(a) Solve the problem using the method of separation of variables;
(b) Solve the problem using Poisson's formula (3.74) based on the image method for electric potentials in Sect. 3.5.

12. Solve the following problem imposed with Robin boundary condition

$$\begin{cases} \Delta u = 0, \text{ in } \Omega = \left\{(x, y, z) | \sqrt{x^2 + y^2 + z^2} < 1\right\}; \\ \left(u + \dfrac{\partial u}{\partial n}\right)\Big|_{\sqrt{x^2+y^2+z^2}=1} = z. \end{cases}$$

13. Given a spherical shell of

$$\Omega = \left\{\frac{R}{2} < \sqrt{x^2 + y^2 + z^2} < R\right\},$$

use the method of separation of variables to solve

$$\begin{cases} \Delta u + k^2 u = 0, \text{ in } \Omega; \\ u|_{r=\frac{R}{2}} = 0, \ \ u|_{r=R} = z. \end{cases}$$

14. Solve the problem modelling wave propagation in a unit sphere formulated as follows:

$$\begin{cases} u_{tt} - \Delta u = 0, \text{ in } \Omega = \left\{(x, y, z) | r = \sqrt{x^2 + y^2 + z^2} < 1\right\}; \\ u|_{t=0} = r^{\frac{1}{2}}(1 - r^2), \ \ u_t|_{t=0} = 0; \\ u|_{r=1} = 0. \end{cases}$$

  Gauss's theorem in an infinitesimal volume centered at R=0 and enclosed by the surface S,

  Pág. 216(227) 7.7

  Maxwell Equations

  → Gauss's law

  The first two equations are the Gauss's laws, the third equation is the Faraday's law, the

Gauss's theorem in an infinitesimal volume centered at $\mathbf{R}=0$ and enclosed by the surface S,

$$\begin{aligned}&\int d\mathbf{R}\Delta\tfrac{1}{R}=\int d\mathbf{R}div\cdot grad\tfrac{1}{R}=\\&=\int d\mathbf{S}grad\tfrac{1}{R}=-\int d\mathbf{S}\tfrac{\mathbf{R}}{R^3}\rightarrow-4\pi\ \ ,\end{aligned}\tag{5.6}$$

which shows that $\Delta(1/R)=-4\pi\delta(\mathbf{R})$.

Therefore, $1/R$ (or $-1/4\pi R$) is the Green function for the laplacian in $3D$, and we can write the solution of the equation

$$\Delta u=f\tag{5.7}$$

as

$$u(\mathbf{R})=-\frac{1}{4\pi}\int d\mathbf{R}^{'}\frac{1}{|\mathbf{R}-\mathbf{R}^{'}|}f(\mathbf{R}^{'})\ .\tag{5.8}$$

The above equation (which is an inhomogeneous Laplace equation) is the Poisson equation. Its solution vanishes at infinity (as the Green function $1/R$ does). With this boundary condition the solution is unique.

It is worth noting that

$$\Delta\frac{1}{|\mathbf{R}-\mathbf{R}_0|}=-4\pi\delta(\mathbf{R}-\mathbf{R}_0)\tag{5.9}$$

for any $\mathbf{R}_0$; also, we note that derivatives of the form $\partial_x^m\partial_y^n\partial_z^p(1/R)$ are harmonic functions for $\mathbf{R}\neq 0$.

In two dimensions we can check easily that

$$\Delta\ln R=2\pi\delta(\mathbf{R})\ ;\tag{5.10}$$

in one dimension

$$\Delta\,|x|=\frac{d^2}{dx^2}\,|x|=\frac{d}{dx}sgn(x)=2\delta(x)\ ;\tag{5.11}$$

$\ln R$ and $|x|$ are Green functions for the laplacian in $2D$ and $1D$, respectively. It is worth noting that they do not vanish at infinity, as $1/R$ does in $3D$. The Poisson equation can be solved in $2D$ or $1D$ by using these Green functions.

In $2D$ the harmonic functions are related to the analytical functions of complex variable $z = x + iy$ (the complex conjugate is $\overline{z} = x - iy$). An analytic function f is the function which has the derivative df/dz, which means that there exists the derivative along any path approaching the point where the derivative is calculated, and all these derivatives are equal; therefore, $df/dx = df/dy$; with $f = u + iv$ we get

$$\frac{\partial u}{\partial x} = \frac{\partial v}{\partial y} \; , \; \frac{\partial u}{\partial y} = -\frac{\partial v}{\partial x} \; ; \tag{5.12}$$

these are the Cauchy-Riemann relations for analytic functions. We can see immediately that $\Delta u = \Delta v = 0$.

5.2 Green theorem (formulae)

Since

$$v\Delta u = div(vgradu) - gradv \cdot gradu \tag{5.13}$$

we have

$$\begin{gathered} \int_V d\mathbf{R} gradv \cdot gradu + \int_V d\mathbf{R} v\Delta u = \\ = \int_S d\mathbf{S} vgradu = \int_S dSv\frac{\partial u}{\partial n} \; , \end{gathered} \tag{5.14}$$

where the surface S encloses the volume V and n is the coordinate along the normal $\mathbf{n}$ to the surface S (taken along the outward direction). This is the first Green theorem (formula); it applies to spaces with any dimensions.

There exist a few interesting consequences of this theorem. For instance, if $v = 1$ and u is harmonic ($\Delta u = 0$), then

$$\int_S dS\frac{\partial u}{\partial n} = 0 \; . \tag{5.15}$$

Next, if $v = u$ and they are harmonic, then

$$\int_V d\mathbf{R}(gradu)^2 = \int_S dSu\frac{\partial u}{\partial n} \; ; \tag{5.16}$$

(this integral is called the Dirichlet integral); we can see that $u = 0$ in V if $u = 0$ on S and $u = const$ in V if $\partial u/\partial n = 0$ on S.

for the external pressure, the boundary condition $p_0 = \rho\omega^2\Phi(r = R)$ leads to

$$\frac{2}{\pi}\int dkk^2\frac{\varphi_{lm}(k)}{c^2k^2-\omega^2}j_l(kR) + C_{lm}j_l(\omega R/c) = \frac{1}{\rho\omega^2}p_{lm} \ , \qquad (7.92)$$

an equation which determines the coefficients C_{lm}.

7.7 Maxwell equations

E and **H** denote the electric and magnetic field, respectively, ρ and $\mathbf{j}$ are the densities of charge and current, respectively, all real functions of time t and position $\mathbf{r}$. Maxwell equations read

$$\begin{gathered} div\mathbf{E} = 4\pi\rho \ , \ div\mathbf{H} = 0 \ , \\ curl\mathbf{E} = -\tfrac{1}{c}\tfrac{\partial\mathbf{H}}{\partial t} \ , \ curl\mathbf{H} = \tfrac{1}{c}\tfrac{\partial\mathbf{E}}{\partial t} + \tfrac{4\pi}{c}\mathbf{j} \ , \end{gathered} \qquad (7.93)$$

where c is the speed of light. The first two equations are the Gauss's laws, the third equation is the Faraday's law, the fourth equation is the Maxwell-Ampere equation (Michael Faraday (1791-1867), James Clerk Maxwell (1831-1979), Andre-Marie Ampere (1775-1836)). The charges and currents are subjected to the continuity equation

$$\frac{\partial\rho}{\partial t} + div\mathbf{j} = 0 \ . \qquad (7.94)$$

Taking the *div* of the *curl* and using the continuity equation, we can see that only the last two are independent equations.

The fields can be obtained from the protentials **A** (vector potential) and Φ (scalar potential):

$$\mathbf{E} = -\frac{1}{c}\frac{\partial\mathbf{A}}{\partial t} - grad\Phi \ , \ \mathbf{H} = curl\mathbf{A} \ , \qquad (7.95)$$

defined up to the gauge transformation

$$\mathbf{A} = \mathbf{A}^{'} + grad\chi \ , \ \Phi = \Phi^{'} - \frac{1}{c}\frac{\partial\chi}{\partial t} \ , \qquad (7.96)$$

which leaves the fields unchanged; χ is an arbitrary function. We can see that the representation given by equation (7.95) satisfies automatically the homogeneous Maxwell equations (charge- and current-free equations). The same representation used in the inhomogeneous equations leads to

$$\begin{aligned} &div\mathbf{E} = -\tfrac{1}{c}div\tfrac{\partial \mathbf{A}}{\partial t} - \Delta\Phi = 4\pi\rho \ , \\ &curl\mathbf{H} = -\Delta\mathbf{A} + grad \cdot div\mathbf{A} = \\ &= -\tfrac{1}{c^2}\tfrac{\partial^2 \mathbf{A}}{\partial t^2} - \tfrac{1}{c}grad\tfrac{\partial\Phi}{\partial t} + \tfrac{4\pi}{c}\mathbf{j} \ . \end{aligned} \tag{7.97}$$

Imposing the Lorenz ("Lorentz") gauge

$$div\mathbf{A} + \frac{1}{c}\frac{\partial\Phi}{\partial t} = 0 \ , \tag{7.98}$$

these equations become the wave equations with sources

$$\frac{1}{c^2}\frac{\partial^2\mathbf{A}}{\partial t^2} - \Delta\mathbf{A} = \frac{4\pi}{c}\mathbf{j} \ , \ \frac{1}{c^2}\frac{\partial^2\Phi}{\partial t^2} - \Delta\Phi = 4\pi\rho \tag{7.99}$$

for electromagnetic waves propagating with the (light) velocity c (Ludvig Lorenz (1829-1891), Hendrik Lorentz (1853-1928)). Subjected to the Lorenz gauge, the potentials are still defined up to a χ-gauge which satisfies the free wave equation $\partial^2\chi/\partial t^2 - \Delta\chi = 0$. The two wave equations (7.99) are not independent; they are coupled by the Lorenz gauge. It is sufficient to solve one equation, for instance the equation for the vector potential **A** and derive the scalar potential by using the Lorenz gauge. Apart from free-waves solutions of the homogeneous equations, the wave equations (7.99) are solved by the Kirchhoff potentials

$$\begin{aligned} \mathbf{A}(t,\mathbf{r}) &= \tfrac{1}{c}\int d\mathbf{r}'\tfrac{\mathbf{j}(\mathbf{r}', t-\left|\mathbf{r}-\mathbf{r}'\right|/c)}{\left|\mathbf{r}-\mathbf{r}'\right|} \ , \\ \Phi(t,\mathbf{r}) &= \int d\mathbf{r}'\tfrac{\rho(\mathbf{r}', t-\left|\mathbf{r}-\mathbf{r}'\right|/c)}{\left|\mathbf{r}-\mathbf{r}'\right|} \end{aligned} \tag{7.100}$$

(particular solutions), which exhibit retardation (according to the causality). Similar wave equations and solutions hold for the fields **E** and **H**.

The propagation of the electromagnetic waves with the speed of light $c = 3 \times 10^8 m/s$ in vacuum is a fact experimentally established. For small distances, we can limit ourselves to quasi-static (quasi-stationary, non-retarded, sub-wavelength regime), or even static solutions. This amounts to neglecting $|\mathbf{r} - \mathbf{r}'| /c$ in equations (7.100). We get then the well-known Coulomb law and Biot-Savart (Ampere) law (Charles-Augustin de Coulomb (1736-1806), Jean-Baptiste Biot (1774-1862), Felix Savart (1791-1841)). In the absence of charges and currents, we may take $\Phi = 0$ (*e.g.*, by a gauge transformation); then, we have $div\mathbf{A} = 0$ and a pure radiation field. We may preserve Φ and, instead of the Lorenz gauge (7.98), impose the Coulomb gauge $div\mathbf{A} = 0$; then, we have the quasi-static (quasi-stationary solution, non-retarded, non-propagating, Coulomb) solution to the first equation (7.97) (Poisson's equation) and a corresponding wave equation for **A**.

We note that the free-wave equation has plane waves $\mathbf{A} \sim e^{-i\omega t + i\mathbf{kr}}$ as elementary solutions (with vanishing boundary conditions at infinity); $\omega = ck$ is the frequency, **k** is the wavevector, $2\pi/k$ is the wavelength, $2\pi/\omega$ is the period. The condition $div\mathbf{A} = 0$ pertains to transverse waves (**A** perpendicular to **k**); $curl\mathbf{A} = 0$ refers to "longitudinal" waves (**A** parallel with **k**). The Lorenz gauge relates the logitudinal waves to the scalar ones (the latter pertaining to Φ). For finite regions of space, the elementary solutions are given by the eigenfunctions of the laplacian (Helmholtz equation) with specific boundary conditions; then, in general, a separation between transverse and longitudinal waves is not possible.

As it is well known, the Maxwell equations are invariant under Lorentz transformations of coordinates, with constant speed of light. They can be cast into the covariant form, the Lorenz gauge is also covariant. We note also that the Maxwell's equations are invariant under spatial inversion ($\mathbf{E} \rightarrow -\mathbf{E}$, $\mathbf{j} \rightarrow -\mathbf{j}$ are polar vectors), providing **H** is not changed (it is an axial vector); the temporal inversion entails the change $\mathbf{H} \rightarrow -\mathbf{H}$.

The above equations are valid in vacuum. In matter there exists a polarization charge density $\rho_p = -div\mathbf{P}$, where **P** is called polarization; it gives a current density $\mathbf{j_p} = \frac{\partial \mathbf{P}}{\partial t}$; in addition, in matter there exists also a magnetization **M** which gives a current density $\mathbf{j}_m = c \cdot curl\mathbf{M}$;

by convention, $\mathbf{H}$ is replaced in matter by $\mathbf{B}$, which is called magnetic induction. The Maxwell equations in matter read

$$\begin{gathered} div\mathbf{D} = 4\pi\rho \ , \ div\mathbf{B} = 0 \ , \\ curl\mathbf{E} = -\tfrac{1}{c}\tfrac{\partial \mathbf{B}}{\partial t} \ , \ curl\mathbf{H} = \tfrac{1}{c}\tfrac{\partial \mathbf{D}}{\partial t} + \tfrac{4\pi}{c}\mathbf{j} \ , \end{gathered} \tag{7.101}$$

where $\mathbf{D} = \mathbf{E} + 4\pi\mathbf{P}$ and $\mathbf{B} = \mathbf{H} + 4\pi\mathbf{M}$, where $\mathbf{D}$ is called electric displacement, or electric induction; additional relations are necessary between the four unknowns $\mathbf{D}$, $\mathbf{E}$, $\mathbf{B}$, $\mathbf{H}$. At the interface of two bodies the tangential components of the electric field $\mathbf{E}$ and the normal components of the magnetic induction $\mathbf{B}$ must be continuous, while the normal components of the electric induction $\mathbf{D}$ and the tangential components of the magnetic field $\mathbf{H}$ may have a jump $4\pi\rho_s$ and $4\pi\mathbf{j}_s/c$, respectively, where ρ_s and $\mathbf{j}_s$ are the surface charge and current densities, respectively.

We note that $\mathbf{E} = -(1/c)\dot{\mathbf{A}} - grad\Phi$, $\mathbf{B} = curl\mathbf{A}$ and the gauge conditions are still useful in matter; in addition, the representation $\mathbf{A} = (1/c)\mathbf{P}_e + curl\mathbf{P}_m$, $\Phi = -div\mathbf{P}_e$ makes the gauge condition an identity; the potentials $\mathbf{P}_{e,m}$ satisfy the wave equation with sources $\mathbf{P}$ and $\mathbf{M}$, respectively; they are known as Hertz potentials.

7.8 Hansen vectors

For vector equations, like the vector Helmholtz equation

$$\Delta\mathbf{u} + K^2\mathbf{u} = 0 \ , \tag{7.102}$$

it is useful to have three complete sets of independent, orthonormal solutions in separable coordinates. The vector

$$\mathbf{L} = \frac{1}{K} grad\Phi \tag{7.103}$$

satisfies the equation, if Φ satisfies it too. The vector

$$\mathbf{M} = curl(\mathbf{a}\psi) \ , \tag{7.104}$$

where $\mathbf{a} = w\mathbf{e}_1$ is perpendicular to $\mathbf{a}$ and tangential to the surface $q_1 = const$, where (q_1, q_2, q_3) are curvilinear coordinates, $\mathbf{e}_1$ is the coordinates q^m and x^m respectively), the expansions

$$\begin{aligned} \eta^m &= (x^n - q^n)\nabla_n \eta^m\,|_q + \mathcal{O}(2), \\ X \equiv \eta^m \eta_m &= (x^m - q^m)(x^n - q^n)\mathcal{H}_{mn}\,|_q + \mathcal{O}(3) \end{aligned} \tag{19.2}$$

hold and therefore the *regularity condition*

$$X_{,a}X^{,a}/4X \to 1 \tag{19.3}$$

in the limit at the rotation axis is satisfied. Otherwise, if (19.3) is violated, there are conical singularities (rods or struts) on the axis.

The behaviour of the metric near the axis was carefully studied by Carlson and Safko (1980) using pseudo-Cartesian coordinates and their transformation to polar coordinates perpendicular to the symmetry axis. Carot (2000) generalized these results and proved some other implications of axial symmetry. Remarkably, a group of motions G_2 containing an axial symmetry must be Abelian. The 'extended' regularity conditions (Van den Bergh and Wils 1985b) do not necessarily hold even when (19.3) is satisfied. A *cyclic* Killing vector has closed orbits but – contrary to the axisymmetric case – fixed points and a regular axis are not assumed to exist, cp. Szabados (1987). The possible Bianchi types of a G_3 containing a cyclic symmetry are determined in Barnes (2000).

In this chapter we demand that there are two commuting Killing vectors $\boldsymbol{\xi}$ and $\boldsymbol{\eta}$,

$$\xi^a{}_{;b}\eta^b - \eta^a{}_{;b}\xi^b = 0, \quad \xi^a\xi_a < 0, \quad \eta^a\eta_a > 0, \tag{19.4}$$

i.e. they generate an Abelian group G_2I, see §17.1. Carter (1970) has shown that the cases of the greatest physical importance, *asymptotically flat* stationary axisymmetric gravitational fields, necessarily admit an Abelian group G_2, so that for them (19.4) does not impose an additional restriction. If the cyclic Killing vector $\boldsymbol{\eta}$ has a non-null orbit, than any G_2 containing $\boldsymbol{\eta}$ is Abelian (Ernotte 1980).

The Killing vectors $\boldsymbol{\xi}$ and $\boldsymbol{\eta}$ are *uniquely* determined if we demand that (i) $\boldsymbol{\eta}$ has compact trajectories (in general other subgroups G_1 will have non-compact trajectories), (ii) $\boldsymbol{\eta}$ is normalized by (19.3) and (iii) space-time is asymptotically flat and $\boldsymbol{\xi}$ is normalized so that $F = \xi^a\xi_a \to -1$ holds in the asymptotic region.

19.2 Orthogonal surfaces

The Killing trajectories form two-dimensional orbits T_2; the simple bivector

$$v_{ab} = 2\xi_{[a}\eta_{b]}, \quad v_{ab}v^{ab} < 0, \tag{19.5}$$

is surface-forming (see (19.4) and (6.12)). The surface element orthogonal to the group orbits is spanned by the dual bivector

$$\tilde{v}_{ab} = \tfrac{1}{2}\varepsilon_{abcd}v^{cd} = 2m_{[a}\overline{m}_{b]}, \quad m_a\xi^a = 0 = m_a\eta^a. \tag{19.6}$$

The simple bivector $\tilde{v}_{ab}$ is surface-forming and the metric is said to be *orthogonally transitive* if and only if the condition

$$\begin{aligned} v_{ab}\tilde{v}^{bc}{}_{;c} = 2\xi_{[a}\eta_{b]}(\overline{m}^c m^b{}_{;c} - m^c\overline{m}^b{}_{;c}) = 0 \\ \Leftrightarrow \quad \varepsilon_{abcd}\eta^a\xi^b\xi^{c;d} = 0 = \varepsilon_{abcd}\xi^a\eta^b\eta^{c;d} \end{aligned} \tag{19.7}$$

is satisfied (cp. (6.12)). In general, the Killing vectors of an arbitrary stationary axisymmetric space-time do not obey (19.7), but only solutions obeying (19.7) are explicitly known.

The condition (19.7) can be formulated as a restriction on the algebraic form of the Ricci tensor:

Theorem 19.1 *Stationary axisymmetric fields admit 2-spaces orthogonal to the group orbits if and only if the conditions*

$$\xi^d R_{d[a}\xi_b\eta_{c]} = 0 = \eta^d R_{d[a}\xi_b\eta_{c]} \tag{19.8}$$

are satisfied (Kundt and Trümper 1966).

Proof (see e.g. also Carter 1972): For a Killing vector $\boldsymbol{\xi}$ the identity (8.22),

$$\xi_{a;bc} = R_{abcd}\xi^d, \tag{19.9}$$

holds. From (19.9) (and an analogous relation for $\boldsymbol{\eta}$) we get

$$(\xi_{[a;b}\xi_{c]})^{;c} = \tfrac{2}{3}\xi^d R_{d[a}\xi_{b]}, \quad (\eta_{[a;b}\eta_{c]})^{;c} = \tfrac{2}{3}\eta^d R_{d[a}\eta_{b]}. \tag{19.10}$$

With the aid of these equations, together with the cyclic symmetry relation of the curvature tensor and the commutativity of $\boldsymbol{\xi}$ and $\boldsymbol{\eta}$, we obtain

$$(\xi_{[a;b}\xi_c\eta_{d]})^{;d} = -\tfrac{1}{2}\xi^d R_{d[a}\xi_b\eta_{c]}, \quad (\eta_{[a;b}\eta_c\xi_{d]})^{;d} = -\tfrac{1}{2}\eta^d R_{d[a}\eta_b\xi_{c]}. \tag{19.11}$$

Using the fact that a completely antisymmetric tensor is proportional to the ε-tensor, we convert (19.11) into the equivalent dual equations

$$\begin{aligned} (\varepsilon^{abcd}\xi_{a;b}\xi_c\eta_d)^{;e} &= -2\varepsilon^{abce}\xi^d R_{da}\xi_b\eta_c, \\ (\varepsilon^{abcd}\eta_{a;b}\eta_c\xi_d)^{;e} &= -2\varepsilon^{abce}\eta^d R_{da}\eta_b\xi_c. \end{aligned} \tag{19.12}$$

From these equations we conclude that the conditions (19.8) are a necessary consequence of the original criterion (19.7). Conversely, if the conditions (19.8) are satisfied, the twist scalars $\varepsilon_{abcd}\eta^a\xi^b\xi^{c;d}$ and $\varepsilon_{abcd}\xi^a\eta^b\eta^{c;d}$

are constants. Both twist scalars vanish on the rotation axis ($\boldsymbol{\eta} = 0$). Hence they vanish in a connected domain which intersects the rotation axis if the conditions (19.8) hold in that domain. Then the geometry admits 2-spaces orthogonal to the orbits of the Abelian group of motions G_2.

For vacuum fields ($R_{ab} = 0$), the existence of orthogonal 2-spaces was first demonstrated by Papapetrou (1966) in his pioneering work on this subject.

Conditions (19.8) hold for a wide class of energy-momentum tensors. For example, decomposition of the metric into orthogonal 2-spaces is possible for perfect fluid solutions, and for Einstein–Maxwell fields, provided that the four-velocity of the fluid, and the electromagnetic 4-current density vector, respectively, satisfy the so-called circularity condition

$$u_{[a}\xi_b\eta_{c]} = 0 = j_{[a}\xi_b\eta_{c]}, \tag{19.13}$$

i.e. the trajectories of $\boldsymbol{u}$ and $\boldsymbol{j}$ lie in the surfaces of transitivity of the group G_2. In this terminology, conditions (19.8) mean that $R^a_b\xi^b$ and $R^a_b\eta^b$ are circular vector fields. The circularity condition (19.13) is a natural generalization of the condition (18.40) (four-velocity and current parallel to the Killing vector) to the case of stationary axisymmetric fields. Obviously, for perfect fluids the condition $u_{[a}\xi_b\eta_{c]} = 0$ implies (19.8).

Now we show that $j_{[a}\xi_b\eta_{c]} = 0$ for Einstein–Maxwell fields also implies (19.8). The Maxwell equations

$$F^{*ab}{}_{;b} = j^a, \tag{19.14}$$

and the assumption that the Lie derivatives of F^*_{ab} with respect to both the commuting Killing vectors $\boldsymbol{\xi}$ and $\boldsymbol{\eta}$ vanish, lead to

$$(F^*_{ab}\xi^a\eta^b)_{;d} = \mathrm{i}\varepsilon_{abcd}\xi^a\eta^b j^c = 0. \tag{19.15}$$

$F^*_{ab}\xi^a\eta^b$ is constant, and it is zero on the axis of rotation. Hence,

$$F^*_{ab}\xi^a\eta^b = 0 = \xi_{[a}\eta_b F^*_{cd]}. \tag{19.16}$$

(In flat space-time electrodynamics this relation says that the azimuthal components of the electric and magnetic field vectors are zero.) Relation (19.16) in turn implies (19.8).

If in an Einstein–Maxwell geometry, outside the sources, two Killing vectors $\boldsymbol{\xi}$, $\boldsymbol{\eta}$ satisfy the conditions (19.4), (19.5), (19.7), then the Maxwell field shares the space-time symmetry: $\mathcal{L}_{\boldsymbol{\xi}}F_{ab} = 0 = \mathcal{L}_{\boldsymbol{\eta}}F_{ab}$ (Michalski and Wainwright 1975).

Gourgoulhon and Bonazzola (1993) considered the more general case when the conditions (19.8) do not hold, e.g. for toroidal magnetic fields. The field equations can be written in an entirely two-dimensional covariant form.

19.3 The metric and the projection formalism

Theorem 19.1 is of fundamental importance in the construction of exact solutions of the Einstein equations. If we adapt the coordinate system to the Killing vectors, the line element of a stationary axisymmetric field admitting 2-spaces orthogonal to the Killing vectors $\boldsymbol{\xi} = \partial_t$ and $\boldsymbol{\eta} = \partial_\varphi$ can be written in the form (Lewis 1932, Papapetrou 1966)

$$\mathrm{d}s^2 = \mathrm{e}^{-2U}(\gamma_{MN}\mathrm{d}x^M\mathrm{d}x^N + W^2\mathrm{d}\varphi^2) - \mathrm{e}^{2U}(\mathrm{d}t + A\mathrm{d}\varphi)^2, \qquad (19.17)$$

where the metric functions U, γ_{MN} , W, A depend only on the coordinates $x^M = (x^1, x^2)$ which label the points on the 2-surfaces S_2 orthogonal to the orbits. The form (19.17) is preserved under the transformations

$$x^{M'} = x^{M'}(x^N), \quad t' = at + b\varphi, \quad \varphi' = c\varphi + dt, \qquad (19.18)$$

($a, \dots, d$ constants). The functions W, U, A behave like scalars under $x^{M'} = x^{M'}(x^N)$. The metric (19.17) has block-diagonal form and exhibits the reflection symmetry $(t, \varphi) \to (-t, -\varphi)$.

Equation (19.17) is the specialization of (18.8) (including the conformal transformation (18.23)) to the stationary axisymmetric fields obeying the conditions (19.7). In the coordinate system (19.17), the scalar products of the Killing vectors are

$$\begin{aligned} \xi^a\xi_a &= -\mathrm{e}^{2U}, & \eta^a\eta_a &= \mathrm{e}^{-2U}W^2 - \mathrm{e}^{2U}A^2, \\ \xi^a\eta_a &= -\mathrm{e}^{2U}A, & 2\xi_{[a}\eta_{b]}\xi^a\eta^b &= W^2. \end{aligned} \qquad (19.19)$$

If a linear combination of the two Killing vectors leads to the relation $A = \pm W\mathrm{e}^{-2U}$, the space-time admits a null Killing vector. This special case will be considered in Chapter 24. Vacuum solutions with this property belong to the class $S = S(A)$ (§20.4), provided that W is not constant.

In general, $\boldsymbol{\xi}$ and $\boldsymbol{\eta}$ are not hypersurface-orthogonal. However, it can easily be verified (Bardeen 1970) that the timelike vector $\boldsymbol{\zeta} = \boldsymbol{\xi} - \xi^a\eta_a(\eta^b\eta_b)^{-1}\boldsymbol{\eta}$ is orthogonal to the hypersurfaces $t = \text{const}$. In general, it is not a Killing vector.

Without loss of generality we can introduce *isotropic coordinates* in V_2,

$$\gamma_{MN} = \mathrm{e}^{2k}\delta_{MN}. \qquad (19.20)$$

Moreover, if W is a non-constant potential function, it can be transformed to $W = x^1$ with the aid of a coordinate transformation $\zeta' = f(\zeta)$, $\sqrt{2}\zeta = x^1 + \mathrm{i}x^2$, preserving the isotropic coordinate condition. The case $W = \text{const}$ is not of interest here because it is not compatible with the regularity condition (19.3); vacuum metrics of this type are plane waves (24.35) with $F = 0$, $f = f(\zeta)$.

The isotropic coordinates with $W = x^1 = \rho$ are called *Weyl's canonical coordinates* ($x^1 = \rho$, $x^2 = z$; $\sqrt{2}\zeta = \rho + \mathrm{i}z$). In these coordinates, the space-time metric (19.17) is given by

$$\mathrm{d}s^2 = \mathrm{e}^{-2U}[\mathrm{e}^{2k}(\mathrm{d}\rho^2 + \mathrm{d}z^2) + \rho^2\mathrm{d}\varphi^2] - \mathrm{e}^{2U}(\mathrm{d}t + A\mathrm{d}\varphi)^2. \tag{19.21}$$

For stationary axisymmetric fields, one can develop a projection formalism (Geroch 1972) similar to that for stationary fields given in §18.1. We introduce the notation

$$\lambda_{AB} \equiv \xi_A{}^a\xi_{Ba}, \quad A, B = 1, 2, \tag{19.22}$$

for the scalar products of the Killing vectors $\boldsymbol{\xi}_1 = \boldsymbol{\xi}$, $\boldsymbol{\xi}_2 = \boldsymbol{\eta}$, and identify the projection tensor

$$H_{ab} \equiv g_{ab} + W^{-2}\lambda^{AB}\xi_{Aa}\xi_{Bb}, \quad W^2 \equiv -\tfrac{1}{2}\lambda^{AB}\lambda_{AB}, \tag{19.23}$$

with the metric tensor on a differentiable manifold Σ_2. Capital Latin indices are raised and lowered with the aid of the alternating symbols (3.66), as in (3.67). Covariant derivatives (denoted by D_a) and the Riemann curvature tensor on Σ_2 are defined in analogy to (18.3) and (18.5) ($h_{ab} \to H_{ab}$).

If 2-spaces V_2 orthogonal to the group orbits exist, Σ_2 can be identified with these 2-spaces and the two scalars $C_A = \varepsilon^{MN}\varepsilon^{abcd}\xi_{Ma}\xi_{Nb}\xi_{Ac;d}$ vanish. Then the Ricci tensor R_{ab} in V_4 can be written in terms of tensors and metric operations on V_2 as follows,

$$\overset{2}{R}_{ab} = (2W)^{-2}\lambda^{AB}{}_{,a}\lambda_{AB,b} + W^{-1}D_aW_{,b} + H_a^cH_b^dR_{cd}, \tag{19.24}$$

$$D^a(W^{-1}\lambda_{AB,a}) = \tfrac{1}{2}W^{-3}\lambda_{AB}H^{ab}\lambda^{CD}{}_{,a}\lambda_{CD,b} - 2W^{-1}R_{ab}\xi_A^a\xi_B^b, \tag{19.25}$$

$$H_a^c\xi_A^dR_{cd} = 0. \tag{19.26}$$

The contracted Bianchi identities (2.82) in the projection formalism are given by Whelan and Romano (1999) and read (for $C_A = 0$)

$$D_a(W\xi_A^bH^{ac}G_{bc}) = 0, \quad D_b(WH_a^cH^{bd}G_{cd}) = \tfrac{1}{2}W\xi_A^c\xi_B^dG_{cd}(W^{-2}\lambda^{AB})_{,a}, \tag{19.27}$$

where G_{ab} is the Einstein tensor.

Kitamura (1978) gave an invariant characterization of the stationary axisymmetric metric (19.17) in terms of a tetrad and its first covariant derivatives. This characterization is independent of the field equations.

in $L^2(\mathbb{R}^d)$,

$$\mathcal{U}_h^{\varepsilon}(t,t_0)g_{z_0}^{\Gamma_0,\varepsilon} = \mathrm{e}^{\frac{i}{\varepsilon}S(t,t_0,z_0)}\left(g_{\Phi^{t,t_0}(z_0)}^{\Gamma(t,t_0,z_0),\varepsilon} + \sum_{j=1}^{N_0}\varepsilon^{\frac{j}{2}}\mathrm{WP}^{\varepsilon}_{\Phi^{t,t_0}(z_0)}(\varphi_j(t))\right) + O(\varepsilon^{\frac{N_0+1}{2}}) \tag{2.7}$$

with

$$\Gamma(t,t_0,z_0) = (C(t,t_0,z_0) + D(t,t_0,z_0)\Gamma_0)(A(t,t_0,z_0) + B(t,t_0,z_0)\Gamma_0)^{-1} \tag{2.8}$$

and

$$c_{\Gamma(t,t_0,z_0)} = c_{\Gamma_0}\det{}^{-\frac{1}{2}}(A(t,t_0,z_0) + B(t,t_0,z_0)\Gamma_0),$$

where the complex square root is continuous in time.

Note that we have $\Gamma(t_0,t_0,z_0) = \Gamma_0$ in the statement above. Actually, explicit information is obtained on the profiles $(\varphi_j(t))_{j\in\mathbb{N}}$, in particular about $\varphi_1(t)$ (see [5, Section 4.1.2] or [8, Proposition 2.3]). As we shall see in Section 5, this result can be a starting point for proving the Herman–Kluk approximation of Theorem 2.1.

The result above also holds for general wave packets as in (2.6) with profiles that are not necessarily Gaussians (see [5, Section 4.1.2]). Moreover, also the norm can be generalized to

$$\|f\|_{\Sigma_k^{\varepsilon}} = \sup_{|\alpha|+|\beta|\leqslant k}\|x^{\alpha}(\varepsilon\partial_x)^{\beta}f\|_{L^2}, \quad k\in\mathbb{N}.$$

Example 2.3. Both Theorem 2.1 and 2.2 are exact when the Hamiltonian h is quadratic. For the Hamiltonians $h_{\pm}(z) = p \pm kq$ associated with the toy model (see (1.3)), the classical flow is linear

$$\Phi_{\pm}^{t,t_0}(z_0) =: (q_{\pm}(t), p_{\pm}(t)) = z_0 + (t-t_0)(1,\mp k), \quad z_0 = (q_0,p_0),$$

the width of the Gaussian is constant, $\Gamma_{\pm}(t,t_0,z_0) = \Gamma_0$, and the actions only depend on q_0 and are given by

$$S_{\pm}(t,t_0,q_0) = \mp kq_0(t-t_0) \mp \frac{k}{2}(t-t_0)^2.$$

3 Herman–Kluk formula in the adiabatic setting

We need adaptations for generalizing the scalar ideas to systems. The first one replaces the scalar Herman–Kluk prefactor $u_0(t,t_0,z_0)$ by a vector-valued one $\vec{U}(t,t_0,z_0)$ that is expanded in a basis of eigenvectors of $H(t,z)$, taken along the classical trajectory $\Phi_{h_j}^{t,t_0}(z)$ of the corresponding eigenvalues (denoted here by $h_j(t,z)$). This is done by parallel transport, and it is sufficient for an order ε approximation as long as the system is gapped.

3.1 Parallel transport

The following construction generalizes [4, Proposition 1.9], which was inspired by the work of G. Hagedorn, see [13, Proposition 3.1]. The details are given in [8]. In the sequel, we denote the complementary orthogonal projector by

$$\Pi^{\perp}(t,z) = \mathbb{I}_{\mathbb{C}^N} - \Pi(t,z)$$

and assume that

$$H(t,z) = h(t,z)\Pi(t,z) + h^{\perp}(t,z)\Pi^{\perp}(t,z) \tag{3.1}$$

with the second eigenvalue given by $h^{\perp}(t,z) = \mathrm{tr}(H(t,z)) - h(t,z)$. We introduce the auxiliary matrices

$$\begin{aligned}
\Omega(t,z) &= -\frac{1}{2}\big(h(t,z) - h^{\perp}(t,z)\big)\Pi(t,z)\{\Pi,\Pi\}(t,z)\Pi(t,z),\\
K(t,z) &= \Pi^{\perp}(t,z)\big(\partial_t \Pi(t,z) + \{h,\Pi\}(t,z)\big)\Pi(t,z),\\
\Theta(t,z) &= i\Omega(t,z) + i(K - K^*)(t,z),
\end{aligned}$$

that are smooth and satisfy some algebraic properties. In particular, Ω is skew-symmetric and Θ is self-adjoint: $\Omega = -\Omega^*$ and $\Theta = \Theta^*$.

Proposition 3.1 ([8]). *Let $H(t,z)$ be a smooth Hamiltonian that satisfies (1.6) and has a smooth spectral decomposition (3.1). We assume that both eigenvalues are of subquadratic growth as well. We consider $\vec{V}_0 \in \mathcal{C}_0^{\infty}(\mathbb{R}^{2d},\mathbb{C}^N)$ and $z_0 \in \mathbb{R}^{2d}$ such that there exists a neighborhood U of z_0 where for all $z \in U$*

$$\vec{V}_0(z) = \Pi(t_0,z)\vec{V}_0(z) \quad \textit{and} \quad \|\vec{V}_0(z)\|_{\mathbb{C}^N} = 1.$$

Then there exists a smooth normalized vector-valued function $\vec{V}(t,t_0)$ satisfying

$$\vec{V}(t,t_0,z) = \Pi(t,z)\vec{V}(t,t_0,z) \quad \textit{for all } z \in \Phi_h^{t,t_0}(U),$$

and such that for all $t \in \mathbb{R}$ and $z \in \Phi_h^{t,t_0}(U)$,

$$\partial_t \vec{V}(t,t_0,z) + \{h,\vec{V}\}(t,t_0,z) = -i\Theta(t,z)\vec{V}(t,t_0,z), \quad \vec{V}(t_0,t_0,z) = \vec{V}_0(z). \tag{3.2}$$

We note that the results of this Proposition are valid as long as smooth eigenprojectors and eigenvalues do exist. It does not require an explicit adiabatic situation and we will use that observation in Section 4. In the case of Schrödinger systems, one refers to (3.2) as parallel transport because the vectors $\partial_t\vec{V}(t) + \{h,\vec{V}\}(t)$ belong to the range of $\Pi^{\perp}(t)$ at any time of the evolution.

Example 3.2. For the toy model $H_{k,\theta}(x,\xi)$, the auxiliary matrices are

$$\Omega_{\pm} = 0, \quad K_{\pm} = \frac{i\theta}{4}\begin{pmatrix} 1 & \pm\,\mathrm{e}^{i\theta x} \\ \mp\,\mathrm{e}^{-i\theta x} & -1 \end{pmatrix}, \quad \Theta_{\pm} = \frac{\theta}{2}\begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}.$$

Initiating the parallel transport equation by the eigenvectors given in (1.3), we obtain

$$\vec{V}_{\pm}(t,t_0,q) = \frac{1}{\sqrt{2}}\begin{pmatrix} \mathrm{e}^{i\frac{\theta}{2}(t-t_0)}\,\mathrm{e}^{i\theta(q-t+t_0)} \\ \pm\,\mathrm{e}^{-i\frac{\theta}{2}(t-t_0)} \end{pmatrix} = \frac{1}{\sqrt{2}}\begin{pmatrix} \mathrm{e}^{-\frac{i}{2}\theta(t-t_0)}\,\mathrm{e}^{i\theta q} \\ \pm\,\mathrm{e}^{-\frac{i}{2}\theta(t-t_0)} \end{pmatrix}.$$

Note that they do not depend on p.

3.2 Herman–Kluk approximation in an adiabatic setting

In the context of the preceding section, and in presence of an eigenvalue gap,

$$\exists\delta > 0: \quad \mathrm{dist}(h(t,z), h^{\perp}(t,z)\}) \geqslant \delta \quad \text{for all } (t,z),$$

it is well known that one has *adiabatic decoupling*: If the initial data are scalar multiples of an eigenvector associated with the eigenvalue h, then the solution keeps this property to leading order in ε. For an approximation to higher order in ε, one has to consider perturbations of the eigenprojector, the so-called *superadiabatic projectors* (see [2, 27] and the new edition of [5] that should appear soon). Adiabatic theory implies a Herman–Kluk approximation of the propagator that we state next.

Theorem 3.3 ([8]). *In the situation of Proposition 3.1, we assume the existence of an eigenvalue gap for the eigenvalue h of H and consider initial data of the form*

$$\psi_0^{\varepsilon} = \widehat{\vec{V}}_0 v_0^{\varepsilon} + O(\varepsilon) \quad \text{in } L^2(\mathbb{R}^d),$$

where $\vec{V}_0$ is a smooth eigenvector and $(v_0^{\varepsilon})_{\varepsilon>0}$ a family of functions uniformly bounded in $L^2(\mathbb{R}^d,\mathbb{C})$. Then, in $L^2(\mathbb{R}^d)$,

$$\mathcal{U}_H^{\varepsilon}(t,t_0)\psi_0^{\varepsilon} = (2\pi\varepsilon)^{-d}\int_{\mathbb{R}^{2d}} \langle g_z^{\varepsilon}, v_0^{\varepsilon}\rangle \vec{U}(t,t_0,z)\,\mathrm{e}^{\frac{i}{\varepsilon}S(t,t_0,z)}\, g^{\varepsilon}_{\Phi_h^{t,t_0}(z)}\, dz + O(\varepsilon)$$

with

$$\vec{U}(t,t_0,z) = u_0(t,t_0,z)\vec{V}(t,t_0,\Phi_h^{t,t_0}(z)),$$

where $u_0(t,t_0,z)$ is given by (2.5) and the eigenvector $\vec{V}(t,t_0,z)$ by (3.2).

We describe in Section 5 a proof of this result that crucially uses the approximate evolution of a Gaussian state, that is [24, Section 3],

$$\begin{aligned}&\mathcal{U}_H^{\varepsilon}(t,t_0)(\widehat{\vec{V}}_0 g_z^{\Gamma,\varepsilon})\\ &\quad = \mathrm{e}^{\frac{i}{\varepsilon}S(t,t_0,z)}\,\widehat{\vec{V}(t,t_0)} g^{\Gamma(t,t_0,z),\varepsilon}_{\Phi_h^{t,t_0}(z)}\left(1 + \sqrt{\varepsilon}\vec{a}(t)\cdot\frac{(x-q(t))}{\sqrt{\varepsilon}}\right) + O(\varepsilon)\end{aligned} \tag{3.3}$$

with $\vec{a}(t) = \vec{a}(t,t_0,z)$ a smooth and bounded map. Note that using superadiabatic projectors [24], one can push the asymptotics further and exhibit $O(\varepsilon)$ contributions that will have components on the other mode. Here again, a formula similar to (3.3) can be proved for general wave packets [5].

3.2 The semigroup $e^{-t\sqrt{H_\alpha}}$

By the spectral theorem,

$$e^{-t\sqrt{H_\alpha}} = \sum_{m\in\mathbb{Z}} \oplus\big(e^{-t\sqrt{h_m}} \otimes \mathrm{id}\big)\Pi_m. \tag{3.3}$$

Denote by $p_m(r, r', t)$ the integral kernel of $e^{-t\sqrt{h_m}}$ in $L^2(\mathbb{R}_+, r\,dr)$. From (3.1) it follows that

$$p_m(r, r', t) = \frac{1}{\sqrt{rr'}} e^{-t\sqrt{L_m}}(r, r').$$

On the other hand, in view of (3.2) we get

$$\begin{aligned}\big(e^{-t\sqrt{L_m}} g\big)(r) &= \big(W_m^{-1} e^{-t\sqrt{p}} W_m g\big)(r)\\ &= \frac{1}{2}\int_0^\infty \sqrt{rr'} \int_0^\infty e^{-t\sqrt{p}} J_{|m+\alpha|}(r\sqrt{p}) J_{|m+\alpha|}(r'\sqrt{p})\, dp\, g(r')\, dr'.\end{aligned}$$

Hence

$$\begin{aligned}p_m(r, r', t) &= \frac{1}{2}\int_0^\infty e^{-t\sqrt{p}} J_{|m+\alpha|}(r\sqrt{p}) J_{|m+\alpha|}(r'\sqrt{p})\, dp\\ &= \int_0^\infty e^{-tp} J_{|m+\alpha|}(rp) J_{|m+\alpha|}(r'p)\, p\, dp.\end{aligned}$$

In order to simplify the notation we will use in the sequel the shorthand

$$z := \frac{r^2}{t^2}. \tag{3.4}$$

From [4, equation 4.14.(16)] we then get the explicit expression for p_m on the diagonal

$$\begin{aligned}p_m(r, r, t) &= \int_0^\infty e^{-tp} J^2_{|m+\alpha|}(rp)\, p\, dp \qquad (3.5)\\ &= \frac{4^\nu}{\pi}(2\nu+1)\, t^{-2}\Big(\frac{r}{t}\Big)^{2\nu} \frac{\Gamma^2(\nu+\frac{1}{2})}{\Gamma(2\nu+1)} F\Big(\nu+\frac{1}{2}, \nu+\frac{3}{2}, 2\nu+1; -4z\Big),\end{aligned}$$

where

$$\nu = |m+\alpha| \tag{3.6}$$

and $F(a, b, c; w)$ denotes the Gauss hypergeometric series, see for example [1, equation 15.1.1]. Using its integral representation

$$F(a, b, c; w) = \frac{\Gamma(c)}{\Gamma(b)\Gamma(c-b)} \int_0^1 s^{b-1}(1-s)^{c-b-1}(1-sw)^{-a}\, ds,$$

where $\mathrm{Re}\, c > \mathrm{Re}\, b > 0$, see [1, equation 15.3.1], in combination with the transformation formula [1, equation 15.3.5]

$$F(a, b, c; w) = (1-w)^{-b} F\Big(b, c-a, c; \frac{w}{w-1}\Big),$$

we find that

$$
\begin{aligned}
&p_m(r,r,t)\\
&\quad= \frac{2\nu+1}{\pi t^2}(4z)^\nu \frac{\Gamma^2(\nu+\frac{1}{2})}{\Gamma(2\nu+1)}(1+4z)^{-\nu-\frac{3}{2}} F\left(\nu+\frac{3}{2}, \nu+\frac{1}{2}, 2\nu+1; \frac{4z}{4z+1}\right)\\
&\quad= \frac{2\nu+1}{\pi t^2}(4z)^\nu (1+4z)^{-\nu-\frac{3}{2}} \int_0^1 s^{\nu-\frac{1}{2}}(1-s)^{\nu-\frac{1}{2}}\left(1-\frac{4zs}{4z+1}\right)^{-\nu-\frac{3}{2}} ds\\
&\quad= \frac{2\nu+1}{\pi t^2}(4z)^\nu \int_0^1 s^{\nu-\frac{1}{2}}(1-s)^{\nu-\frac{1}{2}}(1+4z(1-s))^{-\nu-\frac{3}{2}}\, ds\\
&\quad= \frac{2\nu+1}{\pi t^2}(4z)^\nu \int_0^1 s^{\nu-\frac{1}{2}}(1-s)^{\nu-\frac{1}{2}}(1+4zs)^{-\nu-\frac{3}{2}}\, ds. \qquad (3.7)
\end{aligned}
$$

We have:

Lemma 3.1. *There exists* $\varepsilon_0 > 0$ *such that for every* $\varepsilon \in (0, \varepsilon_0)$ *there is* $C_\varepsilon > 0$ *for which the upper bound*

$$
(1+r)^{-\frac{3}{2}-\varepsilon}(1+r')^{-\frac{3}{2}-\varepsilon} p_m(r,r',t) \le C_\varepsilon \frac{t^{-2-2\kappa}}{(|m+\alpha|+1)^{1+\varepsilon}}
$$

holds for all $m \in \mathbb{Z}$ *and all* $t \ge 1$.

Proof. Put

$$
\varepsilon_0 := \min\left\{ |m+\alpha| - \frac{3}{2} : m \in \mathbb{Z} \wedge |m+\alpha| > \frac{3}{2} \right\}. \qquad (3.8)
$$

Clearly we have $\varepsilon_0 > 0$. Let $\varepsilon < \varepsilon_0$ and put $\rho = \frac{3}{2} + \varepsilon$. Keeping in mind the notation (3.6), we will distinguish two cases depending on the value of ν.

Assume first that $\nu > \frac{3}{2}$. In view of (3.4) and (3.7),

$$
\begin{aligned}
\frac{p_m(r,r,t)}{(1+r^2)^\rho} &= \frac{4\nu+2}{\pi t^3}\frac{r(4z)^{\nu-\frac{1}{2}}}{(1+r^2)^\rho} \int_0^1 s^{\nu-\frac{1}{2}}(1-s)^{\nu-\frac{1}{2}}(1+4zs)^{-\nu-\frac{3}{2}}\, ds\\
&\lesssim t^{-3}\nu (4z)^{\nu-\rho} \int_0^1 s^{\nu-\frac{1}{2}}(1-s)^{\nu-\frac{1}{2}}(1+4zs)^{-\nu-\frac{3}{2}}\, ds\\
&= t^{-3}\nu (4z)^{\nu-\rho} \int_0^1 s^{\nu-\frac{1}{2}}(1+4zs)^{\rho-\nu}(1-s)^{\nu-\frac{1}{2}}(1+4zs)^{-\rho-\frac{3}{2}}\, ds,
\end{aligned}
$$

where we have used the fact that $z \le r^2$ by assumption. From (3.8) it follows that $\rho < \nu$. Hence

$$
\begin{aligned}
(1+r^2)^{-\rho} p_m(r,r,t) &\lesssim t^{-3}\nu (4z)^{\nu-\rho} \int_0^1 s^{\nu-\frac{1}{2}}(4zs)^{\rho-\nu}(1-s)^{\nu-\frac{1}{2}}\, ds\\
&= t^{-3}\nu \int_0^1 s^{\rho-\frac{1}{2}}(1-s)^{\nu-\frac{1}{2}}\, ds = t^{-3}\nu B\left(\rho+\frac{1}{2}, \nu+\frac{1}{2}\right)\\
&= t^{-3}\nu \frac{\Gamma(\rho+\frac{1}{2})\Gamma(\nu+\frac{1}{2})}{\Gamma(\nu+\rho+1)},
\end{aligned}
$$

Blow-ups for the Horn–Kapranov parametrization of the classical discriminant

Evgeny Mikhalkin, Vitaly Stepanenko and Avgust Tsikh

Dedicated to the 70th birthday of our colleague and friend Ari Laptev

The Horn–Kapranov parametrizations describe the singular sets of hypergeometric functions in several variables. These parametrizations are inverses of logarithmic Gauss maps for A-discriminants. In this paper we demonstrate that, despite the multivalued nature of the indicated parametrizations, their blow-ups properties are the same as for single-valued meromorphic mappings. As an application, a new proof of factorization identities for the classical discriminant is given.

1 Introduction

Given a meromorphic mapping $f : X \to Y$ of complex analytic sets (spaces), it is reasonable to treat it as an analytic subset of $X \times Y$ that is the closure $\overline{G}_f$ of the graph of f. Fibers in $\overline{G}_f$ over uncertainty points can be regarded as result of “blow-up” or “shrinkage” procedures [13]. The most transparent scheme for such procedures can be seen for mappings that are inverses of the logarithmic Gauss map [9]. In the modern theory of hypergeometric functions [8], these inverses are known as Horn–Kapranov parametrizations [2, 14, 15].

Our goal in this paper is to study the Horn–Kapranov parametrization and to give a new proof of factorization identities for truncations of the classical discriminant. Such identities were obtained in [7, Chapter 10], using a complicated technique of the theory of A-determinants. In our approach, instead of meromorphic mappings we consider multivalued mappings with abelian monodromy groups.

The classical discriminant relates to a polynomial in one variable

$$f(y) = a_0 + a_1 y + \cdots + a_n y^n. \tag{1.1}$$

Keywords: Discriminant, Horn–Kapranov parametrization, Newton polytope, logarithmic Gauss map, blow-up

2020 Mathematics Subject Classification: Primary 32H04; secondary 32S25

It is an irreducible polynomial

$$\Delta_n = \Delta_n(a_0, a_1, \ldots, a_n)$$

with integer coefficients that vanishes if and only if f has multiple roots. Discriminants play an important role in mathematics, which is demonstrated in the fundamental monographs [7, 16]. The interest in the topic of discriminant identities considered in this article is inspired by studying the universal algebraic function [1, 6, 11, 12, 16] and by research in singularity theory [17], algebraic (tropical) geometry and mathematical physics [3, 5].

It is well known [4, 7] that the Newton polytope $\mathcal{N}(\Delta_n) \subset \mathbb{R}^{n+1}$ of the indicated discriminant is combinatorially equivalent to an $(n-1)$-dimensional cube. Since such a cube has 2^{n-1} vertices, it is natural to encode these vertices by all possible subsets of the set $\{1, \ldots, n-1\}$. The polytope $\mathcal{N}(\Delta_n)$ has $n-1$ hyperfaces $\{h_k^0\}$ lying in the coordinate hyperplanes $\{t_k = 0\}$, $k = 1, \ldots, n-1$ (it is assumed that the coordinates $t_0, t_1, \ldots, t_n$ are chosen in the ambient space $\mathbb{R}^{n+1}$). Each hyperface h_k^0 has 2^{n-2} vertices, which are encoded by subsets $I \subset \{1, \ldots, n-1\}$ that do not contain k. Let h_k denote the face opposite to h_k^0, whose vertices are encoded by subsets I containing k (an explicit equation for a hyperplane containing k is given by formula (2.7) in Section 2).

Our main objects of interest in this paper are truncations of the discriminant Δ_n to the faces of its Newton polytope. Recall that the *truncation* of a polynomial Δ to a face h of its Newton polytope $\mathcal{N}(\Delta)$ is the sum of all monomials from Δ whose exponents belong to h. This truncation is denoted by $\Delta|_h$.

The truncations $\Delta_n|_{h_k^0}$ to the coordinate hyperfaces h_k^0 are irreducible polynomials. In the recent paper [10] we wrote a sketch of proof of the following formula:

$$\Delta_n\Big|_{h_k} = a_k^2\, \Delta_k(a_0, a_1, \ldots, a_k)\Delta_{n-k}(a_k, a_{k+1}, \ldots, a_n), \tag{1.2}$$

where Δ_k, Δ_{n-k} *are the discriminants of polynomials*

$$a_0 + a_1 y + \cdots + a_k y^k, \quad a_k + a_{k+1} y + \cdots + a_n y^{n-k}$$

of degrees k and $n-k$, respectively.

Note that for $k = 1$ the first discriminant on the right-hand side of (1.2) is identically equal to 1: $\Delta_1(a_0, a_1) \equiv 1$. The same is true for the second factor $\Delta_1(a_{n-1}, a_n)$ when $k = n-1$. Thus, the truncations of Δ_n to the hyperfaces h_1 and h_{n-1} coincide, up to the monomials a_1^2 and a_{n-1}^2, respectively, with the discriminants Δ_{n-1} of polynomials of degree $n-1$.

As an example consider the case $n = 3$ when f is a cubic polynomial

$$f = a_0 + a_1 y + a_2 y^2 + a_3 y^3$$

and the discriminant Δ_3 is equal to

$$\Delta_3(a_0, a_1, a_2, a_3) = -27a_0^2 a_3^2 - 4a_1^3 a_3 - 4a_0 a_2^3 + 18a_0 a_1 a_2 a_3 + a_1^2 a_2^2.$$

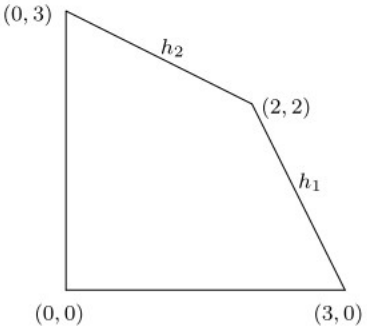

Figure 1.1. The Newton polytope for $\mathcal{N}(\Delta_3^{\mathrm{red}})$.

For a better understanding the geometry of the Newton polytope $\mathcal{N}(\Delta_3) \subset \mathbb{R}^4$ it is convenient to consider its projection onto the subspace $\mathbb{R}^2$ of variables t_1, t_2. For this it is enough to pass from the polynomial f to its reduction f^{red} setting $a_0 = a_3 = 1$. The corresponding reduced discriminant is the following:

$$\Delta_3^{\mathrm{red}}(a_1, a_2) = -27 - 4a_1^3 - 4a_2^3 + 18a_1a_2 + a_1^2a_2^2.$$

For its Newton polytope see Figure 1.1.

The truncations to h_1 and h_2 of the reduced discriminant are

$$\begin{aligned} a_1^2a_2^2 - 4a_1^3 &= a_1^2 \cdot 1 \cdot (a_2^2 - 4a_1) = a_1^2 \cdot \Delta_1(1, a_1) \cdot \Delta_2(a_1, a_2, 1), \\ a_1^2a_2^2 - 4a_2^3 &= a_2^2 \cdot (a_1^2 - 4a_2) \cdot 1 = a_2^2 \cdot \Delta_2(1, a_1, a_2)\Delta_1(a_2, 1), \end{aligned}$$

respectively. For the original discriminant these expressions become as

$$\begin{aligned} \Delta_3\big|_{h_1} &= a_1^2a_2^2 - 4a_1^3a_3 = a_1^2 \cdot \Delta_1(a_0, a_1) \cdot \Delta_2(a_1, a_2, a_3), \\ \Delta_3\big|_{h_2} &= a_1^2a_2^2 - 4a_0a_2^3 = a_2^2 \cdot \Delta_2(a_0, a_1, a_2)\Delta_1(a_2, a_3), \end{aligned}$$

which corresponds to (1.2).

In the present paper we prove more general formulas concerning the truncations of Δ_n to faces

$$h_K := h_{k_1} \cap \cdots \cap h_{k_p}$$

of codimension p, obtained by intersection of p non-coordinate hyperfaces. The multi-index $K = \{k_1, \dots, k_p\}$ determines a partition of the tuple $\{0, 1, \dots, n\}$ into $p + 1$ subtuples (segments)

$$K_i = \{k_i, k_i + 1, \dots, k_{i+1}\}, \quad i = 0, 1, \dots, p,$$

assuming that $k_0 = 0$ and $k_{p+1} = n$. Let $l_i := k_{i+1} - k_i$ denote the length of K_i and

$$f_{K_i} := a_{k_i} + a_{k_i+1}y + \cdots + a_{k_{i+1}}y^{l_i}.$$

Theorem 1.1. *In previous notations, the truncation of* Δ_n *to* h_K *admits the following factorization:*

$$\Delta_n\big|_{h_K} = a_K^2 \prod_{i=0}^{p} \Delta_{l_i}(f_{K_i}), \tag{1.3}$$

where $a_K^2 = a_{k_1}^2 \dots a_{k_p}^2$, *and* Δ_{l_i} *are the discriminants of polynomials of degrees* l_i.

In order to prove this theorem, we start with a similar assertion for the extremal part of Δ_n (Lemma 2.1). Thus we conclude that the Newton polytopes of the polynomials in both sides of (1.3) coincide. Then we prove that the zero set of the truncation $a_K^{-2}\Delta_n|_{h_K}$ contains the union of zero sets of discriminants $\Delta_{l_i}(f_{K_i})$ (Lemma 4.2). To this end, we use the Horn–Kapranov parametrizations of the zero sets of these discriminants. The final conclusion is based on general facts of the intersection theory.

2 Extremal discriminant and factorization of its truncations

Given a discriminant Δ_n, the sum of its monomials with exponents ranging over the vertex set of the polytope $\mathcal{N}(\Delta_n)$ we denote by $\widehat{\Delta}_n$ and call it the *extremal discriminant*.

Lemma 2.1. *The truncation of* $\widehat{\Delta}_n$ *to the face* h_K *admits the factorization*

$$\widehat{\Delta}_n\big|_{h_K} = a_K^2 \prod_{i=0}^{p} \widehat{\Delta}_{l_i}(f_{K_i}), \tag{2.1}$$

where $a_K^2 = a_{k_1}^2 \dots a_{k_p}^2$, *and* Δ_{l_i} *are the discriminants of polynomials of degrees* l_i.

For the proof of this statement we use the formulas for monomials of $\widehat{\Delta}_n$, i.e., for extremal monomials of Δ_n.These formulas were derived by Gelfand, Kapranov and Zelevinsky (see [7, Chapter 12, Theorems 2.2 and 2.3]) with the help of complicated algebraic technique of the theory of A-determinants. Note that another proof of this theorem was given by Batyrev [4] using only the classical Newton method for finding branches of an algebraic function. This assertion about monomials is as follows.

Claim. *The Newton polytope of the discriminant of polynomial* (1.1) *is combinatorially equivalent to an* $(n-1)$*-dimensional cube; it contains* 2^{n-1} *vertices, which are in bijective correspondence with all possible subsets* $I \subset \{1, 2, \dots, n-1\}$. *The vertex* $\mathrm{v}(I)$ *corresponding to a subset* $I = \{i_1 < i_2 < \dots < i_s\}$ *has the coordinates*

$$\begin{aligned} &\mathrm{v}_0 = i_1 - 1, \quad \mathrm{v}_n = n - i_s - 1, \\ &\mathrm{v}_{i_\nu} = i_{\nu+1} - i_{\nu-1} && \text{for } i_\nu \in I, \\ &\mathrm{v}_i = 0 && \text{for } i \notin I \cup \{0, n\}. \end{aligned} \tag{2.2}$$

$$\lim_{x\to 0} k_\nu(x) = \frac{\Gamma(-\nu)}{2^{2\nu+1}\Gamma(1+\nu)}, \qquad \nu < 0, \qquad -\nu \notin \mathbb{N}, \tag{1.27}$$

$$\lim_{x\to 0} x^\alpha k_0(x) = 0, \qquad \alpha > 0, \qquad \lim_{x\to 0} \frac{1}{\ln x} k_0(x) = -1, \tag{1.28}$$

$$\lim_{x\to 0} x^{2\nu+1} \frac{dk_\nu(x)}{dx} = -1, \qquad \nu > -1. \tag{1.29}$$

We will use notations

$$\mathbf{j}_\gamma(x,\xi) = \prod_{i=1}^{n} j_{\frac{\gamma_i-1}{2}}(x_i\xi_i) \tag{1.30}$$

and

$$\mathbf{i}_\gamma(x,\xi) = \prod_{i=1}^{n} i_{\frac{\gamma_i-1}{2}}(x_i\xi_i), \tag{1.31}$$

where $\gamma = (\gamma_1, ..., \gamma_n)$, $\gamma_1 > 0, ..., \gamma_n > 0$.

Information about the Bessel functions is taken from [591].

The Struve function is a solution $y(x)$ of the nonhomogeneous Bessel differential equation:

$$x^2 \frac{d^2y}{dx^2} + x\frac{dy}{dx} + \left(x^2 - \alpha^2\right) y = \frac{4\left(\frac{x}{2}\right)^{\alpha+1}}{\sqrt{\pi}\,\Gamma\left(\alpha + \frac{1}{2}\right)}.$$

Struve functions, denoted as $\mathbf{H}_\alpha(x)$, have the power series form

$$\mathbf{H}_\alpha(x) = \sum_{m=0}^{\infty} \frac{(-1)^m}{\Gamma\left(m+\frac{3}{2}\right)\Gamma\left(m+\alpha+\frac{3}{2}\right)} \left(\frac{x}{2}\right)^{2m+\alpha+1}. \tag{1.32}$$

Another definition of the Struve function, for values of α satisfying $\operatorname{Re}\alpha > -\frac{1}{2}$, is possible using an integral representation:

$$\mathbf{H}_\alpha(x) = \frac{2\left(\frac{x}{2}\right)^\alpha}{\sqrt{\pi}\,\Gamma\left(\alpha+\frac{1}{2}\right)} \int_0^{\frac{\pi}{2}} \sin(x\cos\tau)\sin^{2\alpha}(\tau)\,d\tau.$$

1.1.3 Hypergeometric type functions

The hypergeometric Gauss function inside the circle $|z|<1$ is determined as the sum of the hypergeometric series (see [2], p. 373, formula (15.3.1))

$${}_2F_1(a,b;c;z) = F(a,b,c;z) = \sum_{k=0}^{\infty} \frac{(a)_k(b)_k}{(c)_k} \frac{z^k}{k!}, \tag{1.33}$$

and for $|z| \geq 1$ it is obtained by analytic continuation of this series. In (1.33) parameters a, b, c and variable z can be complex, and $c \neq 0, -1, -2, \ldots$. The multiplier $(a)_k$ is the Pochhammer symbol (1.10).

Since the hypergeometric series (1.33) converges only in the unit circle of the complex plane, it is necessary to construct an analytic continuation of the hypergeometric function beyond the boundary of this circle, to the entire complex plane. One of the ways to continue analytically is to use the Euler integral representation of the form

$$
\begin{aligned}
&{}_2F_1(a, b; c; z) = \frac{\Gamma(c)}{\Gamma(b)\Gamma(b-c)} \int\limits_0^1 t^{b-1}(1-t)^{c-b-1}(1-tz)^{-a}\,dt, \qquad (1.34)\\
&0 < \operatorname{Re} b < \operatorname{Re} c, \qquad |\arg(1-z)| < \pi,
\end{aligned}
$$

in which the right side is defined under the specified conditions, ensuring the convergence of the integral.

An important property of the hypergeometric function is that many special and elementary functions can be obtained from it with certain values of the parameters and the transformation of an independent argument.

Examples for elementary functions are

$$
\begin{aligned}
&(1+x)^n = {}_2F_1(-n, \beta, \beta; -x), \qquad \frac{1}{x}\ln(1+x) = {}_2F_1(1, 1, 2; -x),\\
&e^x = \lim_{n\to\infty} {}_2F_1\left(1, n, 1; \frac{x}{n}\right),\\
&\cos x = \lim_{\alpha,\,\beta\to\infty} {}_2F_1\left(\alpha, \beta, \frac{1}{2}; -\frac{x^2}{4\alpha\beta}\right),\\
&\cosh x = \lim_{\alpha,\,\beta\to\infty} {}_2F_1\left(\alpha, \beta, \frac{1}{2}; \frac{x^2}{4\alpha\beta}\right).
\end{aligned}
$$

The first-kind Bessel function and the Gauss hypergeometric function are related by the formula

$$
J_\nu(z) = \lim_{\alpha,\,\beta\to\infty} \left[\frac{\left(\frac{z}{2}\right)^\nu}{\Gamma(\nu+1)} {}_2F_1\left(\alpha, \beta, \nu+1; -\frac{z^2}{4\alpha\beta}\right) \right].
$$

The degenerate Kummer hypergeometric function ${}_1F_1(a; b; z)$ is

$$
{}_1F_1(a; b; z) = \sum_{n=0}^{\infty} \frac{a^{(n)} z^n}{b^{(n)} n!},
$$

associated with the Gauss hypergeometric function by the limiting relation

$$
{}_1F_1(a; c; z) = \lim_{b\to\infty} {}_2F_1\left(a, b; c; \frac{z}{b}\right).
$$

The degenerate Tricomi hypergeometric function $\Psi(a;b;z)$ is determined by the equality

$$\Psi(a;b;z) = \frac{\Gamma(1-b)}{\Gamma(a+1-b)}\,{}_1F_1(a;b;z) + \frac{\Gamma(b-1)}{\Gamma(a)} z^{1-b}\,{}_1F_1(a+1-b;2-b;z).$$

Next we present Whittaker functions which appear in kernels of integral transforms connected with the fractional Bessel integral.

Whittaker functions $M_{\kappa,\mu}(z)$ and $W_{\kappa,\mu}(z)$ are special solutions of Whittaker's equation

$$\frac{d^2w}{dz^2} + \left(-\frac{1}{4} + \frac{\kappa}{z} + \frac{1/4-\mu^2}{z^2}\right) w = 0.$$

They are modified forms of Kummer's confluent hypergeometric functions and were introduced by Edmund Taylor Whittaker by

$$\begin{aligned} M_{\kappa,\mu}(z) &= \exp(-z/2)\, z^{\mu+\frac{1}{2}} M\left(\mu-\kappa+\frac{1}{2}, 1+2\mu; z\right), \\ W_{\kappa,\mu}(z) &= \exp(-z/2)\, z^{\mu+\frac{1}{2}} U\left(\mu-\kappa+\frac{1}{2}, 1+2\mu; z\right), \end{aligned} \tag{1.35}$$

where

$$M(a,b,z) = \sum_{n=0}^{\infty} \frac{a^{(n)} z^n}{b^{(n)} n!} = {}_1F_1(a;b;z)$$

and

$$U(a,b,z) = \frac{\Gamma(1-b)}{\Gamma(a+1-b)} M(a,b,z) + \frac{\Gamma(b-1)}{\Gamma(a)} z^{1-b} M(a+1-b,2-b,z)$$

are Kummer's functions.

The Whittaker functions $M_{\kappa,\mu}(z)$ and $W_{\kappa,\mu}(z)$ are the same as those with opposite values of μ; in other words, considered as a function of μ at fixed κ and z, they are even functions. When κ and z are real, the functions give real values for real and imaginary values of μ.

A *generalized hypergeometric function* is defined as a power series

$${}_pF_q(a_1,\ldots,a_p;b_1,\ldots,b_q;z) = \sum_{n=0}^{\infty} \frac{(a_1)_n \cdots (a_p)_n}{(b_1)_n \cdots (b_q)_n} \frac{z^n}{n!}.$$

The functions of the form ${}_0F_1(;a;z)$ are called confluent hypergeometric limit functions and are closely related to the Bessel functions J_α and I_α. The relationships are

$$J_\alpha(x) = \frac{(\frac{x}{2})^\alpha}{\Gamma(\alpha+1)} {}_0F_1\left(;\alpha+1; -\tfrac{x^2}{4}\right),$$
$$I_\alpha(x) = \frac{(\frac{x}{2})^\alpha}{\Gamma(\alpha+1)} {}_0F_1\left(;\alpha+1; \tfrac{x^2}{4}\right)$$

or

$${}_0F_1\left(;\alpha+1; -\tfrac{x^2}{4}\right) = j_\alpha(x), \qquad {}_0F_1\left(;\alpha+1; \tfrac{x^2}{4}\right) = i_\alpha(x).$$

We also need the function ${}_1F_2(;a;z)$. It is known (see [456]) that for $\alpha > 0$, $\xi \geq 0$, $t > 0$,

$$\int_0^t \left(t^2-u^2\right)^{\alpha-1} u^{1-\gamma} J_\gamma(u\xi)dt = \frac{\xi^\gamma t^{2\alpha}}{2^{\gamma+1}\alpha\Gamma(\gamma+1)} \times {}_1F_2\left(1;\alpha+1,\gamma+1; -\frac{t^2\xi^2}{4}\right)$$

and for $\gamma < 2$, $\alpha > 0$, $\xi \geq 0$, $t > 0$,

$$\int_0^t \left(t^2-u^2\right)^{\alpha-1} u^{1-\gamma} I_\gamma(u\xi)dt = \frac{\xi^\gamma t^{2\alpha}}{2^{\gamma+1}\alpha\Gamma(\gamma+1)} \times {}_1F_2\left(1;\alpha+1,\gamma+1; \frac{t^2\xi^2}{4}\right).$$

The *Appell hypergeometric function* $F_4(a,b,c_1,c_2;x,y)$ (see [456], p. 658) for $|x|^{1/2}+|y|^{1/2}<1$ has the form

$$F_4(a,b,c_1,c_2;x,y) = \sum_{m,n=0}^{\infty} \frac{(a)_{m+n}(b)_{m+n}}{(c_1)_m(c_2)_n\, m!\, n!} x^m y^n. \tag{1.36}$$

For $|x|^{1/2}+|y|^{1/2} \geq 1$, function $F_4(a,b;c_1,c_2;x,y)$ is understood as an analytical continuation, which is determined by the formulas from [130].

Struve functions (of any order) can be expressed in terms of the generalized hypergeometric function ${}_1F_2$:

$$\mathbf{H}_\alpha(z) = \frac{z^{\alpha+1}}{2^\alpha\sqrt{\pi}\,\Gamma\left(\alpha+\frac{3}{2}\right)} {}_1F_2\left(1, \tfrac{3}{2}, \alpha+\tfrac{3}{2}, -\tfrac{z^2}{4}\right).$$

The Lauricella function ([500], p. 33) is

$$\begin{aligned}&\mathbf{F}_{\gamma}^{(n)}(a_1, ..., a_n, b_1, ..., b_n; c; z_1, ..., z_n)\\&= \sum_{m_1,...,m_n}^{\infty} \frac{(a_1)_{m_1}...(a_n)_{m_n}(b_1)_{m_1}...(b_n)_{m_n}}{(c)_{m_1+...+m_n}} \frac{z_1^{m_1}}{m_1!}...\frac{z_n^{m_n}}{m_n!},\\&\max\{|z_1|, ..., |z_n|\} < 1.\end{aligned} \tag{1.37}$$

The *Fox–Wright function* ${}_p\Psi_q(z)$ is defined for $z \in \mathbb{C}$, $a_l, b_j \in \mathbb{C}$, $\alpha_l, \beta_j \in \mathbb{R}$, $l = 1, ..., p$, $j = 1, ..., q$ by the series

$${}_p\Psi_q(z) = {}_p\Psi_q\left[\begin{matrix}(a_l, \alpha_l)_{1,p}\\(b_j, \beta_j)_{1,q}\end{matrix}\middle| z\right] = \sum_{k=0}^{\infty} \frac{\prod\limits_{l=1}^{p} \Gamma(a_l + \alpha_l k)}{\prod\limits_{j=1}^{q} \Gamma(b_j + \beta_j k)} \frac{z^k}{k!}. \tag{1.38}$$

If the condition

$$\sum_{j=1}^{q} \beta_j - \sum_{l=1}^{p} \alpha_l > -1$$

is satisfied, the series in (1.38) is convergent for any $z \in \mathbb{C}$. Let

$$\begin{aligned}\delta &= \prod_{l=1}^{p} |\alpha_l|^{-\alpha_l} \prod_{j=1}^{q} |\beta_j|^{\beta_j},\\ \mu &= \sum_{j=1}^{q} b_j - \sum_{l=1}^{p} a_l + \frac{p-q}{2}.\end{aligned}$$

If

$$\sum_{j=1}^{q} \beta_j - \sum_{l=1}^{p} \alpha_l = -1,$$

then the series in (1.38) is absolutely convergent for $|z| < \delta$ and for $|z| = \delta$ and $\operatorname{Re}\mu > \frac{1}{2}$.

The *Mittag-Leffler function* $E_{\alpha,\beta}(z)$ is the entire function of order $1/\alpha$ defined by the following series when the real part of α is strictly positive:

$$E_{\alpha,\beta}(z) = \sum_{n=0}^{\infty} \frac{z^n}{\Gamma(\alpha n + \beta)}, \ z \in \mathbb{C}, \ \alpha, \beta \in \mathbb{C}, \ \operatorname{Re}\alpha > 0, \ \operatorname{Re}\beta > 0. \tag{1.39}$$

Function (1.39) was introduced by Gesta Mittag-Leffler in 1903 for $\alpha = 1$ and by A. Wiman in 1905 in the general case. The first applications of these functions by

Mittag-Leffler and Wiman were applications in complex analysis (nontrivial examples of entire functions with noninteger orders of growth and generalized summation methods). In the USSR, these functions became mainly known after the publication of the famous monograph by M. M. Dzhrbashyan [98] (see also his later monograph [106]). The most famous application of the Mittag-Leffler functions in the theory of integro-differential equations and fractional calculus is the fact that through them the resolvent of the Riemann–Liouville fractional integral is explicitly expressed in accordance with the famous Hille–Tamarkin–Dzhrbashyan formula [494]. In view of the numerous applications to the solution of fractional differential equations, this function was deservedly named in [202] "*Royal function of fractional calculus*."

The derivative of the Mittag-Leffler function is calculated by the formula

$$E'_{\alpha,\beta}(z) = \frac{E_{\alpha,\beta}(z)}{dz} = \sum_{k=0}^{\infty} \frac{(1+k)z^k}{\Gamma(\beta+\alpha(1+k))}.$$

Note that

$$\begin{aligned} &E_{\alpha,\beta}(0) = 1, \\ &E_{0,1}(z) = \sum_{k=0}^{\infty} z^k = \frac{1}{1-z}, \\ &E_{1,1}(z) = e^z, \qquad E_{1,2}(z) = \frac{e^z-1}{z}, \qquad E_{2,2}(z) = \frac{\sinh(\sqrt{z})}{\sqrt{z}}. \end{aligned}$$

Using the Fox–Wright function (1.38) we can write

$$E_{\alpha,\beta}(z) = {}_1\Psi_1\left[\left.\begin{matrix}(1,1)\\(\beta,\alpha)\end{matrix}\right| z\right]. \tag{1.40}$$

A general definition of the Meijer G-function is given by the following line integral in the complex plane (see [20], p. 206):

$$\begin{aligned} &G^{m,n}_{p,q}\left(\left.\begin{matrix}a_1,\ldots,a_p\\b_1,\ldots,b_q\end{matrix}\right| z\right) \\ &\quad = \frac{1}{2\pi i}\int_L \frac{\prod\limits_{j=1}^{m}\Gamma(b_j-s)\prod\limits_{j=1}^{n}\Gamma(1-a_j+s)}{\prod\limits_{j=m+1}^{q}\Gamma(1-b_j+s)\prod\limits_{j=n+1}^{p}\Gamma(a_j-s)} z^s\,ds. \end{aligned} \tag{1.41}$$

The general Legendre equation reads

$$(1-x^2)\,y'' - 2xy' + \left[\lambda(\lambda+1) - \frac{\mu^2}{1-x^2}\right] y = 0,$$

where the numbers λ and μ may be complex. This differential equation has two linearly independent solutions, which can both be expressed in terms of the hypergeometric function ${}_2F_1$:

$$P_\lambda^\mu(z) = \frac{1}{\Gamma(1-\mu)}\left[\frac{1+z}{1-z}\right]^{\mu/2} {}_2F_1\left(-\lambda, \lambda+1; 1-\mu; \frac{1-z}{2}\right), \tag{1.42}$$

for $|1-z| < 2$,

$$Q_\lambda^\mu(z) = \frac{\sqrt{\pi}\,\Gamma(\lambda+\mu+1)}{2^{\lambda+1}\Gamma(\lambda+3/2)} \frac{e^{i\mu\pi}(z^2-1)^{\mu/2}}{z^{\lambda+\mu+1}} {}_2F_1\left(\frac{\lambda+\mu+1}{2}, \frac{\lambda+\mu+2}{2}; \lambda+\frac{3}{2}; \frac{1}{z^2}\right), \tag{1.43}$$

for $|z| > 1$.

Functions P_λ^μ and Q_λ^μ are generally known as Legendre functions of the first and second kind of noninteger degree, with the additional qualifier "associated" if μ is nonzero.

We will use also Legendre functions with $z = x$, where $-1 < x < 1$ (see [19]). The interval $(-1, 1)$ is "the cut." If μ is even integer, then the values of $P_\lambda^\mu(z)$ on both sides of the cut are equal and in this case it is sufficient to take the branch cut along the real axis from -1 to $-\infty$. In all other cases $P_\lambda^\mu(x - i0)$ and $P_\lambda^\mu(x + i0)$ are different (here $f(x \pm i0)$ means $\lim\limits_{\varepsilon\to 0} f(x \pm i\varepsilon)$, $\varepsilon > 0$). In order to avoid ambiguity it is usual to introduce slightly modified Legendre functions. These will be denoted by $\mathbb{P}_\nu^\mu(z)$ and $\mathbb{Q}_\nu^\mu(z)$:

$$\mathbb{P}_\nu^\mu(x) = \frac{1}{2}\left[e^{i\frac{\mu\pi}{2}} P_\nu^\mu(x+i0) + e^{-i\frac{\mu\pi}{2}} P_\nu^\mu(x-i0)\right], \tag{1.44}$$

$$\mathbb{Q}_\nu^\mu(x) = \frac{1}{2}e^{-i\mu\pi}\left[e^{-i\frac{\mu\pi}{2}} Q_\nu^\mu(x+i0) + e^{i\frac{\mu\pi}{2}} Q_\nu^\mu(x-i0)\right]. \tag{1.45}$$

1.1.4 Polynomials

Gegenbauer polynomials or ultraspherical polynomials $C_n^{(\alpha)}(x)$ are orthogonal polynomials on the interval $[-1, 1]$ with respect to the weight function $(1-x^2)^{\alpha-\frac{1}{2}}$ that can be defined by the recurrence relation

$$C_0^\alpha(x) = 1, \qquad C_1^\alpha(x) = 2\alpha x,$$
$$C_n^\alpha(x) = \frac{1}{n}[2x(n+\alpha-1)C_{n-1}^\alpha(x) - (n+2\alpha-2)C_{n-2}^\alpha(x)].$$

The next decomposition is valid:

$$\frac{1}{(1-2xt+t^2)^\alpha} = \sum_{n=0}^\infty C_n^{(\alpha)}(x)t^n.$$

for any constant C, which are real for $x < 0$. The characteristics comprise two families of semicubical parabolas lying in the half-plane $x < 0$, with cusps on the line $x = 0$. This is of hyperbolic degeneracy, for which the two characteristic families coincide, perpendicularly to the line $x = 0$.

For $\pm x > 0$, set $\tau = \frac{2}{3}(\pm x)^{\frac{3}{2}}$. Then the Tricomi equation becomes the classical elliptic or hyperbolic Euler–Poisson–Darboux equation:

$$u_{\tau\tau} \pm u_{yy} + \frac{\beta}{\tau} u_\tau = 0.$$

The index $\beta = \frac{1}{3}$ determines the singularity of solutions near $\tau = 0$, equivalently, $x = 0$.

Many important problems in fluid mechanics and differential geometry can be reduced to corresponding problems for the Tricomi equation, particularly transonic flow problems and isometric embedding problems. The Tricomi equation is a prototype of the generalized Tricomi equation:

$$u_{xx} + K(x) u_{yy} = 0.$$

For a steady-state transonic flow in $\mathbb{R}^2$, $u(x; y)$ is the stream function of the flow, $K(x)$ and x are functions of the velocity, which are positive at subsonic and negative at supersonic speeds, and y is the angle of inclination of the velocity. The solutions $u(x; y)$ also serve as entropy generators for entropy pairs of the potential flow system for the velocity. For the isometric embedding problem of two-dimensional Riemannian manifolds into $\mathbb{R}^3$, the function $K(x)$ has the same sign as the Gaussian curvature.

A closely related partial differential equation is the Keldysh equation

$$x u_{xx} + u_{yy} = 0.$$

It is hyperbolic when $x < 0$, is elliptic when $x > 0$, and degenerates on the line $x = 0$. Its characteristics are

$$y \pm \frac{1}{2}(-x)^{\frac{1}{2}} = C$$

for any constant C, which are real for $x < 0$. The two characteristic families are (quadratic) parabolas lying in the half-plane $x < 0$ and coincide tangentially to the degenerate line $x = 0$, which is of parabolic degeneracy. For $\pm x > 0$, the Keldysh equation becomes the elliptic or hyperbolic Euler–Poisson–Darboux equation with index $\beta = -\frac{1}{4}$ by setting $\tau = \frac{1}{2}(\pm x)\frac{1}{2}$. Many important problems in continuum mechanics can also be reduced to corresponding problems for the Keldysh equation, particularly shock reflection–diffraction problems in gas dynamics.

1.4.4 Abstract Euler–Poisson–Darboux equation

The abstract Euler–Poisson–Darboux equation has the form

$$Au = (B_\gamma)_t \, u, \qquad u = u(x, t; \gamma), \tag{1.108}$$

where A is a linear operator acting only by variable $x = (x_1, ..., x_n)$.

Lemma 7. *Let* $u^k = u(x, t; k)$ *be a solution to Eq.* (1.108)*. The two recurrent formulas*

$$u^k = t^{1-k} u^{2-k}, \tag{1.109}$$

$$u^k_t = t u^{k+2} \tag{1.110}$$

are valid.

Proof. Let us show (1.109). Putting $w = t^{k-1} v$, $v = u^k$, we obtain

$$\begin{aligned}
w_t &= (k-1)t^{k-2} v + t^{k-1} v_t = \frac{k-1}{t}\, w + t^{k-1} v_t,\\
w_{tt} &= (k-1)(k-2)t^{k-3} v + (k-1)t^{k-2} v_t + (k-1)t^{k-2} v_t + t^{k-1} v_{tt}\\
&= \frac{(k-1)(k-2)}{t^2}\, w + 2(k-1)t^{k-2} v_t + t^{k-1} v_{tt},\\
\frac{2-k}{t}\, w_t &= -\frac{(k-1)(k-2)}{t^2}\, w + (2-k)t^{k-2} v_t,\\
w_{tt} + \frac{2-k}{t}\, w_t &= 2(k-1)t^{k-2} v_t + t^{k-1} v_{tt} + (2-k)t^{k-2} v_t\\
&= t^{k-1}\left(v_{tt} + \frac{k}{t}\, v_t\right)
\end{aligned}$$

or

$$w_{tt} + \frac{2-k}{t}\, w_t = t^{k-1}\left(v_{tt} + \frac{k}{t}\, v_t\right). \tag{1.111}$$

If $w = t^{k-1} v$ satisfies the equation

$$A w = w_{tt} + \frac{2-k}{t}\, w_t,$$

then using (1.111) we get

$$t^{k-1} A v = t^{k-1}\left(v_{tt} + \frac{k}{t}\, v_t\right),$$

which means that v satisfies the equation

$$A v = v_{tt} + \frac{k}{t}\, v_t.$$

Denoting $w = u^{2-k}$ we obtain (1.109).

Let us prove now (1.110). Putting $t w = v_t$, $v = u^k$, we can write

$$w_t = -\frac{1}{t^2}\, v_t + \frac{1}{t}\, v_{tt},$$

$$w_{tt} = \frac{2}{t^3}\,v_t - \frac{2}{t^2}\,v_{tt} + \frac{1}{t}\,v_{ttt},$$

and

$$\frac{k+2}{t}\,w_t = -\frac{k+2}{t^3}\,v_t + \frac{k+2}{t^2}\,v_{tt}.$$

We have

$$\begin{aligned} w_{tt} + \frac{k+2}{t}\,w_t &= \frac{2}{t^3}\,v_t - \frac{2}{t^2}\,v_{tt} + \frac{1}{t}\,v_{ttt} - \frac{k+2}{t^3}\,v_t + \frac{k+2}{t^2}\,v_{tt} \\ &= \frac{1}{t}\,v_{ttt} - \frac{k}{t^3}\,v_t + \frac{k}{t^2}\,v_{tt} = \frac{1}{t}\left(v_{ttt} - \frac{k}{t^2}\,v_t + \frac{k}{t}\,v_{tt}\right) \\ &= \frac{1}{t}\frac{\partial}{\partial t}\left(v_{tt} + \frac{k}{t}\,v_t\right) \end{aligned}$$

or

$$w_{tt} + \frac{k+2}{t}\,w_t = \frac{1}{t}\frac{\partial}{\partial t}\left(v_{tt} + \frac{k}{t}\,v_t\right). \tag{1.112}$$

If $w = \frac{1}{t}\,v_t$ satisfies the equation

$$Aw = w_{tt} + \frac{k+2}{t}\,w_t,$$

then using (1.112) we obtain

$$\frac{1}{t}\frac{\partial}{\partial t}Av = \frac{1}{t}\frac{\partial}{\partial t}\left(v_{tt} + \frac{k}{t}\,v_t\right),$$

which means that v satisfies the equation

$$Av = v_{tt} + \frac{k}{t}v_t.$$

Denoting $w = u^{k+2}$, $v = u^k$, we get (1.110). □

For $A = \Delta_\gamma$ formula (1.109) is proved in [147] and formula (1.110) is proved in [16]. Both formulas are present in Weinsteins' article [595], but in the case when in Eq. (1.108) for each of variables x_i, $i = 1, ..., n$, the second derivative acts. These recurring formulas will allow using the solution u^k to (1.108) to get a solution to the same equation, but with the parameters $k+2$ and $2-k$, respectively.

So, if the function $u(x,t;k)$ is a solution of the abstract Euler–Poisson–Darboux equation $Au = (B_k)_t\, u$, where A is a linear operator acting only by $x = (x_1, ..., x_n)$, then the function $t^{1-k}u(x,t;2-k)$ also is a solution to this equation.

Now let us construct integral operators of Buschman–Erdélyi with more general functions as kernels. Consider an operator ${}_1S^{\nu}_{0+}$. It has the form

$$ {}_1S^{\nu}_{0+} = \frac{d}{dx}\int\limits_0^x K\left(\frac{x}{y}\right) f(y)\,dy, \tag{5.61} $$

with kernel K expressed by $K(z) = P_\nu(z)$. Simple properties of special functions lead to the fact that ${}_1S^{\nu}_{0+}$ is a special case of (5.61) with the Gegenbauer function kernel

$$ K(z) = \frac{\Gamma(\alpha+1)\,\Gamma(2\beta)}{2^{p-\frac{1}{2}}\Gamma(\alpha+2\beta)\,\Gamma(\beta+\frac{1}{2})}(z^\alpha-1)^{\beta-\frac{1}{2}}C^{\beta}_{\alpha}(z) \tag{5.62} $$

with $\alpha = \nu$, $\beta = \frac{1}{2}$, or with the Jacobi function kernel

$$ K(z) = \frac{\Gamma(\alpha+1)}{2^\rho\Gamma(\alpha+\rho+1)}(z-1)^\rho(z+1)^\sigma P^{(\rho,\sigma)}_{\alpha}(z) \tag{5.63} $$

with $\alpha = \nu$, $\rho = \sigma = 0$. More general are operators with the Gauss hypergeometric function kernel ${}_2F_1$ or Meijer G-function $G^{m,n}_{p,q}$ (1.41) or Fox–Wright $E_{\alpha,\beta}$ function (1.40) kernels (cf. [494]). For studying such operators inequalities for kernel functions are very useful (e.g., [228,528]).

Define the first class of generalized operators.

Definition 40. *Define Gauss–Buschman–Erdélyi operators by formulas*

$$ {}_1F_{0+}(a,b,c)[f] = \frac{1}{2^{c-1}\Gamma(c)}, \tag{5.64} $$

$$ \int\limits_0^x \left(\frac{x}{y}-1\right)^{c-1}\left(\frac{x}{y}+1\right)^{a+b-c} {}_2F_1\left({}^{a,b}_{c}|\frac{1}{2}-\frac{1}{2}\frac{x}{y}\right) f(y)\,dy, $$

$$ {}_2F_{0+}(a,b,c)[f] = \frac{1}{2^{c-1}\Gamma(c)}, \tag{5.65} $$

$$ \int\limits_0^x \left(\frac{y}{x}-1\right)^{c-1}\left(\frac{y}{x}+1\right)^{a+b-c} {}_2F_1\left({}^{a,b}_{c}|\frac{1}{2}-\frac{1}{2}\frac{y}{x}\right) f(y)\,dy, $$

$$ {}_1F_{-}(a,b,c)[f] = \frac{1}{2^{c-1}\Gamma(c)}, \tag{5.66} $$

$$ \int\limits_0^x \left(\frac{y}{x}-1\right)^{c-1}\left(\frac{y}{x}+1\right)^{a+b-c} {}_2F_1\left({}^{a,b}_{c}|\frac{1}{2}-\frac{1}{2}\frac{y}{x}\right) f(y)\,dy, $$

$$
{}_2F_{-}(a,b,c)[f] = \frac{1}{2^{c-1}\Gamma(c)}, \tag{5.67}
$$

$$
\int\limits_0^x \left(\frac{x}{y}-1\right)^{c-1}\left(\frac{x}{y}+1\right)^{a+b-c} {}_2F_1\left({}^{a,b}_{c}|\frac{1}{2}-\frac{1}{2}\frac{x}{y}\right) f(y)\,dy,
$$

$$
{}_3F_{0+}[f] = \frac{d}{dx}\,{}_1F_{0+}[f], \quad {}_4F_{0+}[f] = {}_2F_{0+}\frac{d}{dx}[f], \tag{5.68}
$$

$$
{}_3F_{-}[f] = {}_1F_{-}\left(-\frac{d}{dx}\right)[f], \quad {}_4F_{-}[f] = \left(-\frac{d}{dx}\right){}_2F_{-}[f]. \tag{5.69}
$$

The symbol ${}_2F_1$ in definitions (5.65) and (5.67) means the Gauss hypergeometric function on the natural domain and in (5.64) and (5.66) the main branch of its analytical continuation.

Operators (5.64)–(5.67) generalize Buschman–Erdélyi ones (5.5)–(5.8), respectively. They reduce to Buschman–Erdélyi for the choice of parameters $a=-(\nu+\mu)$, $b=1+\nu-\mu$, $c=1-\mu$. For operators (5.64)–(5.67) the above results are generalized with necessary changes. For example they are factorized via more simple operators (5.68) and (5.69) with a special choice of parameters.

Operators (5.68) and (5.69) are generalizations of (5.14) and (5.15). For them the following result is true.

Theorem 64. *Operators* (5.68) *and* (5.69) *may be extended to isometric in* $L_2(0,\infty)$ *if and only if they coincide with Buschman–Erdélyi operators of zero order smoothness* (5.14) *and* (5.15) *for integer values of* $\nu = \frac{1}{2}(b-a-1)$.

This theorem singles out Buschman–Erdélyi operators of zero order smoothness at least in the class (5.64)–(5.69). Operators (5.64)–(5.67) are generalizations of fractional integrals. Analogously may be studied generalizations to (5.33)–(5.34), (5.43), and (5.46)–(5.47).

More general are operators with G-function kernel,

$$
\begin{aligned}
{}_1G_{0+}(\alpha,\beta,\delta,\gamma)[f] &= \frac{2^{\delta}}{\Gamma(1-\alpha)\Gamma(1-\beta)} \\
&\times \int\limits_0^x \left(\frac{x}{y}-1\right)^{-\delta}\left(\frac{x}{y}+1\right)^{1+\delta-\alpha-\beta} G^{1\,2}_{2\,2}\left(\frac{x}{2y}-\frac{1}{2}\Big|^{\alpha,\,\beta}_{\gamma,\,\delta}\right) f(y)\,dy.
\end{aligned} \tag{5.70}
$$

Other operators are with different intervals of integration and parameters of the G-function. For $\alpha=1-a$, $\beta=1-b$, $\delta=1-c$, $\gamma=0$ (5.70) reduces to (5.64), for $\alpha=1+\nu$, $\beta=-\nu$, $\delta=\gamma=0$ (5.70) reduces to Buschman–Erdélyi operators of zero order smoothness ${}_1S^{\nu}_{0+}$.

Further generalizations are in terms of Wright or Fox functions. They lead to Wright–Buschman–Erdélyi and Fox–Buschman–Erdélyi operators. These classes are connected with Sonine–Dimovski and Poisson–Dimovski transmutations [89,93], and also with generalized fractional integrals introduced by Kiryakova [252].

V. Katrakhov found a new approach for boundary value problems for elliptic equations with strong singularities of infinite order. For example for the Poisson equation he studied problems with solutions of arbitrary growth. At singular points he proposed a new kind of boundary condition: the K-trace. His results are based on constant usage of Buschman–Erdélyi transmutations of the first kind for definition of norms, solution estimates, and correctness proofs [225,227].

Moreover in joint papers with I. Kipriyanov he introduced and studied new classes of pseudodifferential operators based on transmutational techniques [248–250]. These results were paraphrased in a reorganized manner in [52].

5.3 Multi-dimensional integral transforms of Buschman–Erdélyi type with Legendre functions in kernels

In this section we consider generalizations of Buschman–Erdélyi operators for the multi-dimensional case. This case was studied by O. V. Skoromnik and S. M. Sitnik (see [538]).

5.3.1 *Basic definitions*

Let $x = (x_1, x_2, ..., x_n) \in \mathbb{R}^n_+$, $t = (t_1, t_2, ..., t_n) \in \mathbb{R}^n_+$, $x \cdot t = \sum\limits_{n=1}^{n} x_n t_n$ denotes their scalar product, and in particular, $x \cdot 1 = \sum\limits_{n=1}^{n} x_n$. The expression $x > t$ means that $x_1 > t_1, ..., x_n > t_n$, the nonstrict inequality $\geq$ has a similar meaning, by $\mathbb{N} = \{1, 2, ...\}$ we denote the set of positive integers, $\mathbb{N}_0 = \mathbb{N} \bigcup \{0\}$, and $\mathbb{N}^n_0 = \mathbb{N}_0 \times \mathbb{N}_0 \times ... \times \mathbb{N}_0$. We denote

$\mathbf{m} = (m_1, m_2, ..., m_n) \in \mathbb{N}^n_0$, $m_1 = m_2 = ... = m_n$;
$\mathbf{n} = (\overline{n}_1, \overline{n}_2, ..., \overline{n}_n) \in \mathbb{N}^n_0$, $\overline{n}_1 = \overline{n}_2 = ... = \overline{n}_n$;
$\mathbf{p} = (p_1, p_2, ..., p_n) \in \mathbb{N}^n_0$, $p_1 = p_2 = ... = p_n$;
$\mathbf{q} = (q_1, q_2, ..., q_n) \in \mathbb{N}^n_0$, $q_1 = q_2 = ... = q_n$, $(0 \leq \mathbf{m} \leq \mathbf{q}, 0 \leq \mathbf{m} \leq \mathbf{p})$.

We put

$\sigma = (\sigma_1, \sigma_2, ..., \sigma_n) \in \mathbb{C}^n$;
$\kappa = (\kappa_1, \kappa_2, ..., \kappa_n) \in \mathbb{C}^n$;
$\delta = (\delta_1, \delta_2, ..., \delta_n) \in \mathbb{R}^n$;
$\gamma = (\gamma_1, \gamma_2, ..., \gamma_n) \in \mathbb{R}^n$, $0 < \gamma < 1$;
$a_i = (a_{i_1}, a_{i_2}, ..., a_{i_n})$, $1 \leq i \leq p$, $a_{i_1}, a_{i_2}, ..., a_{i_n} \in \mathbb{C}$, $1 \leq i_1 \leq p_1, ..., 1 \leq i_n \leq p_n$;
$b_j = (b_{j_1}, b_{j_2}, ..., b_{j_n})$, $1 \leq j \leq q$, $b_{j_1}, b_{j_2}, ..., b_{j_n} \in \mathbb{C}$, $1 \leq j_1 \leq q_1, ..., 1 \leq j_n \leq q_n$;
$\alpha_i = (\alpha_{i_1}, \alpha_{i_2}, ..., \alpha_{i_n})$, $1 \leq i \leq p$, $\alpha_{i_1}, \alpha_{i_2}, ..., \alpha_{i_n} \in \mathbb{R}^1_+$, $1 \leq i_1 \leq p_1, ..., 1 \leq i_n \leq p_n$;

Obs. Nº 380 - Tangentes à
l'ellipse.

$x = a \cos \varphi$; $y = b \operatorname{sen} \varphi$;

Obs: Ellipse use estas equações para simular a deformação do espaço-tempo com os devidas adequações.

Na realidade a ellipse é uma deformação do círculo, ou seja, com os devidos ajustes das equações matemáticas poderemos simular a curvatura do espaço-tempo do Universo.

Obs: $x = a \cos \varphi$,

$$y_1 = \frac{a}{b} y = a \operatorname{sen} \varphi.$$

On obtiendrait la même condition en supposant $v \neq 0$.

Si l'on a $a^2u^2 + b^2v^2 - w^2 < 0$, la droite rencontre l'ellipse en des points imaginaires; et enfin si $a^2u^2 + b^2v^2 - w^2 = 0$, la droite rencontre l'ellipse en deux points confondus, elle est tangente à l'ellipse.

Il résulte de là que l'équation tangentielle de cette courbe est

$$a^2u^2 + b^2v^2 - w^2 = 0.$$

Tangentes à l'ellipse.

380. Tangente en un point de la courbe. — La tangente en un point (x, y) de la courbe a pour équation

$$\frac{Xx}{a^2} + \frac{Yy}{b^2} - 1 = 0,$$

x et y vérifiant la relation

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} - 1 = 0.$$

L'équation de la tangente renferme donc deux paramètres liés par une relation.

On peut exprimer les coordonnées d'un point de l'ellipse en fonction d'un seul paramètre. En effet, la relation $\frac{x^2}{a^2} + \frac{y^2}{b^2} - 1 = 0$ nous conduit à poser $\frac{x}{a} = \cos\varphi$, $\frac{y}{b} = \sin\varphi$, ou

$$x = a\cos\varphi, \qquad y = b\sin\varphi;$$

en faisant varier φ de 0 à 2π, ces formules donnent les coordonnées de tous les points de l'ellipse.

L'équation de la tangente au point (x, y) peut alors s'écrire

$$\frac{X\cos\varphi}{a} + \frac{Y\sin\varphi}{b} - 1 = 0;$$

elle ne contient plus qu'un seul paramètre.

Posons $\operatorname{tg}\frac{\varphi}{2} = t$, nous avons

$$x = \frac{a(1 - t^2)}{1 + t^2}, \qquad y = \frac{2bt}{1 + t^2};$$

x et y sont alors exprimés rationnellement en fonction d'un paramètre, ce qui montre que *l'ellipse est une courbe unicursale* (229).

L'équation de la tangente est alors

$$\frac{X(1-t^2)}{a}+\frac{2tY}{b}-(1+t^2)=0. \quad (*)$$

L'angle φ a une signification géométrique remarquable. Soit M le point de l'ellipse ayant pour coordonnées

$$x=a\cos\varphi, \qquad y=b\sin\varphi;$$

le point correspondant M_1 du cercle décrit sur AA' comme diamètre a pour coordonnées

$$x=a\cos\varphi, \qquad y_1=\frac{a}{b}y=a\sin\varphi;$$

on en conclut que l'angle φ est l'angle de la demi-droite OM_1 avec la demi-droite OA (*fig.* 120).

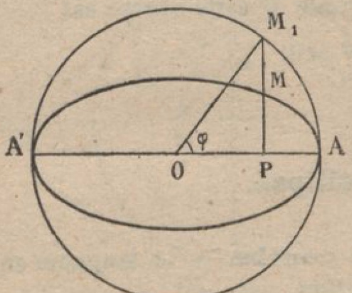

Fig. 120.

L'angle φ est appelé *l'anomalie excentrique* (**) du point M.

381. Condition pour qu'une droite soit tangente à l'ellipse. — Soit la droite $uX+vY+w=0$; pour qu'elle soit tangente à l'ellipse, il faut et il suffit qu'il existe un système de valeurs de x et de y vérifiant la relation $\frac{x^2}{a^2}+\frac{y^2}{b^2}-1=0$ et telles que les deux équations

$$\frac{Xx}{a^2}+\frac{Yy}{b^2}-1=0, \qquad uX+vY+w=0$$

représentent la même droite.

On doit donc avoir

$$\frac{x}{a^2u}=\frac{y}{b^2v}=\frac{-1}{w},$$

d'où $x=-\frac{a^2u}{w}$, $y=-\frac{b^2v}{w}$ et, en portant ces valeurs dans la relation $\frac{x^2}{a^2}+\frac{y^2}{b^2}-1=0$, on a

$$a^2u^2+b^2v^2-w^2=0.$$

C'est l'équation tangentielle de l'ellipse, que nous avons déjà obtenue au nº 379.

(*) Cette équation étant du deuxième degré par rapport à t, la droite qu'elle représente enveloppe une courbe de deuxième classe (289), c'est-à-dire une conique.

(**) Cette appellation est empruntée à l'astronomie.

382. Tangentes par un point non situé sur la courbe. — 1° Les points de contact sont à l'intersection de l'ellipse et de la polaire du point donné P(α, β),

$$\frac{\alpha x}{a^2}+\frac{\beta y}{b^2}-1=0.$$

Cette droite rencontre l'ellipse en des points réels si l'on a (379)

$$\frac{\alpha^2}{a^2}+\frac{\beta^2}{b^2}-1>0,$$

c'est-à-dire si le point P est dans la région positive de l'ellipse (269).

Or le centre de la courbe est dans la région négative; nous appellerons cette région la *région intérieure*, l'autre région qui ne contient pas le centre est appelée la *région extérieure*.

Par conséquent, pour que les tangentes issues d'un point P à une ellipse soient réelles, il faut et il suffit que le point P soit situé dans la région extérieure.

2° On a l'équation aux coefficients angulaires de ces tangentes en écrivant que la droite $y-\beta=t(x-\alpha)$ est tangente, ce qui donne

$$a^2t^2+b^2-(\beta-t\alpha)^2=0,$$

ou

$$t^2(a^2-\alpha^2)+2t\alpha\beta+b^2-\beta^2=0,$$

et cette équation a ses racines réelles si l'on a $\frac{\alpha^2}{a^2}+\frac{\beta^2}{b^2}-1>0.$

3° Enfin on obtient l'équation de l'ensemble des tangentes issues du point P en remplaçant dans cette dernière équation t par $\frac{y-\beta}{x-\alpha}$.

L'équation obtenue peut aussi se mettre sous la forme (292)

$$\left(\frac{\alpha x}{a^2}+\frac{\beta y}{b^2}-1\right)^2-\left(\frac{x^2}{a^2}+\frac{y^2}{b^2}-1\right)\left(\frac{\alpha^2}{a^2}+\frac{\beta^2}{b^2}-1\right)=0.$$

383. Lieu géométrique des points d'où l'on peut mener deux tangentes rectangulaires à l'ellipse. — Soient α, β les coordonnées d'un point du lieu. Les coefficients angulaires des tangentes passant par ce point sont racines de l'équation

$$t^2(a^2-\alpha^2)+2t\alpha\beta+b^2-\beta^2=0;$$

pour que ces tangentes soient perpendiculaires, il faut que le produit des racines de cette équation soit égal à -1, ce qui donne

$$\alpha^2+\beta^2-a^2-b^2=0;$$

en y remplaçant α, β par x, y, on a l'équation du lieu

$$x^2+y^2-a^2-b^2=0.$$

Le lieu cherché est le cercle circonscrit au rectangle construit sur les axes de l'ellipse; ce cercle est appelé le *cercle orthoptique* de l'ellipse.

384. Tangentes parallèles à une direction donnée. — Les points de contact de ces tangentes sont à l'intersection de l'ellipse et du diamètre conjugué de la direction donnée; ces points sont toujours réels, car le diamètre passe par le centre.

Cherchons maintenant les équations de ces tangentes. Soit m le coefficient angulaire de la direction donnée; écrivons que la droite $y = mx + \lambda$ est tangente, nous avons

$$a^2m^2 + b^2 - \lambda^2 = 0;$$

nous en tirons $\lambda = \pm\sqrt{a^2m^2 + b^2}$, et par suite les tangentes à l'ellipse parallèles à la direction donnée ont pour équations

$$y = mx \pm \sqrt{a^2m^2 + b^2}.$$

Normales à l'ellipse.

385. Normale en un point de la courbe. — La normale au point (x, y) a pour équation

$$\frac{X - x}{\frac{x}{a^2}} = \frac{Y - y}{\frac{y}{b^2}}, \qquad \text{ou} \qquad \frac{a^2X}{x} - a^2 = \frac{b^2Y}{y} - b^2.$$

En supposant toujours $a > b$, $a^2 - b^2$ est une quantité positive que l'on désigne par c^2; l'équation de la normale est alors

$$\frac{a^2X}{x} - \frac{b^2Y}{y} - c^2 = 0,$$

avec la condition

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} - 1 = 0.$$

En remplaçant x par $a\cos\varphi$ et y par $b\sin\varphi$, on obtient l'équation de la normale en fonction d'un seul paramètre φ,

$$\frac{aX}{\cos\varphi} - \frac{bY}{\sin\varphi} - c^2 = 0;$$

on peut aussi l'écrire, en posant $\operatorname{tg}\frac{\varphi}{2} = t$,

$$\frac{aX(1 + t^2)}{1 - t^2} - \frac{bY(1 + t^2)}{2t} - c^2 = 0,$$

ou

$$2at(1 + t^2)X - b(1 - t^4)Y - 2c^2t(1 - t^2) = 0.$$

Cette équation étant du quatrième degré par rapport à t, on reconnaît (289) que par un point quelconque du plan on peut mener quatre normales à une ellipse. Par suite, l'enveloppe des normales, ou la développée de l'ellipse, est une courbe algébrique, unicursale et de quatrième classe.

386. Condition pour qu'une droite soit normale à l'ellipse. — Pour que la droite $uX+vY+w=0$ soit normale à l'ellipse, il faut et il suffit qu'il existe un système de valeurs de x et de y vérifiant l'équation $\frac{x^2}{a^2}+\frac{y^2}{b^2}-1=0$, et telles que les deux équations

$$\frac{a^2X}{x}-\frac{b^2Y}{y}-c^2=0, \qquad uX+vY+w=0$$

représentent la même droite.

On doit donc avoir

$$\frac{a^2}{ux}=-\frac{b^2}{vy}=-\frac{c^2}{w},$$

d'où

$$x=-\frac{a^2w}{c^2u}, \qquad y=\frac{b^2w}{c^2v},$$

et, en portant ces valeurs dans la relation $\frac{x^2}{a^2}+\frac{y^2}{b^2}-1=0$, on a

$$\frac{a^2w^2}{c^4u^2}+\frac{b^2w^2}{c^4v^2}-1=0,$$

ou

$$w^2(a^2v^2+b^2u^2)-c^4u^2v^2=0.$$

On retient aisément cette équation en la mettant sous la forme

$$\frac{a^2}{u^2}+\frac{b^2}{v^2}-\frac{c^4}{w^2}=0.$$

C'est l'équation tangentielle de la développée de l'ellipse; et nous voyons de nouveau que cette développée est de quatrième classe.

387. Développée de l'ellipse. — Cherchons maintenant l'équation ponctuelle de la développée.

La normale à l'ellipse au point qui a pour coordonnées λ et μ a pour équation

$$(1) \qquad \frac{a^2x}{\lambda}-\frac{b^2y}{\mu}-c^2=0,$$

λ et μ vérifiant la relation

$$(2) \qquad \frac{\lambda^2}{a^2}+\frac{\mu^2}{b^2}-1=0.$$

Pour avoir l'enveloppe de cette normale (274), il faut éliminer λ et μ entre les équations (1), (2) et la suivante

$$\frac{-\frac{a^2x}{\lambda^2}}{\frac{2\lambda}{a^2}}=\frac{\frac{b^2y}{\mu^2}}{\frac{2\mu}{b^2}},$$

ou

$$\frac{a^4x}{\lambda^3}=-\frac{b^4y}{\mu^3}.$$

On en tire

$$\frac{\lambda}{(a^4x)^{\frac{1}{3}}} = -\frac{\mu}{(b^4y)^{\frac{1}{3}}},$$

et, en égalant ces deux rapports égaux à une inconnue auxiliaire ρ, nous avons

$$\lambda = \rho(a^4x)^{\frac{1}{3}}, \qquad \mu = -\rho(b^4y)^{\frac{1}{3}}.$$

Remplaçons λ et μ par ces valeurs dans les équations (1) et (2), nous obtenons

$$\frac{(ax)^{\frac{2}{3}} + (by)^{\frac{2}{3}}}{\rho} - c^2 = 0, \qquad \rho^2[(ax)^{\frac{2}{3}} + (by)^{\frac{2}{3}}] - 1 = 0.$$

Il ne nous reste plus qu'à éliminer ρ entre ces deux équations, ce qui nous donne

$$[(ax)^{\frac{2}{3}} + (by)^{\frac{2}{3}}]^3 = c^4,$$

ou, en extrayant la racine cubique,

$$a^{\frac{2}{3}}x^{\frac{2}{3}} + b^{\frac{2}{3}}y^{\frac{2}{3}} - c^{\frac{4}{3}} = 0. \tag{3}$$

Telle est l'équation ponctuelle de la développée.

388. Elle se présente sous forme irrationnelle; on peut la rendre rationnelle de la manière suivante.

On vérifie aisément l'identité

$$u^3 + v^3 + w^3 - 3uvw \equiv (u + v + w)\mathrm{P},$$

en posant

$$\mathrm{P} \equiv u^2 + v^2 + w^2 - vw - wu - uv \equiv \frac{1}{2}[(v-w)^2 + (w-u)^2 + (u-v)^2],$$

ce qui montre que si u, v, w sont réels, P est toujours positif, excepté dans le cas où $u = v = w$.

D'autre part, nous avons

$$\mathrm{A}^3 - \mathrm{B}^3 \equiv (\mathrm{A} - \mathrm{B})(\mathrm{A}^2 + \mathrm{AB} + \mathrm{B}^2),$$

et si A et B sont réels, $\mathrm{A}^2 + \mathrm{AB} + \mathrm{B}^2$ est positif.

Remplaçons dans cette identité A par $u^3 + v^3 + w^3$ et B par $3uvw$; nous obtenons

$$(u^3 + v^3 + w^3)^3 - 27u^3v^3w^3 \equiv (u^3 + v^3 + w^3 - 3uvw)\mathrm{Q},$$

Q désignant ce que devient $\mathrm{A}^2 + \mathrm{AB} + \mathrm{B}^2$ par la substitution, ou en remplaçant $u^3 + v^3 + w^3 - 3uvw$ par sa valeur précédente,

$$(u^3 + v^3 + w^3)^3 - 27u^3v^3w^3 \equiv (u + v + w)\mathrm{PQ}.$$

Faisons maintenant

$$u = a^{\frac{2}{3}}x^{\frac{2}{3}}, \qquad v = b^{\frac{2}{3}}y^{\frac{2}{3}}, \qquad w = -c^{\frac{4}{3}},$$

nous avons

$$(4)\qquad (a^2x^2+b^2y^2-c^4)^3+27a^2b^2c^4x^2y^2\equiv\left(a^{\frac{2}{3}}x^{\frac{2}{3}}+b^{\frac{2}{3}}y^{\frac{2}{3}}-c^{\frac{4}{3}}\right)\mathrm{R},$$

et R est toujours positif, car on ne peut avoir $a^{\frac{2}{3}}x^{\frac{2}{3}}=b^{\frac{2}{3}}y^{\frac{2}{3}}=-c^{\frac{4}{3}}$ pour des valeurs réelles de x et de y.

Il en résulte que les équations

$$(3)\qquad a^{\frac{2}{3}}x^{\frac{2}{3}}+b^{\frac{2}{3}}y^{\frac{2}{3}}-c^{\frac{4}{3}}=0,$$

$$(5)\qquad (a^2x^2+b^2y^2-c^4)^3+27a^2b^2c^4x^2y^2=0$$

ont mêmes ensembles de solutions réelles; par suite l'équation (5) est l'équation rationnelle de la développée.

Cette courbe est donc du sixième degré.

389. Mais pour la construire il sera plus facile d'utiliser l'équation (3).

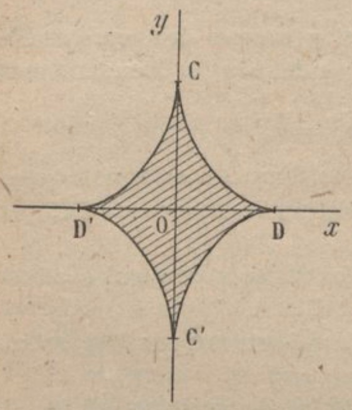

Fig. 121.

Cette équation ne change pas si on change x en $-x$ ou y en $-y$; par suite, la courbe est symétrique par rapport aux deux axes. Nous construirons seulement la portion de cette courbe qui correspond aux valeurs positives de x et de y.

Résolvons l'équation par rapport à y; nous avons

$$y=\frac{a}{b}\left[\left(\frac{c^2}{a}\right)^{\frac{2}{3}}-x^{\frac{2}{3}}\right]^{\frac{3}{2}}.$$

Pour que y soit réel, il faut que x soit plus petit que $\frac{c^2}{a}$, et quand x croît de 0 à $\frac{c^2}{a}$, y décroît de $\frac{c^2}{b}$ à 0; nous obtenons ainsi la branche de courbe CD (*fig.* 121).

D'autre part, la dérivée de y par rapport à x est

$$y'=-\frac{a}{bx^{\frac{1}{3}}}\left[\left(\frac{c^2}{a}\right)^{\frac{2}{3}}-x^{\frac{2}{3}}\right]^{\frac{1}{2}};$$

par suite, au point $\mathrm{C}\left(0,\frac{c^2}{b}\right)$ la tangente est Oy, au point $\mathrm{D}\left(\frac{c^2}{a},0\right)$, la tangente est O$x$.

On achève par symétrie, et on a la courbe représentée par la figure 121. Elle admet quatre points de rebroussement.

390. Normales par un point non situé sur l'ellipse. Détermination des pieds. — Soient α, β les coordonnées du point donné P. Désignons par x, y les coordonnées du pied d'une normale issue du point P; nous avons d'abord

$$\frac{x^2}{a^2}+\frac{y^2}{b^2}-1=0 \tag{1}$$

puisque ce point est sur l'ellipse; en outre, en écrivant que la normale en ce point, $\dfrac{X-x}{\dfrac{x}{a^2}}=\dfrac{Y-y}{\dfrac{y}{b^2}}$, passe par le point P, nous avons

$$\frac{\alpha-x}{\dfrac{x}{a^2}}=\frac{\beta-y}{\dfrac{y}{b^2}}. \tag{2}$$

Les équations (1) et (2) déterminent les coordonnées des pieds des normales issues du point P.

Considérons dans ces équations x et y comme des coordonnées courantes, la première représente l'ellipse donnée; la deuxième peut s'écrire

$$c^2xy+b^2\beta x-a^2\alpha y=0,$$

elle représente une hyperbole équilatère dont les asymptotes sont parallèles aux axes de l'ellipse et qui passe par le centre O de l'ellipse et par le point P.

Cette hyperbole rencontre l'ellipse en quatre points qui sont les pieds des normales issues du point P à l'ellipse.

On l'appelle *l'hyperbole aux pieds des normales* ou *l'hyperbole d'Apollonius* relative au point P.

La branche d'hyperbole qui passe au point O rencontre l'ellipse en deux points réels; il en résulte que sur les quatre normales passant par le point P deux sont toujours réelles.

391. Nous allons chercher dans quel cas les deux autres sont aussi réelles.

Pour cela, nous exprimerons les coordonnées d'un point quelconque de l'hyperbole d'Apollonius en fonction d'un paramètre. Revenons à l'équation (2) et désignons par t la valeur commune des deux membres,

$$\frac{\alpha-x}{\dfrac{x}{a^2}}=\frac{\beta-y}{\dfrac{y}{b^2}}=t;$$

nous en tirons

$$x=\frac{a^2\alpha}{t+a^2},\qquad y=\frac{b^2\beta}{t+b^2}. \tag{3}$$

Ce sont les coordonnées d'un point de l'hyperbole en fonction de t.

We may write $B^+(x,r)$ instead of $B^+_M(x,r)$ for simplicity (when the space in question is transparent), or $B^+_F(x,r)$ to stress that the distance structure is induced from F. Open and closed balls in T_xM are defined in a similar way by using the (asymmetric) distance function $d_{T_xM}(v,w) := F(w-v)$.

Proposition 3.17 (Properties of the Exponential Map)

(i) *The domain* $\mathcal{D}$ *of the exponential map* exp *is an open set including the zero section* $\mathbf{0}$.
(ii) *For any* $x \in M$*, there exist* $\varepsilon > 0$ *and an open neighborhood* U *of* x *such that any two points in* U *are joined by a unique solution to the geodesic equation with length less than* ε.
(iii) *The exponential map* exp *is* C^1 *on* $\mathcal{D}$*, and its restriction to* $\mathcal{D} \setminus \mathbf{0}$ *is* C^∞.
(iv) *Given* $x \in M$*, for sufficiently small* $\varepsilon > 0$*, the map* $\exp_x : B^+_{T_xM}(0,\varepsilon) \longrightarrow B^+_M(x,\varepsilon)$ *is a* C^1*-diffeomorphism and its restriction* $\exp_x : B^+_{T_xM}(0,\varepsilon) \setminus \{0\} \longrightarrow B^+_M(x,\varepsilon) \setminus \{x\}$ *is a* C^∞*-diffeomorphism.*

These assertions essentially follow from the ODE theory. In (iii) and (iv), by construction, we find that the derivative $d(\exp_x)_0 : T_0(T_xM) \longrightarrow T_xM$ of $\exp_x$ at $0 \in T_xM$ is the identity map on T_xM (by identifying its domain $T_0(T_xM)$ with T_xM); we refer to [25, Sect. 5.3] for details. The exponential map becomes C^2 at the zero section $\mathbf{0}$ if and only if F belongs to the special class of Berwald metrics (see Proposition 6.11).

To prove that solutions of the geodesic equation are locally minimizing, we can follow the standard line as follows.

Lemma 3.18 (Gauss' Lemma) *Let* $v \in U_xM$ *and* $\eta : [0,l] \longrightarrow M$ *be the solution to the geodesic equation* (3.15) *with* $\dot\eta(0) = v$*. For* $t \in (0,l)$ *and* $w \in T_v(T_xM)$ *tangent to* U_xM*, we have*

$$g_{\dot\eta(t)}\big(\dot\eta(t), d(\exp_x)_{tv}(w)\big) = 0,$$

where we regard as $w \in T_{tv}(T_xM)$ *by identifying both* $T_v(T_xM)$ *and* $T_{tv}(T_xM)$ *with* T_xM *in the canonical way.*

Proof Fix $T \in (0,l)$ and, for sufficiently small $\varepsilon > 0$, define a variation $\sigma : [0,T] \times (-\varepsilon,\varepsilon) \longrightarrow M$ by $\sigma(t,s) := \exp_x(t(v+sw))$. Then we have on one hand

$$\mathcal{E}\big(\sigma(\cdot,s)\big) = \frac{T}{2} F^2(v+sw),$$

which takes its minimum at $s = 0$ since w is tangent to $U_x M$. On the other hand, observe from the calculation in (3.12) and the geodesic equation (3.15) that

$$\frac{d}{ds}\Big[\mathcal{E}\big(\sigma(\cdot, s)\big)\Big]_{s=0} = \sum_{i,j=1}^{n} g_{ij}\big(\dot\eta(T)\big)\partial_s \sigma^i(T,0) \cdot \dot\eta^j(T)$$
$$= g_{\dot\eta(T)}\big(d(\exp_x)_{Tv}(Tw), \dot\eta(T)\big).$$

This shows the claim at $t = T$, and completes the proof. □

Note that $w \in T_v(T_x M)$ being tangent to $U_x M$ is equivalent to $g_v(v, w) = 0$.

Exercise 3.19 Let $\varepsilon > 0$ and $U \subset M$ be given as in Proposition 3.17(ii), $y, z \in U$, and $\eta : [0, 1] \longrightarrow M$ be the unique solution to the geodesic equation satisfying $\eta(0) = y$, $\eta(1) = z$ and $L(\eta) < \varepsilon$. Then, for any C^1-curve $\xi : [0, 1] \longrightarrow M$ from y to z, show that we have $L(\eta) \le L(\xi)$ and equality holds only if ξ is a reparametrization of η.

We may consider the spherical coordinates about y and make use of Lemma 3.18 (see [66, Sect. I.6] for the Riemannian case). By a similar argument to the characterization of equality in the above exercise, one can also find that a geodesic in the sense of Definition 2.17 is necessarily a solution to the geodesic equation.

3.5 Completenesses and the Hopf–Rinow Theorem

Here we introduce completeness conditions and prove the Hopf–Rinow theorem.

Definition 3.20 (Completenesses) We say that (M, F) is *forward complete* if $\mathcal{D} = TM$, i.e., if the exponential map is defined on the whole tangent bundle TM. If the reverse Finsler structure $(M, \overleftarrow{F})$ (recall Definition 2.19) is forward complete, then (M, F) is said to be *backward complete*.

We remark that the forward completeness is not necessarily equivalent to the backward completeness, when the *reversibility constant*

$$\Lambda_F := \sup_{v \in TM \setminus \mathbf{0}} \frac{F(-v)}{F(v)} \in [1, \infty] \tag{3.17}$$

is infinite. For instance, the Funk metric appearing in Sect. 6.5 is forward complete but not backward complete (see Exercise 6.22).

In order to state the Finsler analogue of the *Hopf–Rinow theorem*, we define two notions for asymmetric metric spaces. We say that a set $A \subset M$ is *forward bounded* if $A \subset B^+_M(x, r)$ for some $x \in M$ and $r > 0$. A sequence $(x_i)_{i \in \mathbb{N}}$ in M is called a *forward Cauchy sequence* if, for any $\varepsilon > 0$, there exists $N \in \mathbb{N}$ such

(/

Chapter 8
Some Comparison Theorems

Comparison theorems are the main subjects of this book. They are concerned with quantitative or qualitative properties of a space with a certain condition on its curvature. In this book, we will consider Finsler manifolds whose flag or (weighted) Ricci curvature is bounded from below or above by a constant. This chapter is devoted to some fundamental examples of geometric comparison theorems. The first two of them (the *Bonnet–Myers* and *Cartan–Hadamard theorems*) are verbatim analogues of the Riemannian counterparts. Then we study the convexity and concavity of the distance function using some non-Riemannian quantities besides the flag curvature. We refer to [66] for the Riemannian case.

8.1 The Bonnet–Myers Theorem

The Riemannian characterization of the Finsler curvature as in Theorem 5.12 has some straightforward applications in comparison geometry. We discuss two such applications in this and the next sections. Although they can be essentially reduced to the Riemannian case, we give detailed proofs for the sake of self-containedness.

We will say that $\mathrm{Ric} \ge K$ holds for some constant $K \in \mathbb{R}$ if $\mathrm{Ric}(v) \ge KF^2(v)$ holds for all $v \in TM$ (or, equivalently, $\mathrm{Ric}(v) \ge K$ for all unit vectors $v \in UM$). The *diameter* of M is defined by

$$\mathrm{diam}(M) := \sup\{d(x, y) \mid x, y \in M\}.$$

Theorem 8.1 (Bonnet–Myers Theorem (Unweighted)) *Assume that* (M, F) *is forward or backward complete and satisfies* $\mathrm{Ric} \ge K$ *for some* $K > 0$*. Then we have*

https://doi.org/10.1007/978-3-030-80650-7_8

$$\mathrm{diam}(M) \le \pi\sqrt{\frac{n-1}{K}}.$$

In particular, M is compact and has finite fundamental group.

Proof We shall prove by contradiction. Assume that there are $x, y \in M$ with $l := d(x, y) > \pi\sqrt{(n-1)/K}$. By the Hopf–Rinow theorem (Theorem 3.21), there exists a unit vector $v \in U_x M$ such that $\eta(t) := \exp_x(tv)$ is a minimal geodesic from x to $y = \eta(l)$. We follow the same lines as the Riemannian case to see that there necessarily exists a conjugate point $\eta(t_0)$ of $\eta(0)$ for some $t_0 \in (0, \pi\sqrt{(n-1)/K}]$.

Choose an orthonormal basis $\{e_i\}_{i=1}^{n-1} \cup \{v\}$ of $(T_x M, g_v)$, and consider the vector fields $E_i(t) := d(\exp_x)_{tv}(te_i) \in T_{\eta(t)}M$ along η for $i = 1, 2, \dots, n-1$. Note that E_i is the variational vector field of the geodesic variation

$$\sigma_i(t, s) := \exp_x\bigl(t(v + se_i)\bigr), \qquad (t, s) \in [0, l) \times (-\varepsilon, \varepsilon).$$

Hence E_i is a Jacobi field (for both F and $g_{\dot\eta}$; recall Proposition 4.6), and we deduce from Gauss' lemma (Lemma 3.18) that $g_{\dot\eta}(\dot\eta, E_i) = 0$ for all i. Then, since $l \le \rho(v)$, we find that $\{E_i(t)\}_{i=1}^{n-1}$ is a basis of the orthogonal complement of $\dot\eta(t)$ in $(T_{\eta(t)}M, g_{\dot\eta})$ for every $t \in (0, l)$ (similarly to the proof of Lemma 7.13).

For brevity, we will denote by E_i' the covariant derivative $D_{\dot\eta}^{\dot\eta} E_i$ along η. Observe from $g_{\dot\eta}(\dot\eta, E_i) = 0$ and Lemma 4.9 that $g_{\dot\eta}(\dot\eta, E_i') = 0$. We define $(n-1)\times(n-1)$-matrices $A(t) = (a_{ij}(t))$ and $B(t) = (b_{ij}(t))$ for $t \in (0, l)$ by

$$a_{ij}(t) = g_{\dot\eta}\bigl(E_i(t), E_j(t)\bigr), \qquad E_i'(t) = \sum_{j=1}^{n-1} b_{ij}(t) E_j(t).$$

We summarize some fundamental properties of A and B in the next claim.

Claim 8.2

(i) We have $BA = AB^{\mathsf{T}}$ and $A' = 2BA$, where B^{T} denotes the transpose matrix of B.

(ii) The matrix $A^{-1/2}BA^{1/2}$ is symmetric. Here we set

$$A^{1/2} := P^{-1}\begin{pmatrix} \sqrt{a_1} & & 0 \\ & \ddots & \\ 0 & & \sqrt{a_{n-1}} \end{pmatrix} P$$

and $A^{-1/2} := (A^{1/2})^{-1}$, where $a_1, \dots, a_{n-1} > 0$ are the eigenvalues of A and P is an orthogonal matrix which diagonalizes A as

$$A = P^{-1} \begin{pmatrix} a_1 & & 0 \\ & \ddots & \\ 0 & & a_{n-1} \end{pmatrix} P.$$

(iii) We have the *Riccati equation*

$$B' + B^2 + RA^{-1} = 0, \tag{8.1}$$

where the matrix $R(t) = (R_{ij}(t))$ is defined by $R_{ij}(t) := g_{\dot\eta}(R_{\dot\eta}(E_i), E_j)(t) = g_{\dot\eta}(E_i, R_{\dot\eta}(E_j))(t)$.

Proof (i) Observe from Lemma 4.9 that $A' = BA + AB^{\mathsf{T}}$. Moreover, it follows from the Jacobi equation (5.3) and Lemma 5.8 that

$$\begin{aligned} \frac{d}{dt}\Big[g_{\dot\eta}(E_i', E_j) - g_{\dot\eta}(E_i, E_j')\Big] &= g_{\dot\eta}(E_i'', E_j) - g_{\dot\eta}(E_i, E_j'') \\ &= -g_{\dot\eta}\big(R_{\dot\eta}(E_i), E_j\big) + g_{\dot\eta}\big(E_i, R_{\dot\eta}(E_j)\big) = 0. \end{aligned}$$

Combining this with $E_i(0) = E_j(0) = 0$, we find that $g_{\dot\eta}(E_i', E_j) = g_{\dot\eta}(E_i, E_j')$ (similarly to the proof of Lemma 7.13), which yields $BA = AB^{\mathsf{T}}$. Thus we have $A' = 2BA$.

(ii) It follows from $BA = AB^{\mathsf{T}}$ that BA is symmetric. Since A is symmetric, we find that $A^{-1/2}(BA)A^{-1/2} = A^{-1/2}BA^{1/2}$ is also symmetric.

(iii) On one hand, we deduce from

$$a_{ij}''(t) = -g_{\dot\eta}\big(R_{\dot\eta}(E_i), E_j\big) - g_{\dot\eta}\big(E_i, R_{\dot\eta}(E_j)\big) + 2g_{\dot\eta}(E_i', E_j'),$$

Lemma 5.8 and (i) that

$$A'' = -2R + 2BAB^{\mathsf{T}} = -2R + 2B^2A.$$

On the other hand, it follows from (i) that

$$A'' = 2B'A + 2BA' = 2B'A + 4B^2A.$$

Comparing these expressions of A'', we obtain the claim. □

Now, we consider the function $h(t) := (\det[A(t)])^{1/(2(n-1))}$ (which can be regarded as the *area form* of the sphere $\partial B^+(x,t)$ at $\eta(t)$ with respect to $g_{\dot\eta}$). Observe from $A' = 2BA$ that

$$(n-1)h' = \frac{h}{2}(\det A)^{-1}(\det A)' = \frac{h}{2}\operatorname{trace}(A'A^{-1}) = h\operatorname{trace}(B).$$

Moreover, by (8.1), we have

$$(n-1)h'' = h' \operatorname{trace}(B) + h \operatorname{trace}(B')$$
$$= \frac{h}{n-1} \operatorname{trace}(B)^2 - h \operatorname{trace}(B^2) - h \operatorname{trace}(RA^{-1}).$$

Since $A^{-1/2}BA^{1/2}$ is symmetric, we deduce from the Cauchy–Schwarz inequality that

$$\operatorname{trace}(B)^2 = \operatorname{trace}(A^{-1/2}BA^{1/2})^2 \le (n-1)\operatorname{trace}(A^{-1/2}B^2A^{1/2})$$
$$= (n-1)\operatorname{trace}(B^2).$$

Furthermore, it follows from the definitions of A and R that

$$\operatorname{trace}(RA^{-1}) = \operatorname{trace}(A^{-1/2}RA^{-1/2}) = \operatorname{Ric}(\dot\eta).$$

Thus we obtain a Finsler analogue of the *Bishop inequality* asserting

$$h''(t) \le -\frac{\operatorname{Ric}(\dot\eta(t))}{n-1}h(t). \tag{8.2}$$

If $\operatorname{Ric} \ge K > 0$, then (8.2) yields

$$h''(t) \le -\frac{K}{n-1}h(t) \tag{8.3}$$

for $t \in (0, l)$. We compare this differential inequality with

$$\mathbf{s}''(t) = -\frac{K}{n-1}\mathbf{s}(t), \qquad \text{where} \quad \mathbf{s}(t) := \sin\left(\sqrt{\frac{K}{n-1}}t\right).$$

Put $f := h/\mathbf{s}$ on $(0, \pi\sqrt{(n-1)/K})$. Observe that $f' = (h'\mathbf{s} - h\mathbf{s}')/\mathbf{s}^2$ and

$$(h'\mathbf{s} - h\mathbf{s}')' = h''\mathbf{s} - h\mathbf{s}'' \le 0$$

by (8.3). Moreover, we have $h(t) = O(t)$ as $t \to 0$ and $\lim_{t\to 0} h'(t) = h'(0) = 1$ (we leave $h'(0) = 1$ as an exercise below). Combining these, we find that f is non-increasing. Hence $h(t) \le (h(\varepsilon)/\mathbf{s}(\varepsilon)) \cdot \mathbf{s}(t)$ holds for $t > \varepsilon > 0$. However, since $\mathbf{s}(\pi\sqrt{(n-1)/K}) = 0$, this implies that $h(t_0) = 0$ necessarily holds at some $t_0 \in (0, \pi\sqrt{(n-1)/K}]$. Then $\eta(t_0)$ is a conjugate point of $\eta(0)$, and η is no longer minimizing beyond t_0 (recall Proposition 7.16). This contradicts the choice of v, therefore we conclude that $\operatorname{diam}(M) \le \pi\sqrt{(n-1)/K}$.

The compactness of M follows from the Hopf–Rinow theorem (Theorem 3.21). To show the assertion on the fundamental group, let us consider the universal cover $\widetilde{M}$ of M equipped with the induced Finsler structure $\widetilde{F}$. Then $\widetilde{F}$ again satisfies $\operatorname{Ric} \ge K$, and $(\widetilde{M}, \widetilde{F})$ is forward (and backward) complete since geodesics in M

can be lifted to $\widetilde{M}$. Therefore, $\widetilde{M}$ is also compact, and hence the fundamental group of M is finite. □

Exercise 8.3 Show that $h'(0) = 1$ holds in the above proof.

The Bonnet–Myers theorem for the weighted Ricci curvature will be discussed in Sect. 9.4. This is the reason why we called Theorem 8.1 the *unweighted* one.

Remark 8.4 (Bishop Inequality) What is commonly called the Bishop inequality (or *Bishop's comparison theorem*) in Riemannian geometry is an upper bound of the volume of a ball by that in a model space of constant curvature (see [36, Sect. 11.10] and, e.g., [66, Theorem III.4.4]). A generalization to a Berwald space equipped with the Busemann–Hausdorff measure will be given in Corollary 10.3. Since the inequality (8.2) is an essential step from which the volume comparison can be deduced rather straightforwardly, we call the inequality (8.2) (and its generalizations) a Bishop inequality.

Remark 8.5 (Reversing Stability) In the proof of Theorem 8.1, we used the Hopf–Rinow theorem for finding a minimal geodesic from x to y and for showing that the finiteness of the diameter implies the compactness. For these assertions, it is sufficient to assume either the forward completeness or the backward completeness. Moreover, if we consider the reverse Finsler structure $\overleftarrow{F}$, then we have $\overleftarrow{\mathrm{Ric}}(v) = \mathrm{Ric}(-v)$ (see Sect. 2.5) and hence the curvature bound $\mathrm{Ric}(v) \ge KF^2(v)$ is equivalent to $\overleftarrow{\mathrm{Ric}}(v) \ge K\overleftarrow{F}^2(v)$. Therefore, Theorem 8.1 is stable when we take the reverse structure.

Finally we explain how to reduce Theorem 8.1 to the Riemannian case. Thanks to Remark 8.5 above, we may assume the forward completeness. Fix arbitrary $x \in M$ and define a vector field V on $M \setminus (\{x\} \cup \mathrm{Cut}(x))$ by $V(\eta_v(t)) := \dot{\eta}_v(t)$ for $t \in (0, \rho(v))$, along each unit speed geodesic $\eta_v : [0, \rho(v)) \longrightarrow M$ with $\dot{\eta}_v(0) = v \in U_xM$. This vector field V is indeed well-defined, and all of its integral curves are geodesic. Therefore, g_V enjoys $\mathrm{Ric}^{g_V}(V) \ge K$ by Theorem 5.12, and the Riemannian Bonnet–Myers theorem asserts that $\rho(v) \le \pi\sqrt{(n-1)/K}$ for all $v \in U_xM$. Hence we obtain $\mathrm{diam}(M) \le \pi\sqrt{(n-1)/K}$.

8.2 The Cartan–Hadamard Theorem

By analyzing Jacobi fields again, we can show another fundamental comparison theorem, under the nonpositive flag curvature this time.

Theorem 8.6 (Cartan–Hadamard Theorem) *Assume that (M, F) is forward complete and satisfies $\mathbf{K} \le 0$. Then we have the following:*

(i) *Any geodesic does not have conjugate points.*
(ii) *For any $x \in M$, the exponential map $\exp_x : T_xM \longrightarrow M$ is a C^1-covering.*

Chapter 10
Examples of Measured Finsler Manifolds

In this chapter, we analyze the weighted Ricci curvature for some examples appearing in Chap. 6. We remark that a suitable choice of a measure is unclear in some cases. In fact, the theory of weighted Ricci curvature has so far been focused on general theory and there are not many investigations on concrete examples.

One of the most important observations in this chapter is the absence of "canonical measures" in some Randers spaces. Precisely, we will see that some Randers spaces do not admit any measure whose **S**-curvature vanishes identically (see Remark 10.11).

10.1 Minkowski Normed Spaces

Let $(\mathbb{R}^n, \|\cdot\|)$ be a Minkowski normed space (recall Example 2.12(a), Sect. 6.1) and consider a measure $\mathfrak{m} = \mathrm{e}^{-\psi}\,\mathfrak{L}_n$ with $\psi \in C^\infty(\mathbb{R}^n)$. Then the weighted Ricci curvature of $(\mathbb{R}^n, \|\cdot\|, \mathfrak{m})$ is given by

$$\mathrm{Ric}_N(v) = (\psi \circ \eta_v)''(0) - \frac{(\psi \circ \eta_v)'(0)^2}{N-n}$$

for $v \in T_x\mathbb{R}^n$, where $\eta_v(t) := x + tv$ for $t \in \mathbb{R}$ (by identifying $T_x\mathbb{R}^n$ and $\mathbb{R}^n$). We also find that $\mathbf{S}(v) = (\psi \circ \eta_v)'(0) = d\psi(v)$ (recall Remark 9.14), and hence the **S**-curvature is identically 0 if and only if ψ is a constant function (see Exercise 10.7 below for a related fact on general measured Finsler manifolds).

Exercise 10.1 Prove the above expression of the weighted Ricci curvature $\mathrm{Ric}_N(v)$.

In the case of $N = \infty$, the weighted Ricci curvature Ric_∞ is directly related to the convexity (or concavity) of ψ. If ψ is K-convex in the sense that $(\psi \circ \eta_v)''(0) \geq K\|v\|^2$ for all $v \in T\mathbb{R}^n$, then we have $\mathrm{Ric}_\infty \geq K$. When $K = 0$ (i.e., ψ

S.-i. Ohta, *Comparison Finsler Geometry*, Springer Monographs in Mathematics,
https://doi.org/10.1007/978-3-030-80650-7_10

is convex), we encounter a log-concave measure as in Remark 9.9(c). Another important example is a Gaussian-type measure

$$\mathfrak{m}(dx) = \mathrm{e}^{-K\|x\|^2/2}\, \mathfrak{L}_n(dx)$$

with $K > 0$, which satisfies $\mathrm{Ric}_\infty \ge K\mathsf{C}^{-1}$ for the uniform convexity constant C of $(\mathbb{R}^n, \|\cdot\|)$ as in (1.2). Here, precisely, $\mathrm{Ric}_\infty \ge K\mathsf{C}^{-1}$ is understood in the weak sense (around the origin) since the weight function $\psi(x) = K\|x\|^2/2$ is only C^1 at the origin (recall Subsect. 1.2.2).

10.2 Berwald Spaces

We next consider Berwald spaces (recall Sect. 6.3). In this case, the Busemann–Hausdorff measure can be regarded as a canonical measure since its **S**-curvature vanishes identically. Recall Definition 9.1 for the definition of the Busemann–Hausdorff measure.

Proposition 10.2 (S-Curvature Vanishes for $\mathfrak{m}_{\mathrm{BH}}$) *Let $(M, F, \mathfrak{m}_{\mathrm{BH}})$ be a Berwald space equipped with the Busemann–Hausdorff measure. Then the corresponding* **S***-curvature is identically* 0.

Proof Given $v \in U_xM$, let $\eta : (-\varepsilon, \varepsilon) \longrightarrow M$ be the geodesic with $\dot\eta(0) = v$. Fix an orthonormal basis $\{e_i\}_{i=1}^{n-1} \cup \{v\} \subset T_xM$ with respect to g_v, and let P_i be the parallel vector field along η with $P_i(0) = e_i$ for $i = 1, 2, \dots, n-1$. (Recall that the covariant derivative is independent of the choice of a reference vector in Berwald spaces.) We consider a local coordinate system around x given by

$$\exp_{\eta(t)}\left(\sum_{i=1}^{n-1} a_i P_i(t)\right) \longmapsto (a_1, a_2, \dots, a_{n-1}, t) \in \mathbb{R}^n.$$

We remark that the exponential map $\exp_{\eta(t)}$ is C^∞ on a neighborhood of 0 by Proposition 6.11. We shall compare $\mathrm{vol}_{g_{\dot\eta}}$ and $\mathfrak{m}_{\mathrm{BH}}$ along η by using this coordinate system.

On one hand, observe that

$$g_{ij}\big(\dot\eta(t)\big) = g_{\dot\eta}\left(\frac{\partial}{\partial x^i}\bigg|_{\eta(t)}, \frac{\partial}{\partial x^j}\bigg|_{\eta(t)}\right) = g_{\dot\eta}\big(P_i(t), P_j(t)\big),$$

where we set $P_n(t) := \dot\eta(t)$. Since P_i is a parallel vector field for all $1 \le i \le n$, we have $g_{ij}(\dot\eta(t)) = \delta_{ij}$ for all t. Therefore we obtain $\mathrm{vol}_{\dot\eta}(dx) = dx^1 dx^2 \cdots dx^n$ along η. On the other hand, since the parallel transport along η preserves F (by Proposition 6.5; here we essentially need the Berwald condition), we find that

$$= \int_{\Omega} d\phi(\nabla u)\, d\mathfrak{m}. \tag{11.12}$$

If u is a minimizer of $\mathcal{E}_{\Omega}$ in the sense above, then it follows from (11.12) that $\int_{\Omega} d\phi(\nabla u)\, d\mathfrak{m} = 0$ necessarily holds for all $\phi \in H_0^1(\Omega)$. Hence, u is harmonic.

Conversely, let u be harmonic and suppose that there is some $\phi \in H_0^1(\Omega)$ such that $\mathcal{E}_{\Omega}(u+\phi) < \mathcal{E}_{\Omega}(u)$. Then the convexity of $\mathcal{E}_{\Omega}$ as in (11.3) implies

$$\mathcal{E}_{\Omega}(u+t\phi) \le (1-t)\mathcal{E}_{\Omega}(u) + t\mathcal{E}_{\Omega}(u+\phi)$$

for any $t \in (0,1)$, and hence

$$\frac{d}{dt}\big[\mathcal{E}_{\Omega}(u+t\phi)\big]_{t=0} \le \mathcal{E}_{\Omega}(u+\phi) - \mathcal{E}_{\Omega}(u) < 0.$$

This contradicts the harmonicity of u due to (11.12). Therefore u is a minimizer of $\mathcal{E}_{\Omega}$ as desired. □

11.3 Laplacian Comparison Theorem

In this section, we show the *Laplacian comparison theorem* as an analytic counterpart to the (directional) area comparison (9.8) (see Remark 11.21 below). This was shown in [206, Theorem 5.2] via a reduction to the Riemannian case, and here we give a direct proof by a calculation similar to Theorem 9.15. We refer to, e.g., [155, Theorem 4.1] for the Riemannian case.

Theorem 11.20 (Laplacian Comparison) *Let $(M, F, \mathfrak{m})$ be forward or backward complete and assume $\mathrm{Ric}_N \ge K$ for some $K \in \mathbb{R}$ and $N \in [n, \infty)$. Then, for any $z \in M$, the distance function $u(x) := d(z,x)$ from z satisfies*

$$\boldsymbol{\Delta} u(x) \le (N-1)\frac{\mathbf{s}'_{K/(N-1)}(d(z,x))}{\mathbf{s}_{K/(N-1)}(d(z,x))} \tag{11.13}$$

pointwise on $M \setminus (\{z\} \cup \mathrm{Cut}(z))$, and in the weak sense on M.

Recall (9.4) for the definition of $\mathbf{s}_{K/(N-1)}$, and Definition 7.10 for the definition of the cut locus $\mathrm{Cut}(z)$. For example, when $K = 0$, the inequality (11.13) means

$$\boldsymbol{\Delta} u(x) \le \frac{N-1}{d(z,x)}.$$

We remark that, in the case of $K > 0$, $\mathrm{diam}(M) \le \pi\sqrt{(N-1)/K}$ holds by the Bonnet–Myers theorem (Corollary 9.17), and hence $d(z,x) = \pi\sqrt{(N-1)/K}$ can be achieved only when x is a cut point of z.

Proof As in the proof of Theorem 9.15, we fix a unit vector $v \in U_zM$ and put $\eta(t) := \exp_z(tv)$. We also take an orthonormal basis $\{e_i\}_{i=1}^{n-1} \cup \{v\}$ of (T_zM, g_v) and define $E_i(t) := d(\exp_z)_{tv}(te_i)$ for $t \in [0, \rho(v))$ and $i = 1, 2, \ldots, n-1$.

Now, let us consider polar coordinates $(x^i)_{i=1}^n$ on a neighborhood of $\eta((0, \rho(v)))$ such that $x^n = u$ and $(\partial/\partial x^i)|_{\eta(t)} = E_i(t)$ for $t \in (0, \rho(v))$ (one may recall Gauss' lemma (Lemma 3.18)). Then we have $\boldsymbol{\nabla} u = \partial/\partial x^n$ and, by (11.9),

$$\boldsymbol{\Delta} u\big(\eta(t)\big) = -\psi_\eta'(t) + \frac{d}{dt}\left[\log\left(\sqrt{\det\big[g_{ij}\big(\dot{\eta}(t)\big)\big]}\right)\right].$$

Notice that

$$g_{ij}\big(\dot{\eta}(t)\big) = g_{\dot{\eta}(t)}\left(\frac{\partial}{\partial x^i}, \frac{\partial}{\partial x^j}\right) = g_{\dot{\eta}(t)}\big(E_i(t), E_j(t)\big),$$

and consider the function $h := (\det[g_{ij}(\dot{\eta})])^{1/(2(n-1))}$ as in the proofs of Theorems 8.1 and 9.15. Then we find

$$\boldsymbol{\Delta} u\big(\eta(t)\big) = -\psi_\eta'(t) + \frac{(h^{n-1})'}{h^{n-1}}(t) = \frac{(\mathrm{e}^{-\psi_\eta} h^{n-1})'}{\mathrm{e}^{-\psi_\eta} h^{n-1}}(t) = \frac{f'}{f}(t), \tag{11.14}$$

where $f(t) := \mathrm{e}^{-\psi_\eta(t)} h(t)^{n-1}$. In the proof of Theorem 9.15, we showed

$$\left(\frac{f(t)}{\mathbf{s}_{K/(N-1)}(t)^{N-1}}\right)' \le 0$$

as a consequence of the weighted Bishop inequality (9.6) under $\mathrm{Ric}_N \ge K$. This is equivalent to

$$\frac{f'}{f}(t) \le (N-1)\frac{\mathbf{s}_{K/(N-1)}'}{\mathbf{s}_{K/(N-1)}}(t), \tag{11.15}$$

which yields the claim on $M \setminus (\{z\} \cup \mathrm{Cut}(z))$.

In order to extend (11.13) to M in the weak sense, let $\phi \in C_c^\infty(M)$ be an arbitrary nonnegative function with compact support. Then the claim is

$$-\int_M d\phi(\boldsymbol{\nabla} u)\, d\mathfrak{m} \le \int_M \phi(x)\Theta\big(d(z,x)\big)\, \mathfrak{m}(dx),$$

where we denote by $\Theta(d(z,x))$ the right-hand side of (11.13). We remark that $\Theta(d(z,\cdot))$ is integrable around z since $\Theta(t) = O(t^{-1})$ as $t \to 0$ and $n \ge 2$. Given a unit vector $v \in U_zM$, let $f_v : (0, \rho(v)) \longrightarrow (0, \infty)$ be the function f as in the first part of this proof associated with v. Recall that

$$d\mathfrak{m} = f_v(t)\, dt\, \mathbf{A}_z(dv)$$

on $M \setminus (\{z\} \cup \mathrm{Cut}(z)) = \{\exp_z(tv) \mid v \in U_zM,\ t \in (0, \rho(v))\}$, where $\mathbf{A}_z$ is the measure on U_zM induced from g_v as in the proof of Theorem 9.15. Thanks to this decomposition of $\mathfrak{m}$ and $f_v'(t) \le \Theta(t) f_v(t)$ from (11.15), we have

$$\begin{aligned}\int_M \phi(x)\Theta\bigl(d(z,x)\bigr)\,\mathfrak{m}(dx) &= \int_{U_zM}\int_0^{\rho(v)} \phi\bigl(\exp_z(tv)\bigr)\Theta(t) f_v(t)\,dt\,\mathbf{A}_z(dv)\\ &\ge \int_{U_zM}\int_0^{\rho(v)} \phi\bigl(\exp_z(tv)\bigr) f_v'(t)\,dt\,\mathbf{A}_z(dv).\end{aligned}$$

Moreover, for each $v \in U_zM$,

$$\begin{aligned}&\int_0^{\rho(v)} \phi\bigl(\exp_z(tv)\bigr) f_v'(t)\,dt\\ &= \Bigl[\phi\bigl(\exp_z(tv)\bigr) f_v(t)\Bigr]_0^{\rho(v)} - \int_0^{\rho(v)} \frac{\partial[\phi(\exp_z(tv))]}{\partial t} f_v(t)\,dt\\ &\ge -\int_0^{\rho(v)} d\phi\Bigl(\nabla u\bigl(\exp_z(tv)\bigr)\Bigr) f_v(t)\,dt\end{aligned}$$

since $\phi \ge 0$ and $f_v(0) = 0$. Therefore we obtain

$$\begin{aligned}\int_M \phi(x)\Theta\bigl(d(z,x)\bigr)\,\mathfrak{m}(dx) &\ge -\int_{U_zM}\int_0^{\rho(v)} d\phi\Bigl(\nabla u\bigl(\exp_z(tv)\bigr)\Bigr) f_v(t)\,dt\,\mathbf{A}_z(dv)\\ &= -\int_M d\phi(\nabla u)\,d\mathfrak{m},\end{aligned}$$

which completes the proof. □

Remark 11.21 (Laplacian and Area Comparisons) As seen in the above proof, the Laplacian comparison is equivalent to the inequality (11.15), which is essentially the integration of the Bishop inequality (9.6). More precisely, (11.15) can be regarded as a directional and infinitesimal version of the area comparison (9.8). This observation, in particular, shows that the Laplacian comparison is closely related to the measure contraction property (see Remark 9.16 and Subsect. 18.5.3).

For the distance function $\bar{u}(x) := d(x,z)$ to z, we have

$$\overleftarrow{\mathbf{\Delta}}\bar{u}(x) = -\mathbf{\Delta}(-\bar{u})(x) \le (N-1)\frac{\mathbf{s}_{K/(N-1)}'(d(x,z))}{\mathbf{s}_{K/(N-1)}(d(x,z))}$$

by Theorem 11.20 for the reverse Finsler structure $\overleftarrow{F}$, since the Ricci curvature bound $\mathrm{Ric}_N \ge K$ is common between $(M, F, \mathfrak{m})$ and $(M, \overleftarrow{F}, \mathfrak{m})$ (recall Sect. 2.5).

(9 $

Clearly we have $\mathcal{I}_{(M,F,\mathfrak{m})}(0) = \mathcal{I}_{(M,F,\mathfrak{m})}(1) = 0$. An *isoperimetric inequality* means a lower bound of $\mathcal{I}_{(M,F,\mathfrak{m})}(\theta)$, i.e., a lower bound of the measure (area) of the boundary of any set of prescribed volume. The main result of this chapter is the following (established in [204]).

Theorem 15.1 (Bakry–Ledoux Isoperimetric Inequality) *Assume that $(M, F, \mathfrak{m})$ is compact and satisfies $\mathfrak{m}(M) = 1$ and $\mathrm{Ric}_\infty \geq K$ for some $K > 0$. Then we have*

$$\mathcal{I}_{(M,F,\mathfrak{m})}(\theta) \geq \mathcal{I}_K(\theta) \tag{15.3}$$

for all $\theta \in (0, 1)$, where

$$\mathcal{I}_K(\theta) := \sqrt{\frac{K}{2\pi}}\mathrm{e}^{-Kc^2(\theta)/2} \quad \textit{with } \theta = \int_{-\infty}^{c(\theta)} \sqrt{\frac{K}{2\pi}}\mathrm{e}^{-Ka^2/2}\,da.$$

In the weighted Riemannian case, Theorem 15.1 (under completeness instead of compactness) is due to Bakry and Ledoux [23]. The inequality (15.3) can be regarded as a dimension-free version of *Lévy–Gromov's isoperimetric inequality*. Lévy–Gromov's classical isoperimetric inequality states that the isoperimetric profile of an n-dimensional (unweighted) Riemannian manifold (M, g) with $\mathrm{Ric}_g \geq n-1$ is bounded from below by the profile of the unit sphere $\mathbb{S}^n$ (both spaces are equipped with the normalized volume measures; see [112, 152, 153]). In $\mathbb{S}^n$, isoperimetric minimizers (i.e., sets attaining the infimum in (15.2)) are given by balls.

In (15.3), the role of the unit sphere is played by the real line $\mathbb{R}$ equipped with the Euclidean distance and the Gaussian measure $\mathfrak{m}_K(dx) := \sqrt{K/(2\pi)}\,\mathrm{e}^{-Kx^2/2}\,dx$, thus (15.3) is also called the *Gaussian isoperimetric inequality*. Recall that $(\mathbb{R}, |\cdot|, \mathfrak{m}_K)$ satisfies $\mathrm{Ric}_\infty = K$. Isoperimetric minimizers in $(\mathbb{R}, |\cdot|, \mathfrak{m}_K)$ are the half-lines $(-\infty, c(\theta)]$ and $[-c(\theta), \infty)$, thus $\mathcal{I}_K$ is indeed the isoperimetric profile of $(\mathbb{R}, |\cdot|, \mathfrak{m}_K)$. Higher dimensional Gaussian spaces $(\mathbb{R}^n, |\cdot|, (K/(2\pi))^{n/2}\,\mathrm{e}^{-K|x|^2/2}\,dx)$ have the same isoperimetric profile $\mathcal{I}_K$, and then isoperimetric minimizers are again half-spaces of the form $\{x \in \mathbb{R}^n \mid \langle x, w\rangle \leq c(\theta)\}$ with $w \in \mathbb{S}^{n-1}$. We refer to [40, 236] for the Gaussian isoperimetric inequality in the classical Euclidean or Hilbert setting, and to [13] for the case of metric measure spaces satisfying the Riemannian curvature-dimension condition $\mathrm{RCD}(K, \infty)$ (by means of the Γ-calculus).

Exercise 15.2 Prove that, in $(\mathbb{R}, |\cdot|, \mathfrak{m}_K)$, the half-lines $(-\infty, c(\theta)]$ and $[-c(\theta), \infty)$ are isoperimetric minimizers.

We will prove Theorem 15.1 by generalizing the argument in [23]. This approach based on the Γ-calculus is known to give a sharp estimate only in the case of $\mathrm{Ric}_\infty \geq K$. As for general Ric_N, we will discuss Lévy–Gromov-type isoperimetric inequalities in Sect. 19.4 as an application of another powerful technique called the *needle decomposition* (or the *localization*). This more geometric method is also available for singular spaces, precisely, for essentially non-branching metric measure spaces satisfying the curvature-dimension condition (see [59]). This wide class of spaces includes, in particular, reversible Finsler manifolds of weighted Ricci curvature bounded below. However, in the non-reversible case, the needle decomposition gives only weaker estimates, e.g.,

$$\mathcal{I}_{(M,F,\mathfrak{m})}(\theta) \ge \Lambda_F^{-1} \cdot \mathcal{I}_K(\theta)$$

instead of (15.3), where $\Lambda_F \ge 1$ is the reversibility constant as in (3.17). See Chap. 19 (and [203]) for more details.

15.2 Poincaré–Lichnerowicz Inequality and Variance Decay

Throughout this and the next chapters, the behavior of heat semigroups as $t \to \infty$ will play an essential role. In this section, as an auxiliary step towards the Bakry–Ledoux isoperimetric inequality, we consider the outcome of the *ergodicity*

$$u_t \to \int_M u_0 \, d\mathfrak{m} \quad \text{in } L^2(M) \tag{15.4}$$

for all global solutions $(u_t)_{t\ge 0}$ to the heat equation (Proposition 13.16(iii)). Another ingredient is the *mass conservation*

$$\int_M P_{s,t}^{\nabla u}(f)\, d\mathfrak{m} = \int_M f \, d\mathfrak{m} \tag{15.5}$$

for any global solution $(u_t)_{t\ge 0}$ to the heat equation, $f \in L^2(M)$ and for any $0 \le s < t < \infty$ (this is a consequence of Lemma 11.5, (13.19) and Proposition 13.20(iii)).

We shall show a Poincaré-type inequality as a crucial step. Since the proof is common, here we consider the more general setting of $\mathrm{Ric}_N \ge K > 0$ with $N \in (-\infty, 0) \cup [n, \infty]$, yielding a Finsler analogue to the *Lichnerowicz inequality* (compare Theorem 15.4 below with Exercise 12.14). We begin with a simple application of the Bochner inequality.

Lemma 15.3 *Assume that* $(M, F, \mathfrak{m})$ *is compact and satisfies* $\mathrm{Ric}_N \ge K$ *for some* $K \in \mathbb{R}$ *and* $N \in (-\infty, 0) \cup [n, \infty]$. *Then we have, for any* $u \in H^2(M) \cap C^1(M)$ *such that* $\boldsymbol{\Delta} u \in H^1(M)$,

$$\int_M \left\{ d(\boldsymbol{\Delta} u)(\nabla u) + K F^2(\nabla u) + \frac{(\boldsymbol{\Delta} u)^2}{N} \right\} d\mathfrak{m} \le 0.$$

In particular, if $K > 0$, *then it holds that*

First, we use the normalized Gauss weighted Euclidean distance as the weight for the interpolation:

$$W = N(\exp(-d^2/2\sigma^2))$$

where d is the Euclidean distance from the point in the region to the regional center, and N(.) is the normalization operator.

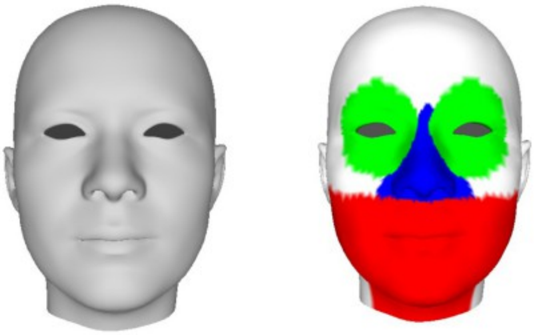

Fig. 1. Visualization of average face and AU-related mask

3D Face Data. In our work, we use the FaceWarehouse dataset [4], which contains 150 individuals aged 7–80. For each person, the dataset includes its neutral expression and 19 other expressional 3D mesh models, all of which have been densely corresponded to meet the conditions for constructing a 3DMM. Each mesh model includes 11,510 points and 11,400 faces. As for the AU labels, we use an open-source AU detection tool, OpenFace [1], to perform AU detection on the RGB images corresponding to all 3D faces in the data. In order to capture a more physical variance of AUs, we select AUs with a high occurrence rate from the data. In this work, we finally selected 8 primary AUs, namely AU10, AU14, AU17, AU20, AU23, AU25, AU28, AU43.

Parameterization of AUs. First, we get the average face $\bar{S}$ and the PCA bases of the identity attribute from 150 faces. Next, we need to obtain the PCA bases of each AU. Considering that the location of muscle movement represented by AU is relatively fixed, so we utilize a region mask to obtain the deformation of the face shape represented by the area where the AU is located and perform PCA on the deformation matrix of each AU to obtain the PCA basis B_i and eigenvalues σ_i for a single AU. Finally, our 3D face model can be expressed as:

$$\hat{S} = \bar{S} + B_{id} \cdot diag(\sigma_{id}) \cdot \alpha_{id} + \sum_{i \in U} f \cdot M_i \cdot B_i \cdot diag(\sigma_i) \cdot \alpha_i, \tag{4}$$

where U is a set of AUs, i is the index of AU, f is a parameter that controls the intensity of AU, and M_i is the mask of the i-th AU. We divide the face into several regions according to the AU positions and get the corresponding region mask in this work. As shown in Fig. 1, we show the average face $\bar{S}$ of the model and the mask area on the average face.

Smooth Processing. At this point, we can randomly generate a set of AU parameters to generate the corresponding 3D face according to Eq. 4. However, the face we generated in this way will appear a little unnatural at the mask's boundary, so we added a smoothing operation to make a face more realistic. First, we use the normalized Gaussian weighted Euclidean distance as the weight for the interpolation:

$$W = N(exp(-d^2/2\sigma^2)) \tag{5}$$

where d is the Euclidean distance from the point in the region to the regional center, and $N(\cdot)$ is the normalization operation. Then, a more natural result is obtained by linear interpolation.

$$\hat{P} = W \cdot P + (1 - W) \cdot P', \tag{6}$$

where $\hat{P}$ is the smoothed final position, P is the origin position, P' is the position before smoothing.

4 Experiments

In this section, we evaluate our proposed model from multiple aspects. Our model can edit the state of 8 AUs, namely AU10, AU14, AU17, AU20, AU23, AU25, AU28, AU43. We analyze our proposed model qualitatively and quantitatively and show our experimental results as below.

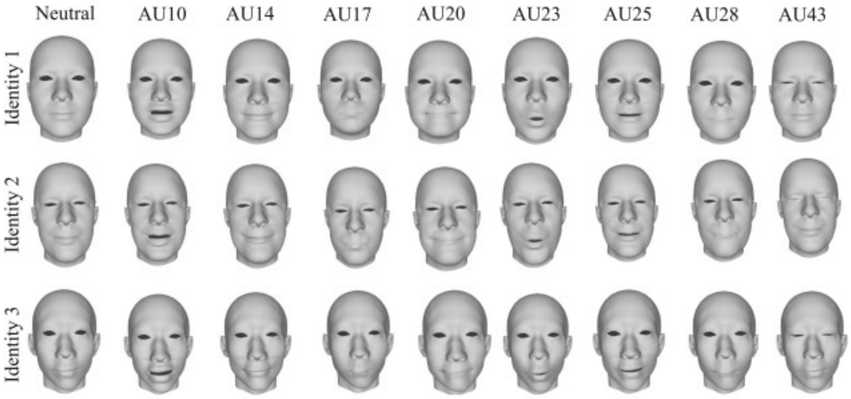

Fig. 2. Synthetic results of different AUs under different identities

Qualitative Results. Our proposed improved 3DMM model can change one of the identity attribute and the AU attribute of the 3D face without changing the other attribute. As shown in Fig. 2, we ensure that one attribute remains unchanged and displays the 3D face after another attribute is changed. Each row represents the result of changing different AU with a fixed identity parameter. In addition, we can observe that the same AU parameters show similar shape deformations on different 3D faces, which also verifies our model's control ability over a single AU.

Abstract. Coordinate prediction is an important signal processing task, which aims to predict 2D or 3D coordinates from a single image or a series of images. Previous techniques utilize Mean Square Error (MSE) loss function to measure the difference between the prediction coordinates and its corresponding ground-truth in training step, which usually assumes that coordinates are independent to each other without considering their correlations, neglecting the geometric context of the object. To address the issue, this paper presents a novel loss function named Geometric Context Sensitive (GCS) loss to model the geometric shape context of general objects by measuring the difference between any pair of prediction coordinates and their corresponding ground-truth coordinates. Our proposed method has several advantages: (1) The proposed GCS loss is trainable and can be optimized by Gauss-Newton in the traditional models. (2) GCS loss can be formulated in both 2D and 3D forms. Thus, the proposed GCS loss is easy to be implemented and can be integrated into current popular 2D/3D coordinates prediction models naturally and effectively, e.g., nonrigid structure from motion. (3) No additional learnable parameters. Though the proposed GCS loss is intuitive in theory, extensive experimental results on several public NRSFM datasets show that GCS loss can significantly boost the performance. We share the implementation code and models of our proposed methods at https://github.com/nianfudong/GCS/tree/master/NRSFM.

problems. On this basis, Broad Learning System (BLS) [22] was proposed as shown in Fig. 2. Later, authors extended BLS to the Fuzzy BLS [23] which can be applied to regression and classification. Firstly, BLS used the characteristics of the input data mapping as the “feature nodes” of the network. Secondly, the features of the mapping are enhanced to “enhanced nodes” that generate weight randomly. Finally, all mapped features and enhancement nodes are directly connected to the output, and the corresponding output coefficients can be derived from the pseudo-reverse of the courier.

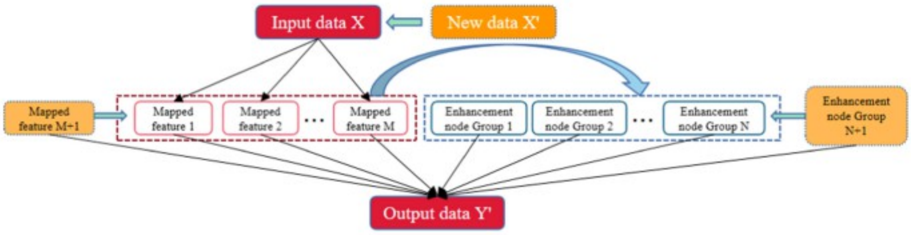

Fig. 2. Broad learning system [23]

The complex structure and numerous hyper parameters lead that DNN has long training time. To obtain higher testing accuracy, we have to increase the number of layers or add the number of parameters. Beyond that, BLS is an alternative method of DL network. The main contributions of this manuscript are as follows:

- A novel NR measure based on a flat neural network;
- A novel NR technique which used statistical distribution of gradient magnitude and the information of luminance;
- An effective fusion of the introduced NR measures;
- Avoiding excessive hyper parameters and deep layers.

3 NR IQA Based BLS

NR IQA is a critical measure in image processing. How to select various features that can describe the image logically is an important factor in IQA. The structure and contour of the image will be changed by extracting gradient features on the other hand the locally normalized luminance coefficients will be used to describe the statistical characteristics of the image.

3.1 Structure Features

Gradients can reflect the structural information of the image, such as Fig. 3. Considering the importance of the Gradient amplitude and LOG response of an image, we combine two common local contrast features and joint statistical normalized [24] as the first set of features. Given an image I,

$$G_I = \sqrt{[I \otimes h_x]^2 + [I \otimes h_y]^2} \tag{1}$$

$$L_I = I \otimes h_{LOG} \tag{2}$$

$$\begin{aligned} h_{LOG}(x, y|\sigma) &= \frac{\partial^2}{\partial x^2} g(x, y|\sigma) + \frac{\partial^2}{\partial y^2} g(x, y|\sigma) \\ &= \frac{1}{2\pi\sigma^2} \frac{x^2 + y^2 - 2\sigma^2}{\sigma^4} \exp\left(-\frac{x^2 + y^2}{2\sigma^2}\right) \end{aligned} \tag{3}$$

where "⊗" is a linear convolution operator, h_d, $d = \{x, y\}$ is Gaussian partial derivative filter along the horizontal and vertical direction

$$\begin{aligned} h_d(x, y|\sigma) &= \frac{\partial}{\partial d} g(x, y|\sigma) \\ &= -\frac{1}{2\pi\sigma^2} \frac{d}{\sigma^2} \exp(-\frac{x^2 + y^2}{2\sigma^2}), d \in \{x, y\} \end{aligned} \tag{4}$$

In Eq. (4). $g(x, y|\sigma) = \frac{1}{2\pi\sigma^2} \exp\left(-\frac{x^2+y^2}{2\sigma^2}\right)$ is an isotropic Gaussian function with scale parameter σ. We use the Weibull distribution [25] and the generalized Gaussian distribution [26] to fit the gradient feature LOG response of image. Firstly, we set

$$F_I(i, j) = \sqrt{G_I^2(i, j) + L_I^2(i, j)} \tag{5}$$

Subsequently, we an add adaptive normalization factor at a local location (i, j)

$$N_I(i, j) = \sqrt{\sum \sum\nolimits_{l,k \in \Omega_{i,j}} \omega(l, k) F_I(l, k)} \tag{6}$$

where $\Omega_{i,j}$ is a window, $\omega(l, k)$ is a weight which obeys Gaussian distribution, and satisfies $\sum\limits_{l,k} \omega(l, k) = 1$. Normalizing the Eq. (1) and Eq. (2) as

$$\overline{G_I} = G_I/(N_I + \varepsilon) \tag{7}$$

$$\overline{L_I} = L_I/(N_I + \varepsilon) \tag{8}$$

where ε is a normal small number to prevent N_I being too small and resulting unstable values.

Then quantified $\overline{G_I}(i, j)$ and $\overline{L_I}(i, j)$ as m levels $\{g_1, g_2, g_3, ...g_m\}$ and n levels $\{l_1, l_2, l_3, ...l_n\}$, expressed as G and L respectively. The joint probability distribution, the marginal distribution and the independence of G and L are defined as follows

$$K_{m,n} = P(G = g_m, L = l_n), m = 1, ...M; n = 1, ...N \tag{9}$$

$$\begin{cases} P_G(G = g_m) = \sum_{n=1}^{N} K_{m,n} \\ P_L(L = l_n) = \sum_{m=1}^{M} K_{m,n} \end{cases} \tag{10}$$

$$D_{m,n} = \frac{K_{m,n}}{P(G = g_m) \times P(L = l_n)} \tag{11}$$

$D_{m,n} = 1$ for all m and n if G and L are independent. Hence

$$\begin{aligned} Q_G(G = g_m) &= \frac{1}{N}\sum\nolimits_{n=1}^{N} \frac{P(G = g_m, L = l_n)}{P(L = l_n)} \\ &= \frac{1}{N}\sum\nolimits_{n=1}^{N} P(G = g_m | L = l_n) \end{aligned} \tag{12}$$

$$\begin{aligned} Q_L(L = l_n) &= \frac{1}{M}\sum\nolimits_{m=1}^{M} \frac{P(G = g_m, L = l_n)}{P(G = g_m)} \\ &= \frac{1}{M}\sum\nolimits_{m=1}^{M} P(L = l_n | G = g_m) \end{aligned} \tag{13}$$

Equation (12) and Eq. (13) describe the independence between G and L. We set the ratio parameter of the filter as 0.5 which can capture more details in the feature maps, we extract 40 dimensional features.

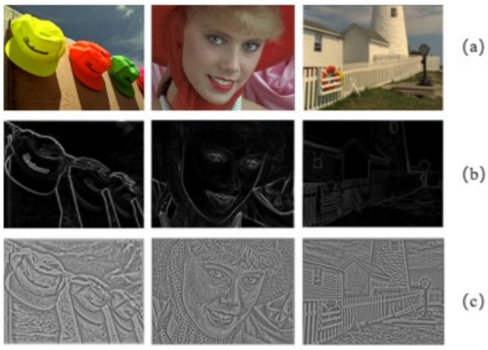

Fig. 3. (a) three example images; (b) the gradient magnitude of (a); (c) locally normalized luminance of (a)

3.2 Statistical Features

Using the scene statistics of the locally normalized luminance coefficients [31] to quantify the loss caused by the distortion. Which as follows

$$\hat{I}(i,j) = \frac{I(i,j) - \mu(i,j)}{\delta(i,j) + C} \tag{14}$$

where

$$\mu(i,j) = \sum_{s=-S}^{S}\sum_{t=-T}^{T} \varpi_{s,t} I_{s,t}(i,j) \tag{15}$$

4.3 Ablation Study

The major contribution of this work is proposing a novel implementation of the SPA attention module based on weighting wavelet layers. Although previous SPA-based attention mechanisms have already experienced remarkable performance, our approach offers a new perspective to this problem and answers new questions of "how does the pyramid level influence the denoising performance of the SPA blocks" and "if the SPA blocks can boost the performance of other networks with arbitrary architectures". Our results prove the superiority of the proposed SPA block compared to the naive channel attention block. At the same time, it also justifies the effect of different levels of SPA blocks. We also conducted an ablation study on the proposed network architecture. We test PSNR on the SIDD validation set for levels-0 to level-4. Notably, we define the naive channel attention as a level-0 pyramid (which means no pyramid). The second row of Table 3 shows that the higher pyramid level of the SPA blocks leads to a high PSNR and a better denoising performance. For evaluating the generalization of the SPA blocks, we conducted another ablation study by deploying SPA blocks at different levels in the RIDNet network as an alternative for its channel attention blocks. The third row of Table 3 shows the results of RIDNet when equipped with SPA blocks of different pyramid levels. The results show that the

SPA blocks generalize well in RIDNet while expecting to confirm that pyramids with more layers lead to better results.

Table 3. Investigation of effects of the pyramid level of SPA block and generalization on RIDNet.

Networks	Level	0	1	2	3	4
Ours	PSNR	39.24	39.33	39.47	39.55	39.57
RIDNet	PSNR	38.71	38.87	38.99	39.04	39.05

The proposed SPA attention is also generalized on the most commonly used AWGN model instead of only specific for real-world noise models. To investigate the AWGN noise, we use images with synthetic noise. We trained the blind denoising RIDNet and our network equipped with levels-0 to level-4 SPA attention on BSD500 [23] dataset with random AWGN (where the deviation σ varies between 5 to 55). The trained models were evaluated on BSD68 [27] dataset with noise level 15, 25, and 50. Table 4 compared the performance of each model. It consistently proves the generalizability.

Table 4. Comparisons on AWGN image denoising.

Noise levels	Method (RIDNet/Ours)			
	Level 1	Level 2	Level 3	Level 4
15	34.01/34.12	34.11/34.25	34.22/34.37	34.22/34.38
25	31.37/31.44	31.49/31.55	31.55/31.65	31.56/31.66
50	28.14/28.23	28.22/28.30	28.31/28.42	28.32/28.42

To further evaluate the performance of the proposed method, denoising is performed for Poisson-Gaussian noise model, which is defined as $y = P(x) + N(0, \sigma^2)$. This model includes Poisson-distribution $P(x)$ related to the clean image x, and followed by a Gaussian-distribution $N(0, \sigma^2)$. Here, we set the standard deviation σ to 15. We trained our network equipped with levels-0 to level-4 SPA attention on DIV2K [2] training set, and test them on DIV2K validation set. Table 5 presents the results of each level. The results show that the proposed SPA works better than naive channel attention (Level 0), and the performance gain still followed the obey the rules we observed in the previous experiments, that higher level pyramid brings more improvement.

Table 5. Comparisons on Poisson-Gaussian noise denoising.

Pyramid level	w/o CA	0	1	2	3	4
PSNR	31.11	31.52	32.21	32.57	33.04	33.06

Table 6. Comparisons on GPU runtime (seconds) and Model size (MB).

	Ours	17.11/0.22	17.13/0.24	17.16/0.29	17.18/0.32	17.21/0.35	17.23/0.41

4.4 Computational Overhead

As mentioned before, the SPA blocks improves the denoising performance while not adding considerable computational overhead. In this section, we compared the model sizes[1] when deployed different-level SPA blocks on both RIDNet and our network. It can be seen in Table 6 that the SPA blocks would not significantly increase the model size. Moreover, comparisons on average GPU runtime were conducted to show the proposed SPA module achieve a good trade-off between the calculation and performance. We fed images with a size of 512 × 512 for runtime evaluation. We tested each model 100 times and calculated the average runtime.

5 Conclusion

A novel channel attention module called Sub-band Pyramid Attention (SPA) is proposed in this work. The SPA blocks are built upon wavelet decomposition to realize a joint sub-band channel attention. The SPA is implemented as a plug-and-play module, hence can replace the naive channel attention in arbitrary deep learning networks. The proposed SPA block performs a more precise feature re-calibration that re-scales both the feature channels and the multi-level frequency components. The achieved gain for the proposed method over the conventional filtering methods and DL methods is considerable, ranging from 0.18 dB to 3.97 dB on the benchmark dataset of DnD. The generalization of the SPA blocks is verified by the ablation study, which suggests that the SPA module is compatible with other network architectures and can be widely used in other networks to boost image restoration performance.

Let us sum up: Even in conventional flat spacetime it is impossible to establish on an accelerated body a rigid coordinate system with a flat (Euclidean) space metric and with synchronized time. Such a coordinate system can be tied only to an inertially moving body. With the exception of special cases (for example, a rigidly rotating disk), any given frame of reference will become deformed in the course of time; its geometrical properties will change, and the rates of clocks tied to it will change.

In Newtonian physics, a rigid Cartesian frame of reference is determined by specifying at each moment of time the location of its origin and the orientation of its axes. In special relativity, to establish an accelerated reference frame one must give not only the motion of one of its points (the origin) but also the motion of all other points. We will mean by reference frame a collection of test particles (each carrying a clock) which fill all of spacetime, and which move along arbitrary paths.[7]

A similar situation occurs in GTR. The key difference is that in STR, where gravitational fields are absent, one can always pass from any noninertial frame of reference to an inertial frame of reference, and use that inertial frame throughout all of spacetime. In GTR, this cannot be done because of the curvature of spacetime.

We turn now to the mathematical formulation of these ideas. All formulae that we shall obtain will be valid not only in flat spacetime but also in the curved spacetime of general relativity, because they are local formulae and by virtue of the equivalence principle a gravitational field is locally indistinguishable from an accelerated frame.

1.4 THE MEASUREMENT OF SPACETIME INTERVALS

In an inertial frame of reference in STR, it is not absolutely necessary to use Cartesian space coordinates. Any curvilinear space coordinates (for example, spherical coordinates) can be used. The transformation from one system of space coordinates to another has the form

$$x^{\alpha} = x^{\alpha}(x^{1'}, x^{2'}, x^{3'}) \, . \qquad (1.4.1)$$

Here the index α takes on the values 1, 2, 3; and x^1, x^2, x^3 denote the three space coordinates.

The expression for ds^2 now takes on a form different from equation (1.2.1). Instead of the three squares of the differentials of the Cartesian coordinates, we have the expression for the square of the space interval in curvilinear coordinates (taken with a minus sign). In spherical coordinates this is $-dl^2 = -(dr^2 + r^2 d\theta^2 + r^2 \sin^2\theta\, d\phi^2)$, and the squared spacetime interval is written

---

[7] *Editors' note.*—More precisely the "reference frame" is identified with the "collection of test particles" moving in a specified manner. A reference frame is not a coordinate system, which includes in addition a parameterization of the particles (by coordinates x^1, x^2, x^3) and a time variable x^0 (not necessarily physical time!) for each particle.

This terminology is used widely in the Soviet Union but is not common in the West.

$$ds^2 = (dct)^2 - dr^2 - r^2 d\theta^2 - r^2 \sin^2\theta\, d\phi^2 \,. \tag{1.4.2}$$

In cylindrical coordinates

$$ds^2 = (dct)^2 - dr^2 - r^2 d\phi^2 - dz^2 \,. \tag{1.4.3}$$

The transformation (1.4.1) corresponds to a passage from one three-dimensional space grid of coordinates to another. However, the frame of reference (cf. § 1.3) remains unchanged. In passing to a different frame of reference, which moves arbitrarily relative to the inertial frame, one must use a time-dependent coordinate transformation

$$x^a = x^a(x^{1'}, x^{2'}, x^{3'}, t) \,. \tag{1.4.4}$$

The spatial part ($a = 1, 2, 3$) of this transformation defines completely the motion of the new reference system. The time part ($a = 0$) of the transformation (which involves coordinate time, not physical time; see below) can be arbitrary.

The transformation to a uniformly rotating reference frame has the form

$$\begin{aligned} x^1 &= x^{1'} \cos \Omega t - x^{2'} \sin \Omega t \,, \\ x^2 &= x^{1'} \sin \Omega t + x^{2'} \cos \Omega t \,, \\ x^3 &= x^{3'} \,, \end{aligned}$$

where Ω is the angular velocity; or, in cylindrical coordinates,

$$r = r' \,, \quad z = z' \,, \quad \phi = \phi' + \Omega t \,. \tag{1.4.5}$$

(The symbol t will be reserved for the time coordinate [not physical time!] in the new reference frame.) In this case, substituting equation (1.4.4) or (1.4.5) into equation (1.4.3), we find that the entire expression for ds^2 changes:

$$ds^2 = (c^2 - \Omega^2 r'^2) dt^2 - 2\Omega r'^2\, d\phi' dt - dz'^2 - r'^2 d\phi'^2 - dr'^2 \tag{1.4.6}$$

for the rotating disk; and

$$ds^2 = g_{ik} dx^i dx^k \tag{1.4.7}$$

in general. Here and throughout this book any index which appears twice must be summed; latin indices take on the values 0, 1, 2, 3; x^1, x^2, x^3 denote space coordinates (generally curvilinear); $x^0 = ct$ is the time coordinate; and g_{ik} are functions of the spacetime coordinates. Each term with $i \neq k$ occurs twice in the sum (1.4.7); for example, $g_{01} dx^0 dx^1$ and $g_{10} dx^1 dx^0$. By definition, g_{ik} always equals g_{ki}.

The quantities g_{ik} are called the components of the *metric* tensor; they define the so-called spacetime metric. The specific forms of g_{ik}, as functions of the coordinates, are determined not only by the properties of spacetime but also by the particular coordinate system used, that is, by the choice of reference frame, by the choice of space coordinates in that frame, and by the choice of the method of measuring time (i.e., the time coordinate).

The expression (1.4.7) contains complete information about the geometric properties of the reference frame and about the geometric properties of spacetime itself. How is this expression to be used? First, to examine the passage of time at a given point it is obviously necessary to regard x^1, x^2, x^3 as constant: $dx^1 = dx^2 = dx^3 = 0$. Then ds will be the time separation between two nearby events; i.e., it will be the interval of time multiplied by the speed of light, $ds = cd\tau$. Consequently,

$$d\tau = [(g_{00})^{1/2}/c]dx^0 \,. \qquad (1.4.8)$$

In any reference frame formed by real bodies, it is always true that $g_{00} > 0$.

Let us now calculate the spatial distance dl between two particles at rest in our reference frame. This cannot be done by simply setting $dx^0 = 0$, $x^0 = \text{constant}$ in expression (1.4.7). The problem with such a procedure is that the same moment of proper time does not always correspond to identical clock readings at different points in space. Therefore, before performing the computation we must determine which value of x^0 at a neighboring point is "simultaneous" with a given value of x^0 at a given point. Clock synchronization between two nearby points is performed by means of light signals.[8] We will not go into the computation here; instead, we refer anyone interested to the textbook of Landau and Lifshitz (1962). The final formula for the square of the spatial distance dl^2 is

$$dl^2 = \left(-g_{\alpha\beta} + \frac{g_{0\alpha}g_{0\beta}}{g_{00}}\right) dx^\alpha dx^\beta, \quad \alpha, \beta = 1, 2, 3 \,. \qquad (1.4.9)$$

The terms in parentheses will be denoted $\gamma_{\alpha\beta}$. They determine the metric of the three-dimensional space in our frame of reference.[9] The volume element of this three-dimensional space is given by the expression $dV = \sqrt{\gamma}\, dx^1 dx^2 dx^3$, where $\gamma = |\gamma_{\alpha\beta}|$ is the determinant of the matrix composed of elements $\gamma_{\alpha\beta}$.

---

[8] See n. 6.

[9] *Editors' note.*—This three-dimensional space is defined only locally, in the following sense: At each event in spacetime it is an infinitesimal three-dimensional surface orthogonal to the world line $(x^1, x^2, x^3) = \textit{constant}$. These infinitesimal "three-surfaces" usually cannot be meshed together to form a family of three-surfaces extending throughout spacetime. According to a theorem of differential geometry, the infinitesimal three-surfaces mesh to form finite three-surfaces if and only if the world lines $(x^1, x^2, x^3) = \textit{constant}$ have zero rotation—which they usually do not—or, equivalently, if and only if the angular-velocity tensor $A_{\alpha\beta}$ of equation (1.6.3) vanishes. Consequently, while the space metric $\gamma_{\alpha\beta}$ is defined at each event in spacetime, it is not usually the metric of a large-scale three-surface embedded in spacetime. Nevertheless, it *is* the metric of a (fictitious) three-surface whose geometric properties (Riemannian and Gaussian curvatures—cf. end of this section and end of § 1.8—deformations [eq. (1.6.4)], etc.) describe the geometric and kinematic properties of the reference frame.

Consider again the rotating disk as an example. Using formula (1.4.8), we obtain from equation (1.4.6) for the time interval (in the future we omit the prime on the coordinates)

$$d\tau = (1 - \Omega^2 r^2/c^2)^{1/2} dt\ .$$

On the axis of rotation, $r = 0$ and $d\tau = dt$. Hence the preceding formula can be rewritten in the form

$$d\tau = (1 - \Omega^2 r^2/c^2)^{1/2} d\tau_{\text{axis}}\ .$$

Time flows more slowly, the further removed one is from the axis of rotation.

For the element of spatial distance, we obtain from equations (1.4.6) and (1.4.9).

$$dl = \left[dr^2 + \frac{r^2 d\phi^2}{1 - \Omega^2 r^2/c^2} + dz^2\right]^{1/2}. \tag{1.4.10}$$

Using equation (1.4.10), we find that, when r and z are constant, then $dl = (1 - \Omega^2 r^2/c^2)^{-1/2} r\, d\phi$, and the ratio of the circumference of the circle to its diameter is

$$\frac{l_{\text{circle}}}{D} = \frac{\pi}{(1 - \Omega^2 r^2/c^2)^{1/2}}\ ,$$

in accordance with the analysis of the preceding section.

For comparison, we present an example of a nonstatic reference frame (i.e., a reference frame deforming with time) in which, as for our rotating disk, the ratio of a circle's circumference to its diameter is less than π.

In Minkowski spacetime consider a collection of particles ejected in all directions with all possible speeds, from a given point in space at some moment of time. The world lines of these particles fill the interior of the light cone. The reference frame tied to the particles is called the Milne frame (after Milne, who introduced such a cosmological model).

The transformation from the spherical coordinates (r', θ', ϕ') of a nondeforming reference frame and from laboratory time, t', to Milne's space coordinates (ψ, θ, ϕ) and the proper time of the particles, t, is given by

$$t^2 = t'^2 - r'^2\ , \quad \tanh\psi = r'/t'\ ,$$

$$\theta = \theta'\ , \quad \phi = \phi'\ .$$

Substituting these transformations into $ds^2 = c^2dt^2 - dr'^2 - r'^2(d\theta'^2 + \sin^2\theta'\, d\phi'^2)$, we obtain the expression for ds^2 in the Milne frame

$$ds^2 = d(ct)^2 - (ct)^2\,[d\psi^2 + \sinh^2\psi(d\theta^2 + \sin^2\theta\, d\phi^2)]\ .$$

At a fixed moment in time, $t = const.$, we examine the curvature of an equatorial "plane," $\theta = \frac{1}{2}\pi$. The ratio of the circumference of a circle in this equatorial plane, $l = 2\pi ct \sinh\psi$, to its diameter, $D = 2ct\psi$, is greater than π: $l/D = \pi(\sinh\psi)/\psi > \pi$.

If at a given point of a two-dimensional surface the ratio of the circumference of a small circle to its diameter, l/D, is smaller than π, then the curvature of the surface is said to be positive, and its geometry is similar to the geometry on a sphere. If $l/D > \pi$, then the curvature is negative, and the geometry is similar to the geometry on a pseudosphere (saddle-shaped surface).

Numerically, the curvature is defined by the square of the radius of curvature, a^2, which is determined in the following manner. A small triangle is drawn on the surface; the sides of the triangle are the shortest lines (geodesics) between its vertices. Let Σ denote the sum of the angles of the triangle. It can be demonstrated that the difference $\Sigma - \pi$ is proportional to the area of the triangle, S:

$$\Sigma - \pi = CS\,.$$

The coefficient of proportionality C is called the curvature, and the quantity $a = 1/C^{1/2}$ is the radius of curvature. If $\Sigma > \pi$, then $C = 1/a^2 > 0$, and the curvature is positive. If $\Sigma < \pi$, then $C = 1/a^2 < 0$, the curvature is negative, and a is imaginary. The smaller $|a^2|$, the larger the curvature and the more the geometry differs from Euclidean geometry.

The curvature at a given point of a three-dimensional space is determined in the following manner. A geodesic surface (analogue of a plane in Euclidean space) is drawn through the point, and its curvature is calculated. This curvature is called the Riemann curvature of space in the two-dimensional direction of the chosen surface. The curvature may be different in different directions. The curvature averaged over all directions is called the Gaussian curvature of the three-space. We will not give here formulae for computing the curvature in the general case. For important specific examples, the formulae are listed at the end of § 1.8.

Thus, a surface of constant time in the expanding Milne reference frame (see above) has negative curvature.

It is not difficult to understand the mathematical source of the non-Euclidean three-geometry of a noninertial reference frame in flat four-dimensional spacetime. The three-dimensional space of an *inertial* frame is a "flat" three-dimensional hypersurface or "slice" passing through the four-dimensional spacetime. The space of a three-dimensional *noninertial* frame results from a curved slice through four-dimensional spacetime. It is hardly surprising that the geometry of this curved slice is non-Euclidean. The situation is completely analogous to the geometry of a curved two-dimensional surface in a conventional (flat) three-dimensional space. In spite of the fact that the space is flat, the geometry on the curved surface is non-Euclidean.

1.5 SOME FORMULAE FOR CURVILINEAR COORDINATES

In STR one introduces the concept of a four-dimensional vector (four-vector) B_i as an aggregate of four quantities (functions of coordinates and time) which, under Lorentz transformations, transform as the coordinates x^i do. Examples of four-vectors are the four-velocity, $u^i = dx^i/ds$, the four-momentum, $p^i = mu^i$, and the four-potential of the electromagnetic field, A_i. A four-tensor of second rank, B_{ik}, is defined as an aggregate of quantities which transform like the product of the coordinates $x^i x^k$. An example is the electromagnetic-field tensor

$$F_{ik} = \partial A_k/\partial x^i - \partial A_i/\partial x^k \, .$$

Tensors of third rank and higher are defined in an analogous manner.

In inertial frames of reference in STR one uses Galilean coordinates, in which the interval takes the form (1.2.1). When passing to curvilinear coordinates in four-dimensional spacetime one must describe vectors and tensors in terms of this new type of coordinates. Most important of all is the introduction of the *covariant* and *contravariant* components of a vector.

A contravariant four-vector is any aggregate of quantities B^i (with index up) which, under a change of coordinates, $x^i = x^i(x^{0'}, x^{1'}, x^{2'}, x^{3'})$, transforms according to the rule

$$B^i = (\partial x^i/\partial x^{k'})B^{k'} \, . \tag{1.5.1}$$

An example of a contravariant vector is the set of coordinate differentials dx^i, since $dx^i = (\partial x^i/\partial x^{k'})dx^{k'}$.

The covariant components of the same vector B_i (with index down) are defined by

$$B_i = g_{ik}B^k \, . \tag{1.5.2}$$

From the determination of g_{ik} as the coefficients in equation (1.4.7), their law of transformation, $g_{ik} = (\partial x^{l'}/\partial x^i)(\partial x^{m'}/\partial x^k)g_{l'm'}$, follows. Using this law, and referring to equation (1.5.2), we obtain the law of transformation for the covariant components of a vector

$$\begin{aligned} B_i = g_{ik}B^k &= (\partial x^{l'}/\partial x^i)(\partial x^{m'}/\partial x^k)g_{l'm'}(\partial x^k/\partial x^{n'})B^{n'} \\ &= (\partial x^{l'}/\partial x^i)B_{l'} \, . \end{aligned} \tag{1.5.3}$$

The concept of a tensor is generalized in the same way: The transformation law for a contravariant tensor, B^{ik}, is

$$B^{ik} = (\partial x^i/\partial x^{l'})(\partial x^k/\partial x^{m'})B^{l'm'} \, , \tag{1.5.4}$$

and for its covariant components the transformation law is

$$B_{ik} = g_{li}g_{mk}B^{lm} = (\partial x^{l'}/\partial x^i)(\partial x^{m'}/\partial x^k)B_{l'm'} \, . \tag{1.5.5}$$

One also uses mixed components, which transform as

$$B^i{}_k = B^{il}g_{lk} = (\partial x^{l'}/\partial x^k)(\partial x^i/\partial x^{m'})B^{m'}{}_{l'} \, . \tag{1.5.6}$$

The concept of a tensor of a higher rank is generalized similarly.

The components g_{ik}, as indicated by their law of transformation, comprise a tensor. This tensor, which plays a fundamental role in the theory, is called the *fundamental metric tensor*.

The determinant

$$g = |g_{ik}| \tag{1.5.7}$$

is called the *fundamental determinant.*

The quantities g^{ik}, defined by

$$g_{ik}g^{im} = \delta^m{}_k \, , \tag{1.5.8}$$

where $\delta^m{}_k$ is the Kronecker delta, are called the *contravariant components* of the metric tensor. From equation (1.5.8), it follows that

$$g^{ik} = (A^{ik}/g) \, , \tag{1.5.9}$$

where A^{ik} is the minor of the matrix g_{ik}.

From equation (1.5.8), by using equation (1.5.5), we find that

$$B^{ik} = g^{il}g^{mk}B_{lm} \, . \tag{1.5.10}$$

Thus, just as the lowering of indices is performed with the covariant components g_{ik}, so the raising of indices is performed with the contravariant components g^{ik}. The mixed tensor $g^i{}_k$ is equal to the Kronecker symbol, $g^i{}_k = \delta^i{}_k$.

Consider the quantity A^iB_i. It is the scalar product of the vectors A^i and B^j, and it is unaffected by a transformation of coordinates. Specifically, the square of the length of a vector is

$$A^2 = A^iA_i \, . \tag{1.5.11}$$

Similarly, we can construct a scalar from two tensors

$$A^{ik}B_{ik} = A_i{}^kB^i{}_k = A_{ik}B^{ik} \, .$$

All three notations are equivalent. If the second tensor is the fundamental tensor, then the scalar $A^{ik}g_{ik} = A^i$, is called the *trace* of the tensor.

In a similar manner, lower-rank tensors can be formed from higher-rank tensors. For example,

$$A_{iklm}g^{mi} = A^i{}_{kli} = A_{kl} \, .$$

This operation is called *tensor contraction*.

In curvilinear coordinates, the concept of differentiation of vectors and tensors must also be generalized. The covariant derivatives (denoted by a semicolon) of a contravariant vector and of a covariant vector are the quantities

$$B^i{}_{;k} = (\partial B^i/\partial x^k) + \Gamma^i{}_{lk}B^l \, , \tag{1.5.12}$$

and

$$B_{i;k} = (\partial B_i/\partial x^k) - \Gamma^l{}_{ik}B_l \, , \tag{1.5.13}$$

respectively. Here $\Gamma^l{}_{mn}$ are Christoffel symbols (not tensors!) which are defined by the expressions

$$\Gamma^l{}_{mn} = \tfrac{1}{2}g^{lk}\left[(\partial g_{km}/\partial x^n) + (\partial g_{kn}/\partial x^m) - (\partial g_{mn}/\partial x^k)\right] . \tag{1.5.14}$$

Obviously, in Cartesian coordinates all the $\Gamma^l{}_{mn}$ vanish, and covariant differentiation reduces to conventional differentiation.

Tensors of higher rank are differentiated in a similar manner:

$$B^{ik}{}_{;l} = (\partial B^{ik}/\partial x^l) + \Gamma^i{}_{ml}B^{mk} + \Gamma^k{}_{ml}B^{im}\,, \tag{1.5.15}$$

$$B^i{}_{k;l} = (\partial B^i{}_k/\partial x^l) - \Gamma^m{}_{kl}B^i{}_m + \Gamma^i{}_{ml}B^m{}_k\,, \tag{1.5.16}$$

$$B_{ik;l} = (\partial B_{ik}/\partial x^l) - \Gamma^m{}_{il}B_{mk} - \Gamma^m{}_{kl}B_{im}\,. \tag{1.5.17}$$

It is important to note that from equations (1.5.12) and (1.5.14) and the expression for ds^2 one can obtain the following expression for the covariant divergence of a vector

$$B^i{}_{;i} = [1/(-g)^{1/2}]\partial[(-g)^{1/2}B^i]/\partial x^i\,. \tag{1.5.18}$$

Finally, we give the equation in curvilinear coordinates which defines the geodesic line connecting two points in four-dimensional space (in flat space, in which we are working in this section, it is a straight line):

$$(d^2x^i/ds^2) + \Gamma^i{}_{kl}\,(dx^k/ds)(dx^l/ds) = 0\,. \tag{1.5.19}$$

In Minkowski space, as we know from STR, a body of finite rest mass moves along a straight (timelike) line; i.e., along a geodesic. Hence, equations (1.5.19) are the equations of motion of a body of finite rest mass, written in the curvilinear coordinates of a noninertial reference frame. The differential equation for a geodesic in curved spacetime has precisely the same form as equation (1.5.19) for a straight line in flat spacetime.

1.6 DYNAMIC AND KINEMATIC QUANTITIES

The quantities g_{ik} of equation (1.4.7) are constructed from derivatives of the transformation (1.4.4), which determines the motion of the reference frame used with respect to the original inertial frame. In particular, g_{ik} includes $\partial x^{i'}/\partial x^0$, the relative velocity of the two frames. Hence, it is natural that g_{ik} contains information not only about the flow of time and the geometry of the reference frame but also about its accelerations and deformation. We shall cite here only the final formulae for the computation of dynamic and kinematic quantities; for more detail see the contributions of Zel'manov (1944, 1959*b*). The three-dimensional vector F^α, describing the acceleration relative to the reference frame of a freely moving body momentarily at rest in it, is determined by the expression

$$F^\alpha = -c^2\Gamma^\alpha{}_{00}/g_{00} \qquad (\alpha = 1, 2, 3)\,, \tag{1.6.1}$$

as we shall demonstrate below (eq. [1.6.1a]). The quantities $\Gamma^\alpha{}_{00}$ were defined in the preceding section (eq. [1.5.14]). The vector F^α forms a field of inertial forces in the reference frame. F^α is a three-dimensional vector; in working with it one must use the tensor $\gamma_{\alpha\beta}$ (see § 4 of this chapter). Rein STR, then, as in GTR, the formula for the number of particles would take the form (1.8.12). Thus, in GTR the law of conservation of particles is written in exactly the same form as when gravity is absent. This is hardly surprising, since gravitation obviously does not change the number of particles.

Finally, let us write an expression for the Gaussian curvature (cf. § 1.4) of the three-dimensional space of the comoving reference frame in the static case (that is, when all time derivatives vanish):

$$C_G = \tfrac{8}{3}\pi(G/c^2)\rho\,. \tag{1.8.13}$$

In the case of an isotropic deformation of matter and vanishing rotation, the Gaussian curvature is

$$C_G = \tfrac{8}{3}\pi(G/c^2)\rho - \tfrac{1}{9}D^2\,. \tag{1.8.14}$$

These formulae are derived, for example, by Zel'manov (1959*b*).

1.9 THE COSMOLOGICAL CONSTANT

The general requirements usually placed on the equations of the theory of gravitation permit one to write a variational principle with the action in the form (where V is the four-dimensional volume)

$$S = -mc\int ds - \frac{c^3}{16\pi G}\left(\int R\,dV + \int 2\Lambda\,dV\right). \tag{1.9.1}$$

The corresponding field equations have the form

$$R_{ik} - \tfrac{1}{2}g_{ik}R - \Lambda g_{ik} = (\kappa/c^2)T_{ik}\,. \tag{1.9.2}$$

Here Λ is the so-called cosmological constant, and quantities that are proportional to it (ΛdV, Λg_{ik}) are called cosmological terms. These field equations obviously satisfy the condition of local Lorentz-invariance and include the equations of motion in the same sense as the equations without Λ do; $T^k{}_{i;k} = 0$, as before.

Einstein initially selected Λ in such a manner as to obtain a stationary cosmological solution with a mean density $T_0{}^0 = \rho c^2 = \text{const.}$ that is different from zero; for this, it is necessary that $\Lambda = 8\pi G\rho/3c^2$. After the discovery of the cosmological redshift, Einstein preferred the equations with $\Lambda \equiv 0$.

Both stationary and nonstationary cosmological solutions with $\Lambda \neq 0$ were investigated in detail before 1930; however, until 1967 there were no observational indications as to the necessity or even desirability of introducing Λ. Since 1967, observational data on quasars have suggested that Λ might not actually be zero, but might instead have a value of the order of $\Lambda \approx 10^{-55}\ \text{cm}^{-2}$. For details, see § 14.1. At present this hypothesis is not at all proved; in fact, it encounters difficulties in explaining the quasar observations. However, in the course of the discussions it has become apparent that the simplest assumption of $\Lambda \equiv 0$, while not refuted, has not been distinctly and uniquely proved. Predictably, difficult and extensive work will be required in years to come, to determine the quantity Λ, or at least to determine limits on it. After a genie is let out of a bottle (i.e., now that the possibility is admitted that $\Lambda \neq 0$), legend has it that the genie can be chased back in only with great difficulty. Even if the specific hypothesis that $\Lambda \approx 10^{-55}\,\mathrm{cm}^{-2}$ is invalidated, we will return not to the simplistic assumption that $\Lambda \equiv 0$, but to a careful $-a < \Lambda < b$, and to a gradual and painful decrease of the limits a and b.

How can the physical meaning of the cosmological constant be understood? Why, in fact, is it interesting for physics as a whole?

One approach was prompted by the dimensions of Λ (cm^{-2}). In this approach one views Λ as the curvature of empty space. But the theory of gravitation links the curvature to the energy, momentum, and pressure of matter. Putting the terms with Λ onto the right side of the field equation, we obtain

$$R_{ik} - \tfrac{1}{2}g_{ik}R = (8\pi G/c^4)T_{ik} + g_{ik}\Lambda\,. \tag{1.9.3}$$

The assumption that $\Lambda \neq 0$ means that empty space creates a gravitational field identical with that in the theory with $\Lambda = 0$, but with matter filling all of spacetime with a mass density $\rho_\Lambda = (c^2\Lambda/8\pi G)$, an energy density $\epsilon_\Lambda = (c^4\Lambda/8\pi G)$, and a pressure $P_\Lambda = -\epsilon_\Lambda$. In this sense one can speak about the energy density and the pressure (stress tensor) of the vacuum.

Notice that our assumptions about ϵ_Λ and P_Λ were formulated in such a manner that the relativistic invariance of the theory was not broken; ϵ_Λ and P_Λ are the same in all coordinate systems moving relative to each other (Lorentz-transformed).

These quantities do not make themselves felt either in elementary-particle experiments or in atomic and molecular physics: the vacuum energy of the vessel in which an experiment takes place plays the role of a constant term which can be canceled in the law of energy conservation.

The only sort of phenomenon in which ϵ_Λ and P_Λ manifest themselves is a gravitational one. In this case ϵ_Λ and P_Λ "work" not only in empty space; they are, as is clear from the above formulae, full and equal members of the field equations even when normal matter is present. Thus, a Cavendish experiment in principle can serve for the discovery and measurement of ϵ_Λ and P_Λ. The attraction of a sphere of lead depends on the sum of the lead density ($11\ \mathrm{g\ cm}^{-3}$), and the vacuum density ($|\rho_\Lambda|$ is less than 10^{-28} g cm^{-3}), integrated over the volume of the sphere.

A practical measurement of the influence of P_Λ and ϵ_Λ is not possible, either in laboratory experiments or in observations of planetary motions in the solar system or stellar motions in the Galaxy. Indeed, the mean density of solar-system matter in a sphere with the radius of the Earth's orbit is $\langle\rho\rangle \approx 10^{-7}\ \mathrm{g\ cm}^{-3}$. The mean density of matter in the Galaxy is of the order of 10^{-24} g cm^{-3}. The influence of ρ_Λ will be significant only on the largest of scales—the scale of the whole Universe—i.e., in cosmology.

Let us dwell on the nature of Λ. One can take the viewpoint that a certain Λ and corresponding ρ_Λ, ϵ_Λ, and P_Λ are universal constants that do not require any further explanation. A different viewpoint is also conceivable: assume that in some zeroth-order approximation $\Lambda = \rho_\Lambda = \epsilon_\Lambda = P_\Lambda \equiv 0$. Higher-order values that are different from zero and characterize the vacuum might be derivable from considerations of the theory of elementary particles. There is no such derivation at the present time, any more than there is a theory proving that $\Lambda = 0$.

We consider the second point of view in more detail. The very first attempts to quantize the electromagnetic field led to the paradoxical conclusion of an infinite energy density for the vacuum. The vacuum is defined as the lowest energy state of the system considered, and can be characterized by the Maxwell equations. The particles—photons in this case—represent the elementary excitations of the system. In the analogous quantum-mechanical problem of the motion of the atomic nuclei in a crystal lattice, the situation is similar: the elementary excitations are phonons (sound quanta), and the ground state of the crystal is that which contains no phonons, i.e., which has a temperature of absolute zero. This state is similar to the vacuum.

The ground-state energy in the case of a crystal has a quite certain value which can be measured. The difference in ground-state energies for different isotopes of the same element leads to the dependence of the heat of evaporation on the atomic weight of the isotope. In the simplest variant of field theory the ground-state energy of the vacuum is infinite. However, the theory can be reformulated so that the ground-state energy of the free field becomes identically zero.

In classical Maxwell theory the energy density is equal to $\epsilon = (E^2 + H^2)/8\pi$, where E and H are the electric and magnetic field strengths. As has been emphasized by Berestetsky, Lifshitz, and Pitaevsky (1969), there is no formulation of quantum electrodynamics in which the mean value of E^2 or H^2 is zero in the vacuum (i.e., far from all charges and in the absence of real photons). Consequently, in order to formulate these theories with the help of the usual products of operators, in such a manner that in vacuum $\epsilon = 0$, one must abandon the classical relation between ϵ and the fields.

A second source of the energy of the vacuum arises from the Dirac theory of the electron: the concept of filled levels with negative energy leads literally to an infinite negative value for the energy density. In this case also the theory was soon reformulated to make ϵ identically zero for the vacuum of noninteracting particles. However, it is not at all guaranteed that, when the interaction of the particles is taken into account, the vacuum energy will remain zero. The peculiarity of present-day theory is that the interaction between particles is effective not only when real particles are present to interact, but also when the particles are virtual.

In the above discussion we must remind ourselves that the term "interaction" is not used in the sense of classical physics. There one speaks about the interaction of two colliding bodies, and about the (Coulomb) interaction of a proton and electron. In quantum field theory one speaks about a four-fermion interaction when a neutron breaks up into an electron, a proton, and a neutrino; and one speaks about a photon-electron interaction when an electron produces a photon.

A freely moving electron cannot emit a real photon which is capable of being detected far from the electron. However, one can say that the free electron emits and then reabsorbs photons, and that this causes a change in the properties of the electron (for example, its mass, its magnetic moment, etc.), as has been proved by the Lamb-Rutherford experiment.

Experimental measurement of the change in the electron mass is impossible because there are no experiments which could, even in principle, measure the mass of an electron stripped of its photons. However, the change in the electron's magnetic moment has been corroborated by experiment, with all the precision which is now available.

There are many other processes similar to the above which take place in the vacuum—for example, the creation and annihilation of electron-positron pairs with the absorption and emission of γ-radiation.

The theory of the vacuum state and its properties is not so simple and obvious today as it was about fifty years ago!

Several possible viewpoints may be delineated.

The first is the supposition that the energy of the vacuum is identically zero when fields and interactions are ignored. When they are taken into account, the vacuum energy becomes nonzero; it acquires an additive constant when processes involving real particles are investigated. Particle theory based on this viewpoint faces the problem of calculating all observable processes in a manner which yields answers that do not depend on the unknown—or indeterminate, or even infinite—energy of the vacuum.

It is in this manner that Feynman formulated the problem and devised a successful solution. In his formulation the transition amplitude A_{12} (amplitude for particles plus vacuum in the initial state to change into particles plus vacuum in the final state) is divided by the transition amplitude A_v (vacuum → vacuum); and only the ratio A_{12}/A_v represents the real value corresponding to the real particle interaction. Such a method of avoiding the question of the energy of the vacuum is good everywhere except in gravitation theory! The energy density of the vacuum in gravitational problems is, as we mentioned above, a real, measurable quantity!

There is a second, so-called axiomatic, viewpoint on the theory of particles: it is taken as an axiom that the energy density of the vacuum and the corresponding pressure are identically zero.

We have no objection if such a statement is postulated openly as one possibility among others. However, one often meets in the literature statements that such an axiom is necessary; that it and no other is in agreement with relativistic invariance. Such a supposition is quite wrong. It was already noted above that the relation between the pressure and energy density of the vacuum which is provided by the cosmological constant, $P_\Lambda = -\epsilon_\Lambda$, is relativistically invariant.

We shall show below how particle theory can give an order-of-magnitude estimate of ϵ_Λ which is nonzero, while maintaining relativistic invariance.

An error frequently committed arises from introducing a particular normalizing volume V, and examining the energy $E = V\epsilon$. The (three-dimensional) momentum $\boldsymbol{P}$ of the vacuum is obviously zero because there is no preferred direction for it. Energy and momentum comprise the four-dimensional vector $(E, \boldsymbol{P})$, which in our case, for a given normalizing volume, is $(E, \boldsymbol{0})$. Such a combination is clearly noninvariant and will give $\boldsymbol{P} \neq 0$ in other coordinate systems, unless one chooses $E = 0$ (and, therefore $\epsilon = 0$).

The error lies in choosing a particular volume, since this itself violates relativistic invariance. An unbounded medium, and the vacuum in particular, must be characterized with an energy density which is the T_{00} component of the second-order stress-energy tensor. The tensor as a whole includes components $T_{0\alpha} = T_{\alpha 0}$ (where $\alpha = 1, 2, 3$ is a spatial index), which describe the energy flow and simultaneously the momentum density in space, $P_\alpha = T_{0\alpha}V$. The components $T_{\alpha\beta}$ of the stress-energy tensor correspond to the stress which enters into the theory of elasticity. In the case of a gas or fluid (without shear stresses) $T_{\alpha\beta} = \delta_{\alpha\beta}P$.

These well-known truths are repeated here in order to emphasize that the problem lies not in the question of whether the vacuum has an energy-momentum vector, but whether it has a stress-energy tensor. There is no relativistically invariant vector (it is identically zero), but there can perfectly well be a relativistically invariant tensor. It must have the form

$$\text{const.} \times \begin{vmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{vmatrix},$$

and it is about precisely such a tensor that one speaks in the case $\Lambda \neq 0$. We cannot rule out such a tensor associated with the vacuum a priori.

The following questions remain:

1. Is there any principle which requires one to set $\Lambda \neq 0$?

2. Must we regard $\Lambda \neq 0$ as a new, independent, universal constant?

3. Is it possible to calculate Λ (even in order of magnitude) from the other universal constants?

An attempt to answer the third question, without touching on the first two, will be made below. This answer (based only on dimensional analysis and comparisons of orders of magnitude) will probably be useful in the construction of a future theory which is more nearly correct and logically consistent.

The theory of elementary particles yields a quantity with the dimensions of ϵ_Λ: from the fundamental constants of the theory one can construct the energy mc^2, the length $\hbar/mc$, the number density $n = (mc/\hbar)^3$, and the energy density $\epsilon_\Lambda = mc^2(mc/\hbar)^3$. This value of ϵ_Λ certainly is not applicable to gravitation theory; for the electron mass we get ϵ_Λ of the order of 10^{25} ergs cm^{-3}, and for the proton mass we get ϵ_Λ of the order of 10^{38}. Apparently the subconscious aversion of physicists to $\Lambda \neq 0$ has been based on the comparison of such a "theoretical" ϵ_Λ with what is admissible in cosmology: If we can't take a large Λ, then let there be none at all!

Under the influence of suggestions from astronomers, it was pointed out recently (Zel'dovich 1967*b*) that a sensible ϵ_Λ can be derived by multiplying $mc^2(mc/\hbar)^3$ by the dimensionless quantity $Gm^2/\hbar c$ which is characteristic of gravitation. We can interpret this expression in the following manner: In the vacuum, virtual particles with mass m and average separation $\lambda = \hbar/mc$ are created. Their total proper energy is identically zero, so the gravitational interaction of the neighboring particles determines the energy density of the vacuum:

$$\epsilon_\Lambda = (Gm^2/\lambda)(1/\lambda^3) = Gm^6c^4/\hbar^4\,,$$

corresponding to the relations mentioned above.

The connection between the theory of particles and the cosmological constant is treated in greater detail by Zel'dovich (1968).

There is another side to the problem: Often it is said that $\Lambda \neq 0$ means that gravitons have a nonzero rest mass. But $\Lambda \neq 0$ leads also to the result that, even in the absence of matter, spacetime cannot be flat everywhere. In curved spacetime the very definition of the mass of a graviton is no longer clear. For a thorough discussion of this point, see Treder (1968).

1.10 NEWTON'S LAW AND WEAK GRAVITATIONAL FIELDS

Consider a weak gravitational field. In this case one obviously can construct a reference frame in which the components of the metric tensor differ very little from their Galilean values [denoted by the superscript (0)]:

$$\left.\begin{aligned} g_{ik} &= g^{(0)}{}_{ik} + h_{ik}\,, \\ g^{(0)}{}_{\alpha\beta} &= -\delta_{\alpha\beta}\,, \quad g^{(0)}{}_{0\alpha} = 0\,, \quad g^{(0)}{}_{00} = 1\,. \end{aligned}\right\} \tag{1.10.1}$$

Actually, the Gaussian curvature (see § 1.4) of space, C_G, at the center of the star is larger than it is at other places. The quantity C_G is given by the formula (see eq. [1.8.13]):

$$C_G = (8\pi/3)(G\rho/c^2) . \qquad (3.3.6)$$

Inasmuch as the density is a maximum at the center of the star, C_G is also a maximum there. Of course, we should not assume on the basis of equation (3.3.6) that space is Euclidean outside the star (where $\rho = 0$), when the gravitational field near the star is strong. Formula (3.3.6) gives only the mean curvature of space averaged over all two-dimensional directions; and this mean curvature actually is zero. However, beyond the star, the Riemannian space curvature (see § 1.4) is nonzero; and, depending on the two-dimensional direction, it may be positive or negative. At the center of the star, all directions are equivalent; there the curvature for any orientation is given by formula (3.3.6), and it is always positive.

The gravitational field obtained by joining the star's interior and exterior solutions has no physical singularities of the type exhibited on the Schwarzschild sphere; everywhere

$$1 \le e^{\lambda} < \infty , \quad \text{and} \quad 0 < e^{\nu} < 1 .$$

3.4 THE RADIAL MOTION OF LIGHT RAYS AND OF ULTRA-RELATIVISTIC PARTICLES

Consider now the radial motion, in a spherical gravitational field, of particles with the fundamental speed c; for example, photons and neutrinos. Since an observer can locally introduce coordinates for which $ds^2 = c^2dt^2 - dx^2 - dy^2 - dz^2$, and since the speed of light c is independent of reference frame, an equation of motion for a particle with zero rest mass is $ds = 0$ in any coordinate system. Because of spherical symmetry, a particle that starts out moving radially will always move radially. Along such a particle's trajectory θ and ϕ are constant, so the condition $ds = 0$ implies

$$dr/dt = ce^{(\nu-\lambda)/2} . \qquad (3.4.1)$$

Everywhere inside the star $e^{(\nu-\lambda)/2} < 1$. Outside the star, in vacuum, $e^{(\nu-\lambda)/2} = 1 - 2GM/c^2r < 1$; and this quantity approaches unity as $r \to \infty$. It follows, for example, that for a neutrino emitted from the star's center, the radial coordinate r, as a function of the time t of a distant observer, must have the form shown in Figure 7. The dotted line in this diagram indicates the motion of the neutrino in the absence of a gravitational field.

In the future we will frequently consider the motion of bodies in the immediate vicinity of the gravitational radius of the central body (where the field is especially strong), and even in the limit $r \to r_g$. As noted in § 3.2, a static body cannot have dimensions $r \le r_g$; and Bondi (1964) has demonstrated that the dimensions of a body in equilibrium cannot be smaller than

$ (

different in different directions.
The curvature averaged over all directions is called the Gaussian curvature of the three-space.

$$
\begin{aligned}
R_{\mp} = &\quad C_1' \, \eta^{\pm \frac{1}{\sqrt{D-1} \mp 1}} \to 0 \\
e^{\Psi_{\mp}} = &\, C_2' \, \eta^{-\frac{\sqrt{D-1}}{\sqrt{D-1} \mp 1}} \to \begin{cases} \infty \\ 0 \end{cases}
\end{aligned}
\tag{6.16}
$$

Where C_1' and C_2' are constants. The branch $(-)$ would describe an expanding non-inflationary behaviour near the initial singularity $T = 0$, while the branch $(+)$ describes a 'big crunch' situation and is rather unphysical.

Similarly, for $R \to \infty$ and $e^{\Phi} \to \infty$, we find

$$
\begin{aligned}
R_{\mp} = &\, D_1 \, T^{\mp 1/\sqrt{D-1}} \to \infty \quad , \\
e^{\Psi_{\mp}} = &\quad D_2 \, T^{-1} \to \begin{cases} \infty \\ 0 \end{cases}
\end{aligned}
\tag{6.17}
$$

Where D_1 and D_2 are constants. Here again, the branches $(-)$ and $(+)$ correspond to $T \to 0$ and to $T \to \infty$ respectively, but now in both regimes $R_{\mp} \to \infty$ and $e^{\Phi_{\mp}} \to \infty$. (In this limit, one is not guaranteed that U can be consistently neglected). In terms of the conformal time, eqs.(6.17) read

$$
\begin{aligned}
R_{\mp} = &\quad D_1' \, \eta^{\mp \frac{1}{\sqrt{D-1} \pm 1}} \to \infty \\
e^{\Psi_{\mp}} = &\, D_2' \, \eta^{-\frac{\sqrt{D-1}}{\sqrt{D-1} \pm 1}} \to \begin{cases} \infty \\ 0 \end{cases}
\end{aligned}
\tag{6.18}
$$

The branch $(+)$ describes a noninflationary expanding behaviour for $T \to \infty$ faster than the standard matter dominated expansion, while the branch $(-)$ describes a super-inflationary behaviour $\eta^{-\alpha}$, since $0 < \alpha < 1$, for all D.

The behaviours (6.15) for $R_{\mp} \to 0$ and (6.17) for $R_{\mp} \to \infty$ are related by duality $R \leftrightarrow 1/R$.

B. String driven inflation?

Let us consider now the question of whether de Sitter spacetime may be a self-consistent solution of the effective string equations (6.7) with the string sources included. The strings in cosmological universes like de Sitter spacetime have the equation of state (5.4)-(5.6). Since $e^{\Psi} = e^{\Phi} \, R^{1-D}$:

$$
\bar{\rho} = e^{\Psi} \left(u \, R + \frac{d}{R} + s \right) \tag{6.19}
$$

$$
\bar{p} = \frac{e^{\Psi}}{D-1} \left(\frac{d}{R} - u \, R \right) \tag{6.20}
$$

In the absence of dilaton potential and cosmological constant term, the string sources do not generate de Sitter spacetime as discussed in sec. V.A. We see that for $U = c = 0$, and $R = e^{HT}$, eqs.(6.11) yields to a contradiction (unless $D = 0$) for the value of Ψ , required to be $-HT +$ constant.

A self-consistent solution describing asymptotically de Sitter spacetime self-sustained by the string equation of state (6.19)-(6.20) is given by

$$\begin{aligned} R &= e^{HT} \quad , \quad H = \text{constant} > 0 \quad , \\ 2U - c &= D\,H^2 = \text{constant} \\ \Psi_{\pm} &= \mp HT \pm i\pi + \log \frac{(D-1)\,H^2}{\rho_{\pm}} \\ \rho_+ &\equiv u \quad , \quad \rho_- \equiv d \end{aligned} \tag{6.21}$$

The branch Ψ_+ describes the solution for $R \to \infty$ ($T \to +\infty$), while the branch Ψ_- corresponds to $R \to 0$ ($T \to -\infty$). De Sitter spacetime with lorentzian signature self-sustained by the strings necessarily requires a constant imaginary piece $\pm i\pi$ in the dilaton field. This makes $e^{\Psi} < 0$ telling us that the gravitational constant $G \sim e^{\Psi} < 0$ here describes antigravity.

Is interesting to notice that in the euclidean signature case, i. e. $(+++\ldots++)$, the Ansatz $\dot{H} = 0$, $2U - c$ =constant, yields a constant curvature geometry with a real dilaton, but which is of Anti-de Sitter type. This solution is obtained from eqs.(6.20)-(6.21) through the transformation

$$\hat{X}^0 = iT \quad , \quad \hat{H} = -iH \quad , \quad X^i = X^i \quad , \quad \Psi = \Psi \tag{6.22}$$

which maps the Lorentzian de Sitter metric into the positive definite one

$$d\hat{s}^2 = (d\hat{X}^0)^2 + e^{\hat{H}\hat{X}^0}\,(d\vec{X})^2. \tag{6.23}$$

The equations of motion (6.11) within the constant curvature Ansatz ($\dot{\hat{H}} = \ddot{\Psi} = 0$) are mapped onto the equations

$$\begin{aligned} (D-1)\,\hat{H}^2 - \left.\frac{\partial U}{\partial \Psi}\right|_R &= \bar{\rho} \\ \hat{H}\,\frac{d\Psi}{d\hat{X}^0} + \frac{R}{D-1}\left.\frac{\partial U}{\partial R}\right|_{\Psi} &= \bar{p} \\ -(\frac{d\Psi}{d\hat{X}^0})^2 + (D-1)\,\hat{H}^2 - 2\,\bar{\rho} - 2U + c = 0 \, , \end{aligned} \tag{6.24}$$

with the solution

$$\begin{aligned} R &= e^{\hat{H}\hat{X}^0} \quad , \quad \hat{H} = \text{constant} > 0 \quad , \\ c - 2U &= D\,\hat{H}^2 = \text{constant} \\ \Psi_{\pm} &= \mp \hat{H}\hat{X}^0 + \log \frac{(D-1)\,\hat{H}^2}{\rho_{\pm}} \\ \rho_+ &\equiv u \quad , \quad \rho_- \equiv d \end{aligned} \tag{6.25}$$

Both solutions (6.25) and (6.21) are mapped one into another through the transformation (6.22).

It could be recalled that in the context of (point particle) field theory, de Sitter spacetime (as well as anti-de Sitter) emerges as an exact selfconsistent solution of the semiclassical Einstein equations with the back reaction included [34] - [35]. (Semiclassical in this context, means that matter fields including the graviton are quantized to the one-loop level and coupled to the (c-number) gravity background through the expectation value of the energy-momentum tensor T_A^B . This expectation value is given by the trace anomaly: $< T_A^A >= \bar{\gamma}\ R^2$). On the other hand, the α' expansion of the effective string action admits anti-de Sitter spacetime (but not de Sitter) as a solution when the quadratic curvature corrections (in terms of the Gauss-Bonnet term) to the Einstein action are included [36]. It appears that the corrections to the anti-de Sitter constant curvature are qualitatively similar in the both cases, with α' playing the rôle of the trace anomaly parameter $\bar{\gamma}$ [35].

The fact that de Sitter inflation with true gravity $G \sim e^{\Psi} > 0$ does not emerge as a solution of the effective string equations does not mean that string theory excludes inflation. What means is that the effective string equations are not enough to get inflation. The effective string action is a low energy field theory approximation to string theory containing only the *massless* string modes (*massless* background fields).

The vacuum energy scales to start inflation (physical or true vacuum) are typically of the order of the Planck mass [26] - [27] where the effective string action approximation breaks down. One must consider the massive string modes (which are absent from the effective string action) in order to properly get the cosmological condensate yielding de Sitter inflation. We do not have at present the solution of such problem.

TABLE 4. Asymptotic solution of the string effective equations (including the dilaton).

EFFECTIVE STRING EQUATIONS SOLUTIONS IN COSMOLOGY

Effective String equations	$R(T) \to 0$ behaviour	$R(T) \to \infty$ behaviour
$T \to 0$	$\simeq T^{+1/\sqrt{D-1}}$	$\simeq T^{-1/\sqrt{D-1}}$
$T \to \infty$	$\simeq T^{-1/\sqrt{D-1}}$	$\simeq T^{+1/\sqrt{D-1}}$

VII. MULTI-STRINGS AND SOLITON METHODS IN DE SITTER UNIVERSE

Among the cosmological backgrounds, de Sitter spacetime occupies a special place. This is, in one hand relevant for inflation and on the other hand string propagation turns to be specially interesting there [2] - [8]. String unstability, in the sense that the string proper length grows indefinitely is particularly present in de Sitter. The string dynamics in de Sitter universe is described by a generalized sinh-Gordon model with a potential unbounded from below [4]. The sinh-Gordon function $\alpha(\sigma, \tau)$ having a clear physical meaning : $H^{-1}e^{\alpha(\sigma,\tau)/2}$ determines the string proper length. Moreover the classical string equations of motion (plus the string constraints) turn to be integrable in de Sitter universe [4,5]. More precisely, they are equivalent

(%' 1! ! " 1 ! "
L! 3 A!D

magnetic background is accompanied by a curvature of space-time. In spite of that, certain closed string magnetic models can be solved exactly. In particular, these are static flux tube type configurations with approximately uniform magnetic field which generalize the Melvin solution of the Einstein-Maxwell theory [1]. Such backgrounds are exact solutions of (super)string theory [2,3] and, moreover, the spectrum of the corresponding unitary conformal string models can be explicitly determined [3,4].

Below we shall first review the solution [4] of this class of magnetic models. In the last section we shall discuss related compact models which may be used for string compactifications and the issue of supersymmetry breaking induced by 'magnetic' twist parameters.

Before turning to closed string theory let us first recall the solution of similar uniform magnetic field problems in particle (field) theory and open string theory.

1.1. Point particles and open strings in magnetic field

The reason why the quantum-mechanical or field-theoretical problem of a particle in a uniform abelian (electro)magnetic field is exactly solvable is that the action $I = \int d\tau[\dot{x}^\mu \dot{x}^\mu + ie\dot{x}^\mu A_\mu(x)]$ (which determines the Hamiltonian in quantum mechanics and the heat kernel in field theory) becomes gaussian if the field strength is constant, $A_\mu = -\frac{1}{2}F_{\mu\nu}x^\nu$, $F_{\mu\nu} = const.$ Assuming the magnetic field is directed along x^3-axis (so that $F_{ij} = H\epsilon_{ij}$, $i,j = 1,2$) and introducing $x = x_1 + ix_2$, $a = -i(\partial_x^* + \frac{1}{4}eHx)$, $a^\dagger = -i(\partial_x - \frac{1}{4}eHx^*)$, $[a, a^\dagger] = \frac{1}{2}eH$, one can reduce the corresponding quantum-mechanical problem to a free oscillator one. The resulting energy spectrum is the special ($S = 0$) case of the Landau spectrum for a particle of charge e, mass M_0 and third component of the spin S (we assume $eH > 0$)

$$E^2 = M_0^2 + p_3^2 - 2eHJ \ , \quad J \equiv -l - \tfrac{1}{2} + \tfrac{1}{2}gS \ , \quad l = 0, 1, 2, \ldots \ . \qquad (1.1)$$

Here l is the Landau level number (which replaces the continuous momenta p_1, p_2) and g is the gyromagnetic ratio which is $1/S$ for minimally coupled particles but can be equal to 2 for non-minimally coupled ones. Thus E^2 can become negative for large enough values of H, e.g., $H > H_{crit} = M_0^2/e$ for spin 1 charged states. That applies, for example, to W-bosons in the context of electroweak theory [5] suggesting the presence of a transition to a phase with a W-condensate. In the case of unbroken gauge theory with massless charged vector particles the instability is present for any (e.g., infinitesimal) value of the magnetic field [5]. This infra-red instability of a magnetic background is not cured by supersymmetry, i.e. it remains also in supersymmetric gauge theories (e.g., in ultra-violet finite $N = 4$ supersymmetric Yang-Mills theory) since the small fluctuation operator for the gauge field $-\delta_{\mu\nu}D^2 - 2F_{\mu\nu}$ still has negative modes due to the 'anomalous magnetic moment' term. This is not surprising given that the magnetic spin-dependent coupling breaks supersymmetry.

The meaning of this instability is that the expansion is carried out near a classical solution of the Yang-Mills equations (abelian $A_i = -\frac{1}{2}H\epsilon_{ij}x^j$ belonging to the Cartan subalgebra) which is *not* a vacuum one: the energy is proportional to H^2 and thus is minimal for $H = 0$. As a result, a non-zero magnetic field will tend to dissipate. The presence of tachyonic modes in the magnetic background with infinitesimal (but non-vanishing H) does not indicate an instability of the trivial vacuum but only that of a configuration with $H \neq 0$ (this corresponds to a resummation of the expansion in small perturbations near the trivial vacuum).

The solution of the uniform magnetic field problem in the open string theory is similar to the one in the particle case. Indeed, the open string is coupled to the (abelian) vector field only at its ends, $I = \frac{1}{4\pi\alpha'}\int d^2\sigma\ \partial_a x^\mu \partial^a x^\mu + ie\int d\tau\ A_\mu(x)\dot{x}^\mu$, and thus for the abelian background $A_\mu = -\frac{1}{2}F_{\mu\nu}x^\nu$ the resulting gaussian path integral can be computed exactly [6]. This is a consistent 'on-shell' problem since $F_{\mu\nu} = \text{const}$ is an exact solution of the effective field equations of the open string theory. The corresponding 2d world-sheet theory is a conformal field theory [7] which can be solved explicitly in terms of free oscillators (thus representing a string generalization of the Landau problem in quantum particle mechanics). As a result, one is able to determine the spectrum of an open string moving in a constant magnetic field [7,8,9]. The Hamiltonian (L_0) of the open (super)string in a constant magnetic field is given by [7,9]

$$\hat{\mathcal{H}} = \tfrac{1}{2}\alpha'\big(-E^2 + p_\alpha^2\big) + \hat{N} - \gamma\hat{J}\ , \tag{1.2}$$

$$\hat{\gamma} \equiv \frac{2}{\pi}\Big|\arctan\big(\tfrac{1}{2}\alpha'\pi e_1 H\big) + \arctan\big(\tfrac{1}{2}\alpha'\pi e_2 H\big)\Big|\ , \quad 0 \leq \hat{\gamma} < 1\ .$$

Here e_1, e_2 are charges at the two ends of the string and H is the magnetic field, $F_{ij} = H\epsilon_{ij}$. $\hat{N} = 0, 1, 2...$ is the number of states operator and $\hat{J} = -l - \frac{1}{2} + S$ is the angular momentum operator of the open string in the $(1,2)$ plane. The energy spectrum is found from the constraint $\hat{\mathcal{H}} = 0$ and for small $e_i H$ is in agreement with (1.1) with $g = 2$. A novel feature of this spectrum as compared to the free (super)string one is the presence of tachyonic states above certain critical values of the magnetic field ($H_{crit} \sim \alpha'^{-1}\hat{N}/S \sim \alpha'^{-1}$). Thus the constant magnetic field background is unstable in the open string theory (as it is in the non-abelian gauge theory). A qualitative reason for this instability is that the free open string spectrum contains electrically charged higher spin massive particle states and the latter have (approximately) the Landau spectrum (1.1) ($\hat{\gamma} \approx \alpha'(e_1 + e_2)H$ for a weak field). The tachyonic states appear only in the bosonic (Neveu-Schwarz) sector and only on the leading Regge trajectory ($l = 0$, maximal S for a given mass level $\hat{N}$, $S = \hat{N} + 1$).

1.2. Closed strings and Melvin-type magnetic flux tube backgrounds

Similar background magnetic field problem is also exactly solvable in *closed* (super)string theories [10,3,4]. This may be unexpected since the abelian vector field is now coupled to the internal points of the string, and such interaction terms, e.g., $\Delta L = \partial y \bar{\partial} y + A_\mu(x) \partial x^\mu \bar{\partial} y + \tilde{A}_\mu(x) \bar{\partial} x^\mu \partial y + \ldots$, do not become gaussian for $A_\mu = -\frac{1}{2} F_{\mu\nu} x^\nu$. Here $y \in (0, 2\pi R)$ is a compact internal Kaluza-Klein coordinate that 'charges' the string. The spectrum of the closed string compactified on a circle contains states with arbitrarily large masses, spins *and* charges $Q_{L,R} = mR^{-1} \pm w\alpha'^{-1} R$, $(m, w = 0, \pm 1, \ldots)$. One difference compared to the open string case is that there are infinitely many possible values of charges. Another is that both Q_L and Q_R are, in general, non-vanishing and coupled to (a combination of) two abelian vector fields ($G_{5\mu}$ and $B_{5\mu}$).[1]

The important observation is that in contrast to the tree level abelian open string case, the $F_{\mu\nu} =$ const background in flat space does not represent a solution of a *closed* string theory, i.e. the above interaction terms added to the free string Lagrangians do not lead to conformally invariant 2d σ-models. Since the closed string theory contains gravity, a uniform magnetic field, which has a non-vanishing energy, must curve the space (as well as possibly induce other 'massless' background fields). One should thus first find a consistent conformal model which is a closed string analogue of the uniform magnetic field background in the flat space field (or open string) theory and then address the question of its solvability. Remarkably, it turns out that extra terms which should be added to the closed string action in order to satisfy the conformal invariance condition (i.e. to satisfy the closed string effective field equations) produce solvable 2d models. Like the particle and open string models, these models are exactly solvable in terms of free oscillators (one is able to find explicitly the spectrum, partition function, etc).

A simple example of an approximately uniform magnetic field background in the Einstein-Maxwell theory is the static cylindrically symmetric Melvin 'magnetic universe' or 'magnetic flux tube' solution [1]. It has R^4 topology and can be considered [12] as a gravitational analogue of the abelian Higgs model vortex [13] with the magnetic pressure (due to repulsion of Faraday's flux lines) being balanced not by the Higgs field but by the gravitational attraction. The magnetic field is approximately constant inside the tube and decays to zero at infinity in the direction orthogonal to x_3-axis. The space is not, however, asymptotically euclidean: the (ρ, φ) 2-plane orthogonal to x_3 asymptotically closes at large ρ (so the solution should be interpreted not as a flux tube embedded in an approximately flat space, but rather as a 'magnetic universe'). Several interesting features of the Melvin solution in the context of Kaluza-Klein (super)gravity (e.g., instability against monopole or magnetic black hole pair creation) were discussed in [12,14,15].

---

[1] As a result, the gyromagnetic ratio of closed string states is $g \leq 2$, e.g., $g = 1$ for standard non-winding Kaluza-Klein states [11,3].

4. Covariant Double-null Dynamics

The classic analysis of Arnowitt, Deser and Misner [15] formulates gravitational dynamics in terms of the evolution of a spatial 3-geometry. The geometrical framework is the imbedding formalism of Gauss and Codazzi for the foliation of spacetime by spacelike hypersurfaces.

Quite often, however, —as in the analysis of Cauchy horizon singularities, but also in other contexts—one encounters circumstances where a lightlike foliation is especially suitable. Because of various degeneracies that arise in the lightlike case, the imbedding relations are quite different and the situation not quite as familiar and under control. To bypass the degeneracies, one is forced to fall back to a foliation of co-dimension 2, by spacelike 2-surfaces.

Several such (2+2)-formalisms are extant, notably Geroch, Held and Penrose [16], d'Inverno and Smallwood [17] and Hayward [18]. Of course, all have basically the same content, but they take very different forms.

The distinguishing feature of the approach I shall present here is that it maintains manifest two-dimensional covariance and operates directly with geometrically significant objects. Two-dimensional covariance permits reduction of the Einstein field equations to an especially concise and geometrically transparent form: the ten Ricci components are embraced in a set of just three compact, two-dimensionally covariant expressions.

$(2 + 2)$-formalisms are a versatile tool having a range of applications which go far beyond the specific problem of Sec. 3. They are useful in the analysis and numerical integration of the characteristic initial-value problem of general relativity, the dynamics of strings, of real and apparent horizons, the study of Planck-energy collisions and light-cone quantization. The covariant formalism has been applied by our group ([20]) to elucidate the singular geometry of the black hole Cauchy horizon.

5. Basic Metric Notions

I shall briefly sketch the elements of the formalism.

We consider a double foliation of spacetime by a net of two intersecting families of lightlike hypersurfaces Σ^0 (with equations $u^0 =$ const.) and Σ^1 (given by $u^1 =$ const.), where $u^A(x^\alpha)$ $(A, B, \ldots, = 0, 1;\ \alpha, \beta, \ldots, = 1, \ldots, 4)$ are a given pair of scalar fields over spacetime, with lightlike gradients:

$$\nabla u^A \cdot \nabla u^B = e^{-\lambda} \eta^{AB},$$

and where the matrix

$$\eta^{AB} = \eta_{AB} = \begin{pmatrix} 0 & -1 \\ -1 & 0 \end{pmatrix}$$

will be used to raise and lower upper-case Latin indices, and $\lambda(x^\alpha)$ is a scalar function. The generators $\ell^{(A)}_\alpha$ of Σ^A are conveniently defined as

$$\ell^{(A)} = e^\lambda \nabla u^A.$$

Two hypersurfaces Σ^0 and Σ^1 intersect in a 2-surface S, with parametric equations

$$x^\alpha = x^\alpha(u^A, \theta^a) \qquad (a, b, \cdots = 2, 3)$$

where (θ^2, θ^3) are intrinsic co-ordinates of S. Both generators $\ell^{(A)}$ are orthogonal to S.

Holonomic basis vectors $e_{(a)}$ and the intrinsic metric of S may now be defined:

$$e^\alpha_{(a)} = \frac{\partial x^\alpha}{\partial \theta^a}, \qquad g_{ab} = e_{(a)} \cdot e_{(b)}.$$

The matrix g_{ab} and its inverse g^{ab} are used to lower and raise lower-case Latin indices, so that $e^{(a)} = g^{ab} e_{(b)}$ are the dual basis vectors tangent to S.

Two-dimensional shift vectors s^a_A are defined by

$$s^a_A = \frac{\partial x^a}{\partial u^A}\, e^{(a)}_\alpha = -\ell^\alpha_{(A)}\, \frac{\partial \theta^a}{\partial x^\alpha}.$$

As in the Arnowitt-Deser-Misner formalism, the shift vector s^a_A measures how much one has to deviate from the normal direction $\ell_{(A)}$ to connect points on different 2-surfaces having the same intrinsic co-ordinates θ^a. An infinitesimal four-dimensional displacement dx^α can be decomposed as

$$dx^\alpha = \ell^\alpha_{(A)} du^A + e^\alpha_{(a)}(d\theta^a + s^a_A du^A).$$

Together with the completeness relation

$$g_{\alpha\beta} = e^{-\lambda}\eta_{AB}\ell^{(A)}_\alpha \ell^{(B)}_\beta + g_{ab} e^{(a)}_\alpha e^{(b)}_\beta$$

for the basis $(\ell^{(A)}, e_{(a)})$, this implies that the spacetime metric is decomposable as

$$g_{\alpha\beta}dx^\alpha\, dx^\beta = e^\lambda \eta_{AB} du^A\, du^B + g_{ab}(d\theta^a + s^a_A du^A)(d\theta^b + s^b_B\, du^B).$$

6. Covariant Geometrical Objects Embodying First Derivatives of Metric

Associated with its two normals $\ell_{(A)}$, a 2-surface S has two extrinsic curvatures, defined by

$$K_{Aab} = (\nabla_\beta \ell_{(A)\alpha}) e^\alpha_{(a)}\, e^\beta_{(b)}$$

and easily shown to be symmetric in a, b. (Since we are free to rescale the null vectors $\ell_{(A)}$, a certain scale-arbitrariness is inherent in this definition.)

A further basic geometrical property of the double foliation is given by the Lie bracket of $\ell_{(0)}$ and $\ell_{(1)}$. One finds

$$[\ell_{(B)}, \ell_{(A)}] = \epsilon_{AB}\omega^a e_{(a)} \tag{4}$$

where

$$\omega^a = \epsilon^{AB}(\partial_B s^a_A - s^b_B s^a_{A;b}),$$

the semicolon indicates two-dimensional covariant differentiation associated with metric g_{ab}, and ϵ_{AB} is the two-dimensional permutation symbol.

These are the "simplest" equations in the following sense: Among non-trivial gauge covariant expressions, the left side of the first equation is the only one which is at most linear in E and A; that of the second is the only one that is at most linear in E and quadratic in A; and, that of the third is the only one that is at most quadratic in each of E and A. (There is no gauge covariant expression which is linear in A and at most quadratic in E.) Somewhat surprisingly, the first two equations provide us precisely with the 6 of 7 constraints of general relativity: the Gauss constraint $\mathcal{G}_i$ which generates internal frame rotations and the vector constraint $\mathcal{V}_b$ that generates spatial diffeomorphisms [12]. The third equation is almost –but not quite– the last (scalar or Hamiltonian) constraint we seek. To see this, let us translate it in to geometrodynamical variables. It then reduces to the familiar *Euclidean* Hamiltonian constraint [13]

$$R + K^{ab}K_{ab} - K^2 = 0, \tag{3a}$$

rather than the Lorentzian Hamiltonian constraint

$$R - K^{ab}K_{ab} + K^2 = 0, \tag{3b}$$

which, as one might expect, carries opposite signs in front of terms which are quadratic in momenta. (Intuitively, the "Wick" rotation should map the momentum to i times the momentum.) The Gauss and the vector constraints are insensitive to the signature.

To get the Lorentzian theory, the most straightforward avenue is to consider *complex* connections ${}^{\mathbb{C}}A_a{}^i := \Gamma_a^i - iK_a^i$. This avenue has been pursued vigorously in the literature [8-11]. In this article, however, I will present another possibility which has arisen from a recent idea of Thomas Thiemann's and which may allow one to pass from the solutions to the Euclidean quantum constraints to the Lorentzian ones via a generalized Wick transformation. This strategy will be discussed in Section 5. For the moment, let us note only that $SU(2)$ connections can be regarded as the configuration variables also in general relativity. Thus, the classical configuration space is $\mathcal{A}/\mathcal{G}$, the space of suitably smooth connections modulo gauge transformations. Our task is to find the corresponding quantum configuration space and to develop functional calculus on it.

I will conclude this discussion with a curiosity: The Euclidean signature seems to be easier to handle in other approaches as well, in particular, Connes' non-commutative geometry and string theory. In the Connes' "geometrization" of the standard model, one is naturally led to work with the Euclidean signature and the extension of the framework to the Lorentzian regime is still to be worked out. In string theory, while one can allow the target space geometry to be Lorentzian, in all the discussions that I am aware of, the world sheet is kept Euclidean. In perturbation theory off Minkowskian backgrounds, as far as the S-matrix theory is concerned, this seems like an obvious extension of the strategy one adopts in field theory. However, in non-perturbative contexts, such as the discussion of mirror symmetry, restriction to Riemannian world-sheets appears artificial from a physical the expression of the operator is a sum over intersections. At each intersection, the graph has a number of edges. So, all that the operator can do is to act on the copies of groups associated with these edges. That is, thanks to diffeomorphism invariance, the action of operators is reduced to simple algebraic operations in the representation theory of $SU(2)$!

2. Since the two operators are self-adjoint, one can compute their spectra. *They are purely discrete!* Each of the Penrose spin network state is an eigenstate of *both* the operators. The area operators reduce to a sum of $SU(2)$-Laplacians, each of which has the familiar eigenvalues $\sqrt{j(j+1)}$. The eigenvalue of the volume operator on these states is, however, zero [30, 28]. Thus, higher valent spin networks are essential. Both operators again leave the (finite dimensional) Hilbert space associated with any of these networks invariant. They can therefore be diagonalized separately on each network. (Already in the 4-valent case, there exist states with non-zero volume.) This overall picture shows that *the microscopic geometry at Planck scale is very different from what the continuum picture suggests.* As we argued in the Introduction, this basic fact may well be the essential reason why the perturbation theory fails.

3. The geometrical observables can be defined on the full phase space of the classical theory; one need not restrict oneself to the constraint surface. Similarly, in the quantum theory, the analogous operators have been defined on the kinematic Hilbert space H_o, before imposing quantum constraints. The results are thus robust; they are not sensitive to the details of quantum dynamics. For example, they will continue to hold also in supergravity, and more generally, in any theory in which the triads and connections feature as a basic canonical pair.

4. There is, however, a subtlety. To see this, recall a basic difference between quantum mechanics and quantum field theory. In quantum mechanics, kinematics and dynamics are largely decoupled in the sense the same representation of the canonical commutation relations supports all interesting Hamiltonians. In quantum field theory, on the other hand, kinematics and dynamics are always weakly coupled: there are infinitely many *inequivalent* representations of the canonical commutation relations and, in general, different Hamiltonians are meaningful on different representations. In the present case, then, the key question is whether the quantum constraints of a given theory can be meaningfully imposed on H_o. Results to date indicate (but do not yet prove) that this is likely to be the case for constraints of general relativity. My general expectation is that this will also be the case for a class of theories such as supergravity which are "near general relativity" as far as geometry is concerned. What we have here is a glimpse into the nature of quantum geometry underlying *this* class of quantum gravity theories.

5. Note that $\hat{A}(S)$ and $\hat{V}(R)$ have been defined for *any* surface S and *any* region R in Σ and will therefore not be Dirac observables; they are not expected to commute with the quantum constraints. To obtain Dirac observables, one would have to specify S and R *intrinsically.* (For example, if we had only the Gauss and the diffeomorphism constraints, the total volume of Σ would be a Dirac observable.) A natural strategy is to specify S and R using matter fields (see, e.g.,[31]). In view of the Hamiltonian constraint, the problem of providing an explicit specification of

the product of the principal curvatures

(/ 4 7! ! A! +J

(iii) By (19), the induced metric g_{ij} on a surface $r = r(u, v)$ is given by

$$g_{12} = \langle r_u, r_v \rangle, \qquad g_{11} = \langle r_u, r_u \rangle, \qquad g_{22} = \langle r_v, r_v \rangle.$$

It is then easy to verify that $g = g_{11}g_{22} - g_{12}^2 = |[r_u, r_v]|^2$, whence the result. ☐

Using Definition 7.4.1 to give us a definition of area in an arbitrary 2-dimensional space with a Riemannian metric, we see that the concept of area, like arc length and angle, is defined in terms of the scalar product of vectors attached to each point, or, what amounts to the same thing, the metric g_{ij}.

7.5. Exercises

1. The torus T^2 in Euclidean 3-space can be realized as the surface of revolution obtained by revolving a circle about a straight line which it does not intersect, and which lies in the same plane. Find parametric equations for this torus, and calculate the induced metric on it.
2. Find the first fundamental form of the ellipsoid of revolution
$$\frac{x^2}{a^2} + \frac{y^2 + z^2}{b^2} = 1.$$
3. Find the metric induced on the surface of revolution
$$r(u, \varphi) = (\rho(u) \cos \varphi, \rho(u) \sin \varphi, z(u)).$$
Verify that its meridians ($\varphi = \text{const.}$) and circles of latitude ($u = \text{const.}$) form an orthogonal net. Find those curves which bisect the angles between the meridians and circles of latitude.
4. Find those curves on a sphere which intersect the meridians at a fixed angle α ("loxodromes"). Find the length of a loxodrome.
5. Let $F(x, y, z)$ be a smooth homogeneous function of degree n (i.e. $F(cx, cy, cz) = c^nF(x, y, z)$). Prove that away from the origin the induced metric on the conical surface $F(x, y, z) = 0$ is Euclidean.

§8. The Second Fundamental Form

8.1. Curvature of Curves on a Surface in Euclidean Space

Suppose we are given a surface in Euclidean 3-space and a non-singular point (x_0, y_0, z_0) on it. We shall assume initially that the z-axis is perpendicular to the tangent plane to the surface at the point (x_0, y_0, z_0), in which case the x-axis and y-axis will be parallel to it. The surface may then be given locally about (i.e. in a neighbourhood of) the point (x_0, y_0, z_0) by an equation of the form $z = f(x, y)$, where $z_0 = f(x_0, y_0)$ and

$$\left.\frac{\partial f}{\partial x}\right|_{\substack{x=x_0\\y=y_0}} = \left.\frac{\partial f}{\partial y}\right|_{\substack{x=x_0\\y=y_0}} = 0, \quad \text{i.e. grad } f\,|_{\substack{x=x_0\\y=y_0}} = 0. \tag{1}$$

We now consider the second differential of the function $z = f(x, y)$ (which we now assume has continuous second derivatives), i.e. $d^2l = f_{xx}\,dx^2 + 2f_{xy}\,dx\,dy + f_{yy}\,dy^2$. The matrix of this quadratic form, i.e. the matrix (a_{ij}) where $a_{ij} = f_{x^ix^j}$, $x^1 = x$, $x^2 = y$, is known as the *Hessian* of the function f.

8.1.1. Definition. Given a surface $z = f(x, y)$, and a point (x_0, y_0, z_0) on it at which grad $f = 0$, we define the *principal curvatures* of the surface at the point to be the eigenvalues of the matrix (a_{ij}) evaluated at the point. (These eigenvalues are real since (a_{ij}) is symmetric.) In addition we call $\det(a_{ij})$ at the point the *Gaussian curvature* K, and the trace of (a_{ij}), $\operatorname{tr}(a_{ij})$, at the point, the *mean curvature*, of the surface at (x_0, y_0, z_0).

Thus the eigenvalues k_1, k_2 say, of (a_{ij}) evaluated at (x_0, y_0, z_0) are the principal curvatures, while the Gaussian curvature is $K = k_1k_2 = a_{11}a_{22} - a_{12}a_{21}$, and the mean curvature is $a_{11} + a_{22} = k_1 + k_2$. As we shall see later (in Chapter 4), the Gaussian curvature of the surface is an "intrinsic" invariant of the surface, i.e. depends only on the internal metrical properties of the surface; this is Gauss' famous "Theorema Egregium."

The disadvantage of Definition 8.1.1 is that it tells us what the curvatures at a point of the surface are in terms of a rather special co-ordinate system, influenced by the point under scrutiny in that the z-axis was chosen perpendicular to the surface at the point. To define these quantities in terms of arbitrary co-ordinates, we turn to the theory of the curvature of curves lying in the surface.

Thus suppose the surface given in parametric form

$$r = r(u, v). \tag{2}$$

We saw in §7.3 that the vector $[r_u, r_v]$ is normal to the surface at each non-singular point; hence if m denotes a unit vector in the same direction, then $[r_u, r_v] = |[r_u, r_v]|m$. If now $r = r(u(t), v(t))$ is a curve on the surface, then we have $\dot{r} = r_u\dot{u} + r_v\dot{v}$, and

$$\ddot{r} = (r_{uu}\dot{u}^2 + 2r_{uv}\dot{u}\dot{v} + r_{vv}\dot{v}^2) + (r_u\ddot{u} + r_v\ddot{v}).$$

Using $r_u \perp m$ and $r_v \perp m$, we deduce that

$$\langle \ddot{r}, m\rangle = \langle r_{uu}, m\rangle\dot{u}^2 + 2\langle r_{uv}, m\rangle\dot{u}\dot{v} + \langle r_{vv}, m\rangle\dot{v}^2 = b_{11}\dot{u}^2 + 2b_{12}\dot{u}\dot{v} + b_{22}\dot{v}^2. \tag{3}$$

From (3) we conclude that: *In terms of local co-ordinates $u = x^1$, $v = x^2$ the projection $\langle \ddot{r}, m\rangle$ of the acceleration vector $\ddot{r}$ on the normal to the surface, is a quadratic form in the components $\dot{u}$, $\dot{v}$ of the tangent vector.*

If we put $b_{11} = L$, $b_{12} = M$, $b_{22} = N$, then in terms of differentials (3) can be rewritten as

$$\langle \ddot{r}, m\rangle\, dt^2 = b_{ij}\, dx^i\, dx^j = L(du)^2 + 2M\, du\, dv + N(dv)^2. \tag{4}$$

We call this expression for $\langle \ddot{r}, m\rangle\, dt^2$, the *second fundamental form of the surface* (2). (Note that its coefficients L, M, N depend only on the point of the surface under scrutiny, and not on the curve $r = r(u(t), v(t))$.)

Suppose now that the curve $r = r(u(t), v(t))$ is parametrized by the natural parameter, i.e. $t = l$, where l is arc length. (Thus with this parametrization the curve is a "unit-speed curve.") By the first of the Serret–Frenet formulae (see 5.2.3), we have

$$\ddot{r} = \frac{d^2 r}{dl^2} = kn,$$

where n is the principal normal to the curve, and k is its curvature. Hence $\langle \ddot{r}, m\rangle = k\langle n, m\rangle = k \cos \theta$, where θ is the angle between the unit vectors m and n. From this and (4) we obtain

$$k \cos \theta (dl)^2 = \langle \ddot{r}, m) \, dl^2 = L(du)^2 + 2M\, du\, dv + N(dv)^2 = b_{ij}\, dx^i\, dx^j.$$

Comparing this with the formula for the induced metric on the surface:

$$dl^2 = g_{ij}\, dx^i\, dx^j = E(du)^2 + 2F\, du\, dv + G(dv)^2,$$

where $u = x^1$, $v = x^2$, we conclude that

$$k \cos \theta = \frac{b_{ij}\dot{x}^i \dot{x}^j}{g_{ij}\dot{x}^i \dot{x}^j},$$

where here the dots denote differentiation with respect to any parameter t. In the convenient differential notation we may rewrite this as

$$k \cos \theta = \frac{b_{ij}\, dx^i\, dx^j}{g_{ij}\, dx^i\, dx^j}, \qquad x^1 = u, \quad x^2 = v, \tag{5}$$

(although, as usual with this notation, we need to bear in mind that strictly speaking here dx^i is not an independent differential, but just $\dot{x}^i\, dt$).

We restate (5) in words, as a

8.1.2. Theorem. *The curvature at a point of a curve on a surface in Euclidean 3-space, when multiplied by the cosine of the angle between the normal to the surface and the principal normal of the curve at the point, is the same as the ratio of the second and first fundamental forms in the components of the tangent vector to the curve at the point.*

8.1.3. Corollary. *If the curve is obtained by sectioning the surface with a plane normal to the surface at the point, then (since* $\cos\theta = \pm 1$*) the corresponding "normal curvature" is given by*

$$k = \frac{b_{ij}\dot{x}^i\dot{x}^j}{g_{ij}\dot{x}^i\dot{x}^j} \tag{6}$$

(where here we allow k to be negative if m and n have opposite directions).

8.2. Invariants of a Pair of Quadratic Forms

Our main achievement so far in this chapter, is the association with each point of a surface in Euclidean 3-space, of the pair of quadratic ("fundamental") forms

$$dl^2 = g_{ij}\,dx^i\,dx^j, \tag{7}$$

$$\langle \ddot{r}, m\rangle\,dt^2 = b_{ij}\,dx^i\,dx^j, \tag{8}$$

the first of which is positive definite. Our aim is to deduce from these quadratic forms invariants of the surface. What are the known algebraic invariants of a pair of quadratic forms?

To answer this, consider any pair of quadratic forms in the plane with co-ordinates x, y, having matrices relative to these co-ordinates

$$G = \begin{pmatrix} g_{11} & g_{12} \\ g_{21} & g_{22} \end{pmatrix}, \qquad Q = \begin{pmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \end{pmatrix}, \tag{9}$$

(using the same symbols as in (7) and (8)), where G is positive definite and $g_{12} = g_{21}$, $b_{12} = b_{21}$. (Note that in contrast with the general context of (7) and (8), the g_{ij} and b_{ij} are assumed here to be fixed numbers.) Next consider the equation

$$\det(Q - \lambda G) = 0, \tag{10}$$

which, when written out in detail, becomes

$$(b_{11} - \lambda g_{11})(b_{22} - \lambda g_{22}) - (b_{12} - \lambda g_{12})^2 = 0. \tag{11}$$

We call the roots λ_1, λ_2 of this equation *the eigenvalues of the pair of quadratic forms.*

For each $i = 1, 2$ we look for solutions of the system of equations

$$\left.\begin{aligned}(b_{11} - \lambda_i g_{11})\xi_i^1 + (b_{12} - \lambda_i g_{12})\xi_i^2 = 0,\\ (b_{12} - \lambda_i g_{12})\xi_i^1 + (b_{22} - \lambda_i g_{22})\xi_i^2 = 0,\end{aligned}\right\} \tag{12}$$

in the unknowns ξ_i^1, ξ_i^2. Since λ_1, λ_2 satisfy (11), the coefficient matrix of each of the systems (12) is singular, so that there exist non-trivial solutions, say

$$f_1 = \xi_1^1 e_1 + \xi_1^2 e_2, \qquad f_2 = \xi_2^1 e_1 + \xi_2^2 e_2,$$

(/B 5 ! ! ! > !" !

and all solutions will be scalar multiples of the appropriate one of f_1, f_2 (i.e. the solution space of (12) has dimension 1). The directions of the vectors f_1 and f_2 are called the *principal directions* in the plane of the pair of quadratic forms, that of f_1 corresponding to λ_1, and that of f_2 to λ_2.

We now equip our plane with a scalar product defined in terms of the positive definite quadratic form with matrix G, by setting $\langle e_i, e_j \rangle = g_{ij}$, where $e_1 = (1, 0)$, $e_2 = (0, 1)$.

8.2.1. Lemma. *If the eigenvalues of the pair of quadratic forms* (9) *are distinct, then the principal directions are orthogonal.*

Proof. We wish to show that the two vectors $f_1 = \xi_1^1 e_1 + \xi_1^2 e_2$ and $f_2 = \xi_2^1 e_1 + \xi_2^2 e_2$ are orthogonal, i.e. that

$$\langle f_1, f_2 \rangle = g_{ij}\xi_1^i \xi_2^j = 0.$$

Multiplying the first of the equations (12), with $i = 1$, by ξ_2^1, and the second by ξ_2^2, we obtain

$$(b_{11} - \lambda_1 g_{11})\xi_1^1\xi_2^1 + (b_{12} - \lambda_1 g_{12})\xi_1^2\xi_2^1 = 0,$$

$$(b_{11} - \lambda_1 g_{12})\xi_1^1\xi_2^2 + (b_{22} - \lambda_1 g_{22})\xi_1^2\xi_2^2 = 0.$$

On adding these equations we get

$$b_{ij}\xi_1^i\xi_2^j - \lambda_1 g_{ij}\xi_1^i\xi_2^j = 0. \tag{13}$$

If now we take $i = 2$ in the equations (12), and multiply the first of them by ξ_1^1 and the second by ξ_1^2, and again add the resulting equations, we obtain

$$b_{ij}\xi_1^i\xi_2^j - \lambda_2 g_{ij}\xi_1^i\xi_2^j = 0. \tag{14}$$

Finally, subtracting (13) from (14), and using the hypothesis that $\lambda_1 \neq \lambda_2$, we obtain the desired conclusion. ☐

This lemma may be regarded as a variant of the theorem from linear algebra which states that a real quadratic form assumes diagonal form relative to a suitable orthogonal basis; hence a real quadratic form can be brought to diagonal form by a rotation of the given orthogonal co-ordinate system.

8.3. Properties of the Second Fundamental Form

We now return to the first and second fundamental forms of a surface $r = r(u, v)$ in Euclidean 3-space:

$$dl^2 = g_{ij}dx^i\,dx^j, \tag{15}$$

$$\langle \ddot{r}, m \rangle\, dt^2 = b_{ij}dx^i\,dx^j, \qquad x^1 = u, \quad x^2 = v. \tag{16}$$

Recall that the ratio of these quadratic forms in the components of the tangent vector to the section of the surface by a plane orthogonal to the surface at a point (i.e. a "normal section"), gives the curvature of the section (i.e. "normal curvature") at that point (Corollary 8.1.3).

Having at our disposal the concepts introduced in the preceding subsection, we can now formulate the general definition of the principal, Gaussian, and mean curvatures of a surface at a point.

8.3.1. Definition. The eigenvalues of the pair of quadratic forms (15) and (16) (see §8.2) are called the *principal curvatures* of the surface at the point under investigation. The product of the principal curvatures is called the *Gaussian curvature* K of the surface at the point, and their sum the *mean curvature*.†

8.3.2. Example. As at the beginning of §8.1 (see especially 8.1.1), we suppose we are given our surface in the form $z = f(x, y)$, and further that at the point (x_0, y_0, z_0) of it under study, $f_x = f_y = 0$ (i.e. that the z-axis is perpendicular to the tangent plane to the surface at (x_0, y_0, z_0)). Putting $x = u$, $y = v$, the first and second fundamental forms at the point (x_0, y_0, z_0) are given by

$$g_{11} = 1, \qquad g_{22} = 1, \qquad g_{12} = g_{21} = 0 \qquad (g_{ij} = \delta_{ij}), \tag{17}$$

$$\begin{aligned} L = b_{11} &= \langle r_{uu}, m\rangle = f_{xx}(x_0, y_0), \\ M = b_{12} &= \langle r_{uv}, m\rangle = f_{xy}(x_0, y_0), \\ N = b_{22} &= \langle r_{vv}, m\rangle = f_{yy}(x_0, y_0). \end{aligned} \tag{18}$$

(Here of course the unit normal m to the surface at (x_0, y_0, z_0) is in the direction of the positive z-axis.) Thus at the point under scrutiny, the second fundamental form of the surface is

$$b_{11}\,dx^2 + 2b_{12}\,dx\,dy + b_{22}\,dy^2 = f_{xx}\,dx^2 + 2f_{xy}\,dx\,dy + f_{yy}\,dy^2 = d^2 f,$$

so that since $g_{ij} = \delta_{ij}$, the principal curvatures are the eigenvalues λ_1, λ_2 of the matrix

$$\begin{pmatrix} f_{xx} & f_{xy} \\ f_{xy} & f_{yy} \end{pmatrix}, \tag{19}$$

i.e. the roots of the equation $(f_{xx} - \lambda)(f_{yy} - \lambda) - (f_{xy})^2 = 0$, and the Gaussian curvature is $f_{xx}f_{yy} - (f_{xy})^2$, the determinant of the Hessian (19) of the function f. The mean curvature is $f_{xx} + f_{yy} = \lambda_1 + \lambda_2$. Thus our general Definition 8.3.1 does agree with the earlier one (8.1.1) where the various curvatures were defined in terms of a co-ordinate system dependent (as in the present example) very much on the particular point under consideration.

---

† It is perhaps more usual to define the mean curvature as the arithmetic mean of the principal curvatures.

Continuing with our example, let us now consider the principal directions at our point, of the pair of quadratic forms given by (17) and (18). As defined in the preceding subsection (see (12)), these are (the directions of) the non-zero vectors in the (x, y)-plane $f_1 = (\xi_1^1, \xi_1^2)$ and $f_2 = (\xi_2^1, \xi_2^2)$, where ξ_i^1, ξ_i^2 are non-trivial solutions of the following system of linear equations ($i = 1, 2$):

$$(f_{xx} - \lambda_i \delta_{11})\xi_i^1 + (f_{xy} - \lambda_i \delta_{12})\xi_i^2 = 0,$$
$$(f_{xy} - \lambda_i \delta_{12})\xi_i^1 + (f_{yy} - \lambda_i \delta_{22})\xi_i^2 = 0.$$

If we assume that the eigenvalues λ_1, λ_2 are distinct, then by Lemma 8.2.1, we have $f_1 \perp f_2$ (in the usual Euclidean sense since $g_{ij} = \delta_{ij}$). Hence we can replace the co-ordinate system x, y by a new system x', y', with axes in the principal directions, obtained from the old system by means of a rotation of the (x, y)-plane through an angle φ. Then in terms of the new co-ordinates x', y', z, we have

$$z = f(x(x', y'), y(x', y')),$$

where $x = x' \cos\varphi + y' \sin\varphi$, $y = -x' \sin\varphi + y' \cos\varphi$. Relative to these new co-ordinates, the second fundamental form becomes (at the point (x_0, y_0, z_0))

$$\lambda_1 (dx')^2 + \lambda_2 (dy')^2.$$

By Corollary 8.1.3, the curvature at our point (x_0, y_0, z_0) of a normal section of the surface through that point (i.e. the "normal curvature" at the point) is therefore

$$k = \frac{\lambda_1 (\dot{x}')^2 + \lambda_2 (\dot{y}')^2}{(\dot{x}')^2 + (\dot{y}')^2}, \tag{20}$$

where we are taking the normal section to have parametric equations $x' = x'(t)$, $y' = y'(t)$, $z = z(t)$.

Clearly the tangent vector to this normal section at the point (x_0, y_0, z_0) is $e = (\dot{x}', \dot{y}', 0)$. Hence the angle α between this tangent vector and the x'-axis satisfies

$$\cos^2\alpha = \frac{(\dot{x}')^2}{(\dot{x}')^2 + (\dot{y}')^2}, \qquad \sin^2\alpha = \frac{(\dot{y}')^2}{(\dot{x}')^2 + (\dot{y}')^2}. \tag{21}$$

From (20) and (21) we deduce that at the point (x_0, y_0, z_0), at least for our special choice of co-ordinates,

$$k = \lambda_1 \cos^2\alpha + \lambda_2 \sin^2\alpha.$$

This formula, called "Euler's formula," holds in any system of co-ordinates. We shall now prove this. (Thus our example ends here, although the argument we have used actually comprises the bulk of the proof.)

8.3.3. Theorem. *The curvature of a normal section* (*i.e. the* "*normal curvature*") *through a point on a surface, is given by the formula*

$$k = \lambda_1 \cos^2\alpha + \lambda_2 \sin^2\alpha, \tag{22}$$

where λ_1, λ_2 *are the principal curvatures of the surface at the point, and* α *is the angle between the tangent vector to the normal section at the point, and the principal direction corresponding to* λ_1.

PROOF. In Example 8.3.2 above we deduced Euler's formula in the case where the surface is given in the form $z = f(x, y)$, and the z-axis is perpendicular to the surface at the point (x_0, y_0, z_0) being studied. However since nothing of this special co-ordinate system is involved in the formula, for any particular (non-singular) point of the surface we simply choose a co-ordinate system with these properties (as we can, locally at least, by §7.1), i.e. so that the z-axis is normal to the surface at the point, and the x- and y-axes mutually orthogonal, and parallel to the tangent plane through the point (we may even choose them parallel to the principal directions). Then in a neighbourhood of the point the surface can be given by a function $z = f(x, y)$, with, of course, $f_x = f_y = 0$ at the point. Moreover if the x-axis and y-axis are chosen in the principal directions then $f_{xy} = f_{yx} = 0$, and $\lambda_1 = f_{xx}, \lambda_2 = f_{yy}$ at the point. We may then argue as in the example, provided $\lambda_1 \neq \lambda_2$ (which is assumed implicitly in the theorem since otherwise the principal directions remain undefined). This completes the proof. □

Note that if we reverse the direction of the z-axis in the above, then the signs of the principal curvatures are also reversed.

8.3.4. Corollary. *If* λ_1 *and* λ_2 *are the principal curvatures of a surface at a point and* $\lambda_1 > \lambda_2$, *then* λ_1 *and* λ_2 *are respectively the greatest and smallest values of the normal curvature (i.e. curvature of a normal section) at the point. (Here the signs are taken into account—see Corollary* 8.1.3.)

We next derive useful formulae for the second fundamental form and the Gaussian curvature in the case that the surface is given in the form $z = f(x, y)$ (but where we are no longer assuming a particular direction for the z-axis at any point). In that case, with $x = u$, $y = v$, and $r(u, v) = (u, v, f(u, v))$ we have

$$r_u = (1, 0, f_x), \qquad r_v = (0, 1, f_y),$$

$$[r_u, r_v] = (-f_x, -f_y, 1),$$

$$r_{uu} = (0, 0, f_{xx}), \qquad r_{uv} = (0, 0, f_{xy}), \qquad r_{vv} = (0, 0, f_{yy}),$$

$$m = \frac{[r_u, r_v]}{|[r_u, r_v]|} = \frac{(-f_x, -f_y, 1)}{\sqrt{1 + f_x^2 + f_y^2}}, \tag{23}$$

$$L = b_{11} = \frac{f_{xx}}{\sqrt{1 + f_x^2 + f_y^2}}, \qquad M = b_{12} = b_{21} = \frac{f_{xy}}{\sqrt{1 + f_x^2 + f_y^2}},$$

$$N = b_{22} = \frac{f_{yy}}{\sqrt{1 + f_x^2 + f_y^2}}.$$

Hence

$$b_{ij}\,dx^i\,dx^j = \frac{1}{\sqrt{1+f_{x^1}^2+f_{x^2}^2}}\,f_{x^ix^j}\,dx^i\,dx^j), \tag{24}$$
$$x^1 = u = x, \qquad x^2 = v = y.$$

Recall also the formulae (20) of §7 for the g_{ij}:

$$\begin{aligned} g_{11} &= 1 + f_x^2, \qquad g_{12} = g_{21} = f_x f_y, \qquad g_{22} = 1 + f_y^2, \\ g &= g_{11}g_{22} - g_{12}^2 = 1 + f_x^2 + f_y^2. \end{aligned} \tag{25}$$

We shall use formulae (24) and (25) in the proof of the following

8.3.5. Theorem. *The Gaussian curvature of a surface is equal to the ratio of the determinants of the second and the first fundamental forms:*

$$K = \frac{b_{11}b_{22} - b_{12}^2}{g_{11}g_{22} - g_{12}^2}. \tag{26}$$

In particular, if the surface is given in the form $z = f(x, y)$, then we have

$$K = \frac{f_{xx}f_{yy} - f_{xy}^2}{(1 + f_x^2 + f_y^2)^2}. \tag{27}$$

Proof. By definition, the principal curvatures λ_1, λ_2 are the solutions of equation (10) above:

$$\det(Q - \lambda G) = 0,$$

where $Q = (b_{ij})$ is the matrix of the second fundamental form, and $G = (g_{ij})$. Since the first fundamental form is positive definite, its matrix G is nonsingular. Hence

$$\det(Q - \lambda G) = \det G \det(G^{-1}Q - \lambda \cdot 1),$$

from which it follows that λ_1 and λ_2 are just the eigenvalues of the matrix $G^{-1}Q$. Since the product of the eigenvalues of a matrix is the same as the determinant (a fact we have used before!), we deduce that

$$K = \lambda_1\lambda_2 = \det(G^{-1}Q) = \frac{\det Q}{\det G},$$

which proves (26).

To get formula (27), simply substitute in (26) the expressions for the b_{ij} and g_{ij} given in (24) and (25). □

8.3.6. Corollary. *If a surface is given in the form $z = f(x, y)$, then the sign of the Gaussian curvature K is the same as the sign of the determinant $f_{xx}f_{yy} - f_{xy}^2$ of the Hessian of $f(x, y)$.*

8.3.7. Example. Suppose that we are given a surface in the form $z = f(x, y)$, where the function $f(x, y)$ is a solution of Laplace's equation $f_{xx} + f_{yy} = 0$. Then for all points of the surface we shall have $f_{xx}f_{yy} - f_{xy}^2 \leqq 0$, since $f_{xx} = -f_{yy}$. Hence by Corollary 8.3.6, at all points of the surface where at least one of the partial derivatives f_{xx}, f_{xy} is non-zero, we shall have that the Gaussian curvature $K < 0$.

Finally we explain the geometric significance of the sign of the Gaussian curvature at a point. As usual we choose a co-ordinate system x, y, z, with mutually orthogonal co-ordinate axes, such that the z-axis is perpendicular to the surface at the point (x_0, y_0, z_0). Then locally (about the point) the surface is given by a function $z = f(x, y)$, where $f_x = f_y = 0$. We consider three cases:

(i) $K > 0$; $\lambda_1 > 0, \lambda_2 > 0$. Since the smallest value of the normal curvature is positive, all values of it are positive, i.e. at the point the surface bends upwards in all directions, so the function $f(x, y)$ has a local minimum at the point (x_0, y_0) (see Figure 10(a)).

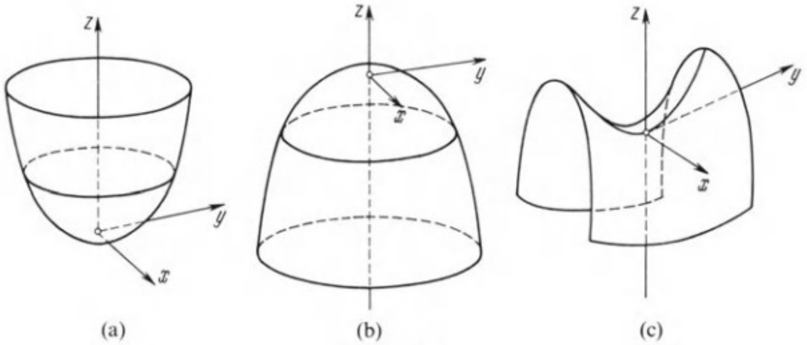
(ii) $K > 0$; $\lambda_1 < 0, \lambda_2 < 0$. The function $f(x, y)$ has a local maximum at (x_0, y_0) (see Figure 10(b)).

(iii) $K < 0$. In this case we must have $\lambda_1 > 0, \lambda_2 < 0$, or $\lambda_1 < 0, \lambda_2 > 0$. The function has a "saddle" or "pass" at the point (Figure 10(c)).

We conclude that: *If $K > 0$ there is a neighbourhood of the point throughout which the surface lies on one side of the tangent plane at the point. If $K < 0$ then the surface intersects the tangent plane at the point arbitrarily close to the point.*

If the Gaussian curvature is positive at every point of a surface, then we say that the surface is *strictly convex*.

Note that in the above, by using Corollary 8.3.6, and the fact that λ_1, λ_2 are the eigenvalues of the Hessian of $f(x, y)$ (since $g_{ij} = \delta_{ij}$ at the point), it is easy to see that cases (i) and (ii) are respectively equivalent to: $K > 0$; $f_{xx}, f_{yy} > 0$, and $K > 0$; $f_{xx}, f_{yy} < 0$. In this form, (i), (ii) and (iii) comprise the familiar "second-partials test" for determining the nature of a surface in a neighbourhood of a point at which the tangent plane is "horizontal."



(a) (b) (c)

is called the Gaussian curvature K of the surface at the point, and their sum the mean curvature.

Pag. 84 (99)-

8.3.5. Theorem

The Gaussian curvature of a surface is equal to the ratio of the determinants of the second and the first fundamental forms:

$$K = \frac{b_{11}\, b_{22} - b_{12}^2}{g_{11}\, g_{22} - g_{12}^2} . \;\ldots$$

Pág. 85 (100) 8.3.7. Example

Gaussian curvature $K < 0$

Finally we explain the geometric significance of the sign of the Gaussian curvature at a point.

Pág. 95 (110) the Language of Complex Numbers in Geometry

Then by partial analogy with Theorem 8.3.5, we define Gaussian curvature K of a space-like surface in R_1^3 by

('// %$ 9 9 7! ! A! ! ! >! !
" ! "!" "! ! (/

Hence

$$b_{ij}\,dx^i\,dx^j = \frac{1}{\sqrt{1 + f_{x^1}^2 + f_{x^2}^2}}\, f_{x^ix^j}\,dx^i\,dx^j), \tag{24}$$

$$x^1 = u = x, \qquad x^2 = v = y.$$

Recall also the formulae (20) of §7 for the g_{ij}:

$$\begin{aligned} g_{11} &= 1 + f_x^2, \qquad g_{12} = g_{21} = f_x f_y, \qquad g_{22} = 1 + f_y^2, \\ g &= g_{11}g_{22} - g_{12}^2 = 1 + f_x^2 + f_y^2. \end{aligned} \tag{25}$$

We shall use formulae (24) and (25) in the proof of the following

8.3.5. Theorem. *The Gaussian curvature of a surface is equal to the ratio of the determinants of the second and the first fundamental forms*:

$$K = \frac{b_{11}b_{22} - b_{12}^2}{g_{11}g_{22} - g_{12}^2}. \tag{26}$$

In particular, if the surface is given in the form $z = f(x, y)$, *then we have*

$$K = \frac{f_{xx}f_{yy} - f_{xy}^2}{(1 + f_x^2 + f_y^2)^2}. \tag{27}$$

PROOF. By definition, the principal curvatures λ_1, λ_2 are the solutions of equation (10) above:

$$\det(Q - \lambda G) = 0,$$

where $Q = (b_{ij})$ is the matrix of the second fundamental form, and $G = (g_{ij})$. Since the first fundamental form is positive definite, its matrix G is nonsingular. Hence

$$\det(Q - \lambda G) = \det G \det(G^{-1}Q - \lambda \cdot 1),$$

from which it follows that λ_1 and λ_2 are just the eigenvalues of the matrix $G^{-1}Q$. Since the product of the eigenvalues of a matrix is the same as the determinant (a fact we have used before!), we deduce that

$$K = \lambda_1\lambda_2 = \det(G^{-1}Q) = \frac{\det Q}{\det G},$$

which proves (26).

To get formula (27), simply substitute in (26) the expressions for the b_{ij} and g_{ij} given in (24) and (25). ☐

8.3.6. Corollary. *If a surface is given in the form* $z = f(x, y)$, *then the sign of the Gaussian curvature* K *is the same as the sign of the determinant* $f_{xx}f_{yy} - f_{xy}^2$ *of the Hessian of* $f(x, y)$.

8.3.7. Example. Suppose that we are given a surface in the form $z = f(x, y)$, where the function $f(x, y)$ is a solution of Laplace's equation $f_{xx} + f_{yy} = 0$. Then for all points of the surface we shall have $f_{xx}f_{yy} - f_{xy}^2 \leqq 0$, since $f_{xx} = -f_{yy}$. Hence by Corollary 8.3.6, at all points of the surface where at least one of the partial derivatives f_{xx}, f_{xy} is non-zero, we shall have that the Gaussian curvature $K < 0$.

Finally we explain the geometric significance of the sign of the Gaussian curvature at a point. As usual we choose a co-ordinate system x, y, z, with mutually orthogonal co-ordinate axes, such that the z-axis is perpendicular to the surface at the point (x_0, y_0, z_0). Then locally (about the point) the surface is given by a function $z = f(x, y)$, where $f_x = f_y = 0$. We consider three cases:

(i) $K > 0$; $\lambda_1 > 0$, $\lambda_2 > 0$. Since the smallest value of the normal curvature is positive, all values of it are positive, i.e. at the point the surface bends upwards in all directions, so the function $f(x, y)$ has a local minimum at the point (x_0, y_0) (see Figure 10(a)).

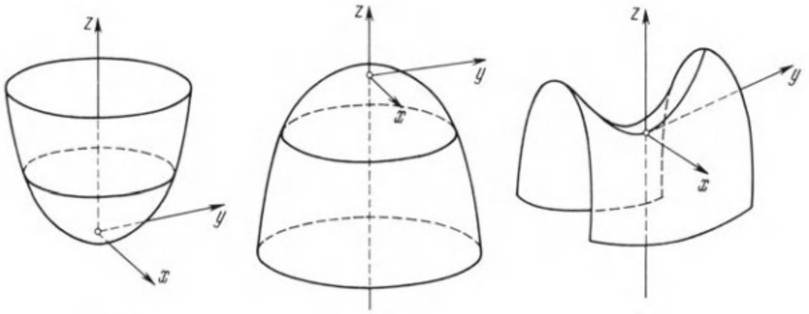
(ii) $K > 0$; $\lambda_1 < 0$, $\lambda_2 < 0$. The function $f(x, y)$ has a local maximum at (x_0, y_0) (see Figure 10(b)).

(iii) $K < 0$. In this case we must have $\lambda_1 > 0$, $\lambda_2 < 0$, or $\lambda_1 < 0$, $\lambda_2 > 0$. The function has a "saddle" or "pass" at the point (Figure 10(c)).

We conclude that: *If $K > 0$ there is a neighbourhood of the point throughout which the surface lies on one side of the tangent plane at the point. If $K < 0$ then the surface intersects the tangent plane at the point arbitrarily close to the point.*

If the Gaussian curvature is positive at every point of a surface, then we say that the surface is *strictly convex*.

Note that in the above, by using Corollary 8.3.6, and the fact that λ_1, λ_2 are the eigenvalues of the Hessian of $f(x, y)$ (since $g_{ij} = \delta_{ij}$ at the point), it is easy to see that cases (i) and (ii) are respectively equivalent to: $K > 0$; $f_{xx}, f_{yy} > 0$, and $K > 0$; $f_{xx}, f_{yy} < 0$. In this form, (i), (ii) and (iii) comprise the familiar "second-partials test" for determining the nature of a surface in a neighbourhood of a point at which the tangent plane is "horizontal."



(a) (b) (c)

Figure 10

where m is the unit normal to the surface (at the point under study). Then by partial analogy with Theorem 8.3.5, we define the *Gaussian curvature K of a space-like surface* in $\mathbb{R}_1^3$ by

$$K = -\frac{\det(b_{ij})}{\det(g_{ij})}. \tag{14}$$

(The minus sign is explained below.) It follows that if the surface is given in the form $t = f(x, y)$, with $1 - f_x^2 - f_y^2 > 0$ (see above), then (cf. §8.3 (27))

$$K = \frac{f_{xy}^2 - f_{xx}f_{yy}}{(1 - f_x^2 - f_y^2)^2}. \tag{15}$$

In particular for the hyperboloid $t^2 - x^2 - y^2 = 1$, we obtain $K \equiv -1$.

Remarks. 1. In Chapter 4 we shall compute the curvature of the Lobachevskian plane in terms of its intrinsic geometry. We shall again arrive at $K \equiv -1$, vindicating the choice of sign in the definition (14).

2. By analogy with the definition given in §8.3, we shall say that a space-like surface in $\mathbb{R}_1^3$ is *convex* if $K < 0$ at all points of the surface.

§11. The Language of Complex Numbers in Geometry

11.1. Complex and Real Co-ordinates

Many geometrical problems are most conveniently formulated and solved in terms of the language of complex numbers. We therefore expound here the simple facts about complex numbers that we shall be needing.

We denote by $\mathbb{C}^n$ the vector space of dimension n over the field of complex numbers $\mathbb{C}$. (A vector space is determined up to isomorphism by its dimension.) If $e_1, \ldots, e_n$ form a basis for this vector space, then every vector $\xi \in \mathbb{C}^n$ has the unique form

$$\xi = z^k e_k, \qquad z^k = x^k + iy^k, \tag{1}$$

where the z^k are the (complex) components.

We can regard $\mathbb{C}^n$ also as a $2n$-dimensional vector space $\mathbb{R}^{2n}$ over the reals; as a basis for this space we might then take

$$e_1, \ldots, e_n, ie_1, \ldots, ie_n. \tag{2}$$

Since

$$\xi = z^k e_k = x^k e_k + y^k(ie_k), \tag{3}$$

the real components of the vector ξ relative to the basis (2), are the numbers $x^1, \ldots, x^n, y^1, \ldots, y^n$. This process of going from a complex vector space to a real one is called *realization.*

The non-singular (i.e. invertible) linear transformations of the vector space $\mathbb{C}^n$ form a group, called the *general linear group of degree n over* $\mathbb{C}$, and denoted by $GL(n, \mathbb{C})$. This group is of course isomorphic to the group of $n \times n$ non-singular matrices with complex entries (so that, as usual, we shall often think of $GL(n, \mathbb{C})$ as consisting of matrices). Upon realization of $\mathbb{C}^n$, each of these transformations becomes a linear transformation of the real vector space $\mathbb{R}^{2n}$. This defines a monomorphism (i.e. one-to-one homomorphism)

$$r\colon GL(n, \mathbb{C}) \to GL(2n, \mathbb{R}), \tag{4}$$

called the *realization map.*

11.1.1. Example. In the case $n = 1$, our space is just the one-dimensional complex vector space $\mathbb{C}$ co-ordinatized by $z = x + iy$. The invertible linear transformations are just multiplications by a complex number $\lambda \neq 0$ (one such λ for each linear transformation):

$$z \mapsto \lambda z. \tag{5}$$

Writing $\lambda = a + ib$, $a^2 + b^2 \neq 0$, this takes the form

$$z = x + iy \mapsto (a + ib)(x + iy) = (ax - by) + i(bx + ay).$$

Hence the corresponding linear transformation of $\mathbb{R}^2$ has matrix

$$\begin{pmatrix} a & b \\ -b & a \end{pmatrix} = r(\lambda), \qquad a^2 + b^2 \neq 0. \tag{6}$$

Thus we see that certainly not all (invertible) linear transformation of $\mathbb{R}^2$ are obtained in this way from the complex linear transformations of $\mathbb{C}$; in other words, r is not onto.

This example generalizes to the n-dimensional case: It is not difficult to show that if Λ is a matrix in $GL(n, \mathbb{C})$, and $\Lambda = A + iB$ where A and B are real matrices, then

$$r(\Lambda) = \begin{pmatrix} A & B \\ -B & A \end{pmatrix}. \tag{7}$$

11.1.2 Exercise. Prove that $\det(r(\Lambda)) = |\det \Lambda|^2$.

Here is a quick proof of (7) which incidentally yields an alternative characterization of the matrices of the form $r(\Lambda)$, i.e. of the matrices occurring as images under the map $r\colon GL(n, \mathbb{C}) \to GL(2n, \mathbb{R})$. If Λ is any element of $GL(n, \mathbb{C})$, and ξ is any vector in $\mathbb{C}^n$, then

$$\Lambda(i\xi) = i\Lambda(\xi). \tag{8}$$

Now the linear transformation of $\mathbb{C}^n$ which simply multiplies each vector by the scalar i, goes under r to a linear transformation I of $\mathbb{R}^{2n}$, given by

$$r(i) = I = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \quad \text{where } 1 = n \times n \text{ identity matrix.} \tag{9}$$

(To see this consider the action of i on the basis vectors e_k, ie_k.) It follows from (8) that the matrix I commutes with the matrix $r(\Lambda)$ (since ξ was arbitrary). But then it is straightforward to check that matrices commuting with I must have the form $\begin{pmatrix} A & B \\ -B & A \end{pmatrix}$. We leave to the reader the verification that a matrix of this form does indeed arise from a "complex operator" on $\mathbb{C}^n$.

We conclude by mentioning an important subgroup of $GL(n, \mathbb{C})$, namely that consisting of all matrices of determinant 1, called the *special linear group of degree n over* $\mathbb{C}$, and denoted by $SL(n, \mathbb{C})$.

11.2. The Hermitian Scalar Product

We define a scalar product on the space $\mathbb{C}^n$ as follows:

$$\langle \xi_1, \xi_2 \rangle_{\mathbb{C}} = \sum_{k=1}^{n} z_1^k \bar{z}_2^k, \tag{10}$$

where $\xi_1 = z_1^i e_i$, $\xi_2 = z_2^i e_i$, and the bar indicates the complex conjugate. It follows that if $\xi = z^i e_i$, then

$$\langle \xi, \xi \rangle_{\mathbb{C}} = \sum_{k=1}^{n} |z^k|^2. \tag{11}$$

This scalar product has the following main properties:

$$\begin{gathered} \langle \lambda\xi, \eta \rangle_{\mathbb{C}} = \lambda \langle \xi, \eta \rangle_{\mathbb{C}}, \\ \langle \xi, \lambda\eta \rangle_{\mathbb{C}} = \bar{\lambda} \langle \xi, \eta \rangle_{\mathbb{C}}, \\ \langle \xi, \eta \rangle_{\mathbb{C}} = \overline{\langle \eta, \xi \rangle}_{\mathbb{C}}, \\ \langle \xi_1 + \xi_2, \eta \rangle_{\mathbb{C}} = \langle \xi_1, \eta \rangle_{\mathbb{C}} + \langle \xi_2, \eta \rangle_{\mathbb{C}}, \\ \langle \xi, \xi \rangle_{\mathbb{C}} > 0 \quad \text{if } \xi \neq 0. \end{gathered} \tag{12}$$

Any scalar product on $\mathbb{C}^n$ with the properties (12) is called an *Hermitian scalar product*, or *Hermitian form.*

If on the realized space $\mathbb{R}^{2n}$ we introduce the usual Euclidean scalar product, defined for a pair of vectors

$$\xi_1 = (x_1^1, \ldots, x_1^n, y_1^1, \ldots, y_1^n), \ \xi_2 = (x_2^1, \ldots, x_2^n, y_2^1, \ldots, y_2^n)$$

by

$$\langle \xi_1, \xi_2 \rangle_{\mathbb{R}} = \sum_{k=1}^{n} (x_1^k x_2^k + y_1^k y_2^k), \tag{13}$$

Let $z = z(w)$ define a complex analytic co-ordinate change, so that $\partial z/\partial \bar{w} = 0$. Then as in the derivation of (33) we have

$$dz = \left(\frac{dz}{dw}\right) dw, \qquad d\bar{z} = \overline{\left(\frac{dz}{dw}\right)}\, d\bar{w},$$

whence

$$dl^2 = h(z, \bar{z})\, dz\, d\bar{z} = h(z(w, \bar{w}), \overline{z(w, \bar{w})}) \left|\frac{dz}{dw}\right|^2 dw\, d\bar{w},$$

which still has conformal form. That complex conjugation preserves the conformal form, is easily verified.

For the converse, suppose that we have a co-ordinate change $z = z(w) = z(w, \bar{w})$, which is neither analytic (so that $\partial z/\partial \bar{w} \not\equiv 0$), nor the composite of an analytic function and complex conjugation (so that $\partial z/\partial w \not\equiv 0$). It follows from our underlying assumption of continuity of the partial derivatives of $z(u, v)$ (where $w = u + iv$), that there exist points at which $\partial z/\partial \bar{w} \neq 0 \neq \partial z/\partial w$ (since otherwise from (6) we should have, at every point, $\partial z/\partial u = \pm i(\partial z/\partial v)$ with neither equality holding everywhere). Now by Lemma 12.1.1, $dz = (\partial z/\partial w)\, dw + (\partial z/\partial \bar{w})\, d\bar{w}$; hence

$$dl^2 = h\left|\frac{\partial z}{\partial w} dw + \frac{\partial z}{\partial \bar{w}} d\bar{w}\right|^2 = h(a_{11}\, du^2 + 2a_{12}\, du\, dv + a_{22}\, dv^2),$$

where $w = u + iv$. Calculation of the a_{ij} shows that the equations $a_{11} = a_{22}$, $a_{12} = 0$ imply that either $\partial z/\partial \bar{w} = 0$ or $\partial z/\partial w = 0$. Since there are points at which neither of these hold, we deduce that our transformation does not preserve the conformal form, completing the proof. ☐

§13. The Conformal Form of the Metric on a Surface

13.1. Isothermal Co-ordinates. Gaussian Curvature in Terms of Conformal Co-ordinates

Suppose that we have in Euclidean space $\mathbb{R}^3$, a 2-dimensional surface with parametric equations

$$x = x(p, q), \qquad y = y(p, q), \qquad z = z(p, q), \tag{1}$$

where (p, q) ranges over some region of $\mathbb{R}^2$. Then, as we saw in §7.3, the Euclidean metric in $\mathbb{R}^3$ induces on this surface a Riemannian metric

$$dl^2 = E(dp)^2 + 2F\, dp\, dq + G(dq)^2, \tag{2}$$

where $g = EG - F^2 > 0$ (since the form given by (2) is positive definite). It turns out that by means of a change of the local co-ordinates p, q, this metric can be brought into conformal form. (We have already seen this in the case of the sphere (§9).) We state this result precisely as

13.1.1. Theorem. *With the above notation, suppose that E, F, G are real-valued analytic functions of the real variables p, q (i.e. are representable as power series in p, q). Then there exist new (real) local co-ordinates u, v for the surface in terms of which the induced metric* (2) *takes the form*

$$dl^2 = f(u, v)(du^2 + dv^2). \tag{3}$$

Co-ordinates with this property are called *isothermal* or *conformal* (cf. Definition 12.3.3). Thus for local co-ordinates on a surface to be isothermal the induced metric must have conformal form (i.e. the form (3)) in those co-ordinates.

Proof of Theorem 13.1.1. Factorizing the right-hand side of (2), we obtain

$$dl^2 = \left(\sqrt{E}\,dp + \frac{F + i\sqrt{g}}{\sqrt{E}}\,dq\right)\left(\sqrt{E}\,dp + \frac{F - i\sqrt{g}}{\sqrt{E}}\,dq\right).$$

We are seeking new co-ordinates u, v as functions $u = u(p, q)$, $v = v(p, q)$ of p and q, with the property that in terms of u, v the metric (2) takes the form (3). We shall certainly have achieved this if we can find an "integrating factor," i.e. a complex-valued function $\lambda = \lambda(p, q)$ such that

$$\begin{aligned} \lambda\left(\sqrt{E}\,dp + \frac{F + i\sqrt{g}}{\sqrt{E}}\,dq\right) &= du + i\,dv, \\ \bar{\lambda}\left(\sqrt{E}\,dp + \frac{F - i\sqrt{g}}{\sqrt{E}}\,dq\right) &= du - i\,dv, \end{aligned} \tag{4}$$

since on multiplying these two equations together, we obtain

$$|\lambda|^2\,dl^2 = du^2 + dv^2, \qquad dl^2 = |\lambda|^{-2}(du^2 + dv^2), \tag{5}$$

so that as $f(u, v)$ the function $|\lambda|^{-2}$ will serve. Since the second of the equations (4) is just the complex conjugate of the first, our problem has now become that of finding functions $u(p, q)$, $v(p, q)$, $\lambda(p, q)$ satisfying the equation

$$\lambda\left(\sqrt{E}\,dp + \frac{F + i\sqrt{g}}{\sqrt{E}}\,dq\right) = du + i\,dv = \left(\frac{\partial u}{\partial p} + i\frac{\partial v}{\partial p}\right)dp + \left(\frac{\partial u}{\partial q} + i\frac{\partial v}{\partial q}\right)dq, \tag{6}$$

or, equivalently,

$$\lambda\sqrt{E} = \frac{\partial u}{\partial p} + i\frac{\partial v}{\partial p}, \qquad \lambda\frac{F + i\sqrt{g}}{\sqrt{E}} = \frac{\partial u}{\partial q} + i\frac{\partial v}{\partial q}. \tag{7}$$

Eliminating λ, we get

$$(F + i\sqrt{g})\left(\frac{\partial u}{\partial p} + i\frac{\partial v}{\partial p}\right) = E\left(\frac{\partial u}{\partial q} + i\frac{\partial v}{\partial q}\right), \tag{8}$$

which is equivalent to

$$F\frac{\partial u}{\partial p} - \sqrt{g}\frac{\partial v}{\partial p} = E\frac{\partial u}{\partial q}, \qquad \sqrt{g}\frac{\partial u}{\partial p} + E\frac{\partial v}{\partial p} = E\frac{\partial v}{\partial q}.$$

Hence

$$\begin{aligned} \frac{\partial v}{\partial p} &= \frac{F\dfrac{\partial u}{\partial p} - E\dfrac{\partial u}{\partial q}}{\sqrt{g}}, \qquad & \frac{\partial v}{\partial q} &= \frac{G\dfrac{\partial u}{\partial p} - F\dfrac{\partial u}{\partial q}}{\sqrt{g}}, \\ \frac{\partial u}{\partial p} &= \frac{E\dfrac{\partial v}{\partial q} - F\dfrac{\partial v}{\partial p}}{\sqrt{g}}, \qquad & \frac{\partial u}{\partial q} &= \frac{F\dfrac{\partial v}{\partial q} - G\dfrac{\partial v}{\partial p}}{\sqrt{g}}, \end{aligned} \tag{9}$$

where the two equations on the right-hand side of (9) follow on multiplying equation (8) by $(F - i\sqrt{g})/E$. If we now also demand of the functions u, v that their second partial derivatives be continuous, we shall have $\partial^2 u/\partial p\,\partial q = \partial^2 u/\partial q \partial p$ and $\partial^2 v/\partial p \partial q = \partial^2 v/\partial q \partial p$, and then from (9) we get $Lu = 0$, $Lv = 0$ where the differential operator L is given by

$$L = \frac{\partial}{\partial q}\left[\frac{F\dfrac{\partial}{\partial p} - E\dfrac{\partial}{\partial q}}{\sqrt{EG - F^2}}\right] + \frac{\partial}{\partial p}\left[\frac{F\dfrac{\partial}{\partial q} - G\dfrac{\partial}{\partial p}}{\sqrt{EG - F^2}}\right]. \tag{10}$$

The partial differential equation $Lf = 0$ is known as "Beltrami's equation," and the operator Las the "Beltrami operator." Thus the upshot is that u, v are solutions of Beltrami's equation. Now it is known from the theory of partial differential equations (but we shall not prove it here) that if the functions E, F, G are real analytic, then Beltrami's equation always has solutions of the type we seek, namely functions u, v such that in the region over which (p, q) ranges, the map $(p, q) \mapsto (u(p, q), v(p, q))$ is one-to-one. (Note that once u, say is chosen (as a solution of Betrami's equation) then the equations in the first row of (9) determine grad u, and therefore (essentially) u. The function λ is then determined using (7).) With this we conclude the proof. ☐

Hence (assuming E, F, G real analytic) isothermal co-ordinates always exist on a surface in Euclidean 3-space. Lemma 12.3.4 then tells us exactly which local co-ordinate changes lead to other isothermal co-ordinates p, q on the surface. For if we write $z = p + iq$, $w = u + iv$, then regarding w as usual as a function of $z, \bar{z}$, i.e. $w = w(z, \bar{z})$, we know from 12.3.4 that p, q are isothermal co-ordinates on the surface if and only if $w(z, \bar{z})$ is analytic in either z or $\bar{z}$.

13.1.2. Example. Consider the complex plane (or line) $\mathbb{C}$ with complex co-ordinate $z = x + iy$. The Euclidean metric $dl^2 = dx^2 + dy^2 = dz\, d\bar{z}$ certainly has conformal form. Since linear-fractional transformations are analytic, we should expect (in view of 12.3.4) that they will preserve the conformal form of the Euclidean metric; and indeed if

$$w = \frac{az + b}{cz + d}, \qquad ad - bc = 1,$$

is any linear-fractional transformation, then $dw = [-1/(cz + d)^2]\, dz$, so that

$$dl^2 = dz\, d\bar{z} = |cz + d|^4\, dw\, d\bar{w},$$

as expected.

We next compute the Gaussian curvature of a surface in Euclidean 3-space, in terms of conformal co-ordinates on the surface.

13.1.3. Theorem. *If u, v are conformal co-ordinates on a surface in Euclidean 3-space, in terms of which the induced metric has the form*

$$dl^2 = g(u, v)(du^2 + dv^2),$$

then the Gaussian curvature of the surface is given by

$$K = -\frac{1}{2g(u, v)} \Delta \ln g(u, v), \tag{11}$$

where $\Delta = \partial^2/\partial u^2 + \partial^2/\partial v^2$ is the Laplace operator.

PROOF. Suppose that in terms of the conformal co-ordinates u, v, the surface is given (locally) by $r = r(u, v)$; $r = (x, y, z)$ (where x, y, z are Euclidean co-ordinates for $\mathbb{R}^3$). Since the metric on the surface in terms of these co-ordinates is given by $dl^2 = g(u, v)(du^2 + dv^2)$, we have (by §7.3 (19)) that

$$\langle r_u, r_u \rangle = \langle r_v, r_v \rangle = g(u, v), \qquad \langle r_u, r_v \rangle = 0. \tag{12}$$

On differentiating these equations with respect to u and v (and, as usual, assuming enough continuity and differentiability), we obtain

$$\begin{aligned} \frac{1}{2}\frac{\partial g(u, v)}{\partial u} &= \langle r_{uu}, r_u \rangle = \langle r_{uv}, r_v \rangle, \\ \frac{1}{2}\frac{\partial g(u, v)}{\partial v} &= \langle r_{vv}, r_v \rangle = \langle r_{uv}, r_u \rangle, \\ \langle r_{uu}, r_v \rangle + \langle r_u, r_{uv} \rangle &= 0 = \langle r_{uv}, r_v \rangle + \langle r_u, r_{vv} \rangle. \end{aligned} \tag{13}$$

Define unit vectors e_1, e_2, n by

$$e_1 = \frac{r_u}{\sqrt{g(u, v)}}, \qquad e_2 = \frac{r_v}{\sqrt{g(u, v)}}, \qquad n = [e_1, e_2]. \tag{14}$$

By (12) and the properties of the vector product the frame e_1, e_2, n is orthonormal at each point of the surface; in addition the vectors e_1, e_2 are tangent to the surface, and the vector n normal to it. By definition (§8.1(3)), the coefficients of the second fundamental form of the surface are

$$\begin{aligned} b_{11} &= L = \langle r_{uu}, n\rangle, \qquad b_{12} = M = \langle r_{uv}, n\rangle, \\ b_{22} &= \langle r_{vv}, n\rangle = N. \end{aligned} \tag{15}$$

It follows from (13) and (15) that relative to the basis e_1, e_2, n, the components of the vectors r_{uu}, r_{uv}, r_{vv} are as follows:

$$\begin{aligned} r_{uu} &= \left(\frac{1}{2\sqrt{g}}\frac{\partial g}{\partial u}, -\frac{1}{2\sqrt{g}}\frac{\partial g}{\partial v}, L\right), \\ r_{uv} &= \left(\frac{1}{2\sqrt{g}}\frac{\partial g}{\partial v}, \frac{1}{2\sqrt{g}}\frac{\partial g}{\partial u}, M\right), \\ r_{vv} &= \left(-\frac{1}{2\sqrt{g}}\frac{\partial g}{\partial u}, \frac{1}{2\sqrt{g}}\frac{\partial g}{\partial v}, N\right), \end{aligned} \tag{16}$$

where of course $g = g(u, v)$. Hence

$$\langle r_{uu}, r_{vv}\rangle - \langle r_{uv}, r_{uv}\rangle = LN - M^2 - \frac{1}{2g}\left[\left(\frac{\partial g}{\partial v}\right)^2 + \left(\frac{\partial g}{\partial u}\right)^2\right].$$

From this and (13) we obtain

$$\begin{aligned} \frac{1}{2}\frac{\partial^2 g}{\partial u^2} &= \langle r_{uuv}, r_v\rangle + \langle r_{uv}, r_{uv}\rangle \\ &= \frac{\partial}{\partial v}\langle r_{uu}, r_v\rangle - \langle r_{uu}, r_{vv}\rangle + \langle r_{uv}, r_{uv}\rangle \\ &= -\frac{1}{2}\frac{\partial^2 g}{\partial v^2} - (LN - M^2) + \frac{1}{2g}\left[\left(\frac{\partial g}{\partial u}\right)^2 + \left(\frac{\partial g}{\partial v}\right)^2\right], \end{aligned}$$

whence it follows (using §8(26) and a little manipulation) that the Gaussian curvature is given by

$$K = \frac{\det(b_{ij})}{\det(g_{ij})} = \frac{LN - M^2}{(g(u, v))^2} = -\frac{1}{2g(u, v)}\Delta \ln g(u, v),$$

concluding the proof of the theorem. □

Note finally that in complex notation the metric $dl^2 = g(u, v)(du^2 + dv^2)$ becomes (setting $z = u + iv$)

$$dl^2 = g(z, \bar{z})\, dz\, d\bar{z},$$

and the formula (11) for the Gaussian curvature of the surface with this metric becomes (again after a little calculation)

$$K = -\frac{2}{g}\frac{\partial^2}{\partial z\,\partial\bar{z}}(\ln g). \tag{17}$$

13.2. Conformal Form of the Metrics on the Sphere and the Lobachevskian Plane

We have already found (in §9) conformal co-ordinates x, y for the sphere: they were obtained by means of the stereographic projection of the sphere onto the plane with Euclidean co-ordinates x, y. Thus for the sphere of radius $R = 1$, the induced metric was found to have the form (see §9(4))

$$dl^2 = 4\frac{dx^2 + dy^2}{(1 + x^2 + y^2)^2}. \tag{18}$$

Setting $z = x + iy$, this takes the form

$$dl^2 = \frac{4}{(1 + |z|^2)^2}\,dz\,d\bar{z}, \tag{19}$$

where z co-ordinatizes the complex plane $\mathbb{C}$.

In §10 we derived (again by means of a stereographic projection) the following formula for the metric of the Lobachevskian plane (with $R = 1$; see §10(10)):

$$dl^2 = \frac{4}{(1 - (x^2 + y^2))^2}(dx^2 + dy^2), \qquad x^2 + y^2 < 1. \tag{20}$$

In complex notation this formula becomes

$$dl^2 = \frac{4}{(1 - |z|^2)^2}\,dz\,d\bar{z}, \qquad |z| < 1, \tag{21}$$

where the complex co-ordinate z ranges over the open unit disc. Recall that the open unit disc with metric (21) (or (20)) is known as the "Poincaré model" of the hyperbolic (i.e. Lobachevskian) plane. If we map the unit disc onto the the upper half-plane Im $w > 0$ by means of the map $z = (1 + iw)/(1 - iw)$, then we obtain the metric in "Klein's model" of the hyperbolic plane (see §10(13)):

$$dl^2 = -\frac{4}{(w - \bar{w})^2}\,dw\,d\bar{w}, \qquad \operatorname{Im} w > 0. \tag{22}$$

We shall now determine in terms of complex co-ordinates, the isometry groups of the sphere and the Lobachevskian plane. As we saw in the preceding section (Lemma 12.3.4), the conformal form of a metric on a surface is complex number k say. Then from $ad - bc = 1$ it follows that we may take $k = 1$ or i. However if $k = i$, then it is easy to see that, for example, $(ai + b)/(ci + d)$ is in the lower half-plane. The upshot is that the transformation (23) maps the upper half-plane onto itself precisely if a, b, c, d are all real.

It turns out that all transformations (23) with a, b, c, d real are in fact isometries of the Klein model of the Lobachevskian plane, i.e. they all preserve the metric

$$dl^2 = \frac{4\,dz\,d\bar{z}}{-(z - \bar{z})^2}.$$

We shall omit the verification of this, which is similar to that of the preceding two cases. It is noteworthy that in both models of the Lobachevskian plane, all linear-fractional transformations preserving the region of the complex plane on which the metric is defined, turn out to be isometries.

We gather the above results together in the following

13.2.3. Theorem. *The group of direct isometries of the Lobachevskian plane is isomorphic to:*

(i) $SU(1, 1)/\{\pm 1\}$ *(using the Poincaré model)*;
(ii) $SL(2, \mathbb{R})/\{\pm 1\}$ *(using Klein's model)*;
(iii) *the connected component of the identity of* $SO(1, 2)$ *(see* §6.2).

Again we are assuming the result (to be established in Chapter 4 of Part II) that these groups do indeed account for all direct isometries of the Lobachevskian plane. The statement (iii) follows in part from the fact that the connected component of the identity of $SO(1, 2)$, consists of just those isometries of $\mathbb{R}^3_1$ preserving the upper sheet of the pseudo-sphere (see §10.1).

Note also that, analogously to the case of the sphere, the full isometry group of the Lobachevskian plane is generated by all the direct isometries of the Poincaré model (i.e. by $SU(1, 1)/\{\pm 1\}$) together with the map $z \mapsto \bar{z}$, which sends the unit disc onto itself, and is obviously an isometry of that model. In terms of Klein's model, the full isometry group is obtained by including (as a generator) the map $z \mapsto -\bar{z}$, along with the transformations (23) with a, b, c, d real (forming a group isomorphic to $SL(2, \mathbb{R})/\{\pm 1\}$).

13.2.4. Corollary. *The groups* $SU(1, 1)/\{\pm 1\}$, $SL(2, \mathbb{R})/\{\pm 1\}$, *and the connected component of the identity of* $SO(1, 2)$, *are isomorphic.*

As an exercise, prove this directly by using appropriate co-ordinate changes!

13.3. Surfaces of Constant Curvature

Before broaching the theme of this section, we need to answer the following natural question: Are there surfaces in Euclidean 3-space whose induced metrics are hyperbolic (i.e. Lobachevskian)? It turns out that the answer is affirmative: there are surfaces in Euclidean 3-space which are, as they say "locally isometric" to the hyperbolic plane. (However there is no such surface that is globally isometric to the hyperbolic plane; i.e. from which there is a one-to-one metric-preserving map onto, say, the Poincaré model of the hyperbolic plane.) An example is provided by the following hornshaped surface of revolution (to which the name "pseudo-sphere" was first applied):

$$x = \operatorname{sech} u \cos v, \qquad y = \operatorname{sech} u \sin v, \qquad z = u - \tanh u, \qquad u \geqq 0,$$

where x, y, z are Euclidean co-ordinates for $\mathbb{R}^3$. The induced metric is easily calculated to be given by

$$dl^2 = (\tanh^2 u)\, du^2 + (\operatorname{sech}^2 u)\, dv^2,$$

which by a change of local co-ordinates can be brought into one of the usual forms for the Lobachevskian metric (we omit the verification of this). It is also easy to calculate that the Gaussian curvature $K \equiv -1$ (cf. the first of the remarks at the end of §10).

To return to our theme, suppose we are given a surface in Euclidean 3-space whose metric (in terms of certain local co-ordinates) has complex conformal form $dl^2 = g(z, \bar{z})\, dz\, d\bar{z}$. (By 13.1.1 the metrics of many surfaces in Euclidean 3-space can (locally) be brought into this form. By the preceding remarks there are such surfaces locally isometric to the Lobachevskian plane.) Since $g(z, \bar{z}) > 0$, we can define a new function $\varphi(z, \bar{z})$ unambiguously by $g(z, \bar{z}) = e^{\varphi}$. In terms of φ, the formulae (11) and (17) for the Gaussian curvature become

$$K = -\tfrac{1}{2} e^{-\varphi} \Delta\varphi, \qquad K = -2e^{-\varphi} \frac{\partial^2 \varphi}{\partial z\, \partial \bar{z}}. \tag{29}$$

If K is constant, then in the following form these equations are known as "Liouville's equations":

$$\Delta\varphi = -2Ke^{\varphi}, \qquad \frac{\partial^2 \varphi}{\partial z\, \partial \bar{z}} = -\frac{K}{2} e^{\varphi}. \tag{30}$$

13.3.1. Theorem. *A surface in Euclidean 3-space with metric $dl^2 = g(z, \bar{z})\, dz\, d\bar{z}$, and with constant Gaussian curvature K is locally isometric to:*

(i) *the sphere if $K > 0$;*
(ii) *the Euclidean plane if $K = 0$;*
(iii) *the Lobachevskian plane if $K < 0$.*

PROOF. From (29), with K assumed constant, we have

$$0 = \frac{\partial}{\partial z}\left(-\frac{K}{2}\right) = \frac{\partial}{\partial z}\left(e^{-\varphi} \frac{\partial^2 \varphi}{\partial z\, \partial \bar{z}}\right) = e^{-\varphi}\left(\frac{\partial^3 \varphi}{\partial z^2\, \partial \bar{z}} - \frac{\partial \varphi}{\partial z} \frac{\partial^2 \varphi}{\partial z\, \partial \bar{z}}\right)$$
$$= e^{-\varphi} \frac{\partial}{\partial \bar{z}}\left(\frac{\partial^2 \varphi}{\partial z^2} - \frac{1}{2}\left(\frac{\partial \varphi}{\partial z}\right)^2\right),$$

so that the function $\partial^2\varphi/\partial z^2 - \frac{1}{2}(\partial\varphi/\partial z)^2 = \psi(z)$ say, is analytic. Under a complex analytic co-ordinate change $z = f(w)$ the metric takes the form (see Lemma 12.1.1)

$$dl^2 = g(z, \bar{z}) \left| \frac{df}{dw} \right|^2 dw\, d\bar{w} = \tilde{g}(w, \bar{w})\, dw\, d\bar{w}.$$

If we then define $\tilde{\varphi}(w, \bar{w})$ by $\tilde{g}(w, \bar{w}) = e^{\tilde{\varphi}}$, it follows that

$$\tilde{\varphi}(w, \bar{w}) = \varphi(z, \bar{z}) + \ln \frac{df}{dw} + \ln \frac{d\bar{f}}{d\bar{w}}. \tag{31}$$

Of course since $\tilde{\varphi}$ was defined completely analogously to φ, the function $\partial^2\tilde{\varphi}/\partial w^2 - \frac{1}{2}(\partial\tilde{\varphi}/\partial w)^2 = \tilde{\psi}(w)$ say, will also be analytic (as a function of w). From this and (31) (and a little computation), we obtain

$$\tilde{\psi}(w) = \psi(z)(f')^2 + \frac{f'''}{f'} - \frac{3}{2}\left(\frac{f''}{f'}\right)^2,$$

where $f' = df/dw$. We wish to choose the function f so that $\tilde{\psi}(w)$ is identically zero, i.e. we seek an analytic function f satisfying the differential equation

$$\frac{f'''}{f'} - \frac{3}{2}\left(\frac{f''}{f'}\right)^2 = -\psi(f(w))(f')^2. \tag{32}$$

It can be shown using the theory of differential equations that (32) has an analytic solution; we shall not give the proof. (In the theory of functions of a complex variable, the left-hand side of (32) is known as the "Schwarz derivative.")

With f chosen to satisfy (32), we have $\tilde{\psi}(w) \equiv 0$, whence

$$\frac{\partial^2 e^{-\tilde{\varphi}/2}}{\partial w^2} = -\tfrac{1}{2} e^{-\tilde{\varphi}/2}\left(\frac{\partial^2\tilde{\varphi}}{\partial w^2} - \frac{1}{2}\left(\frac{\partial\tilde{\varphi}}{\partial w}\right)^2\right) = 0. \tag{33}$$

If we put $w = u + iv$, and analyse the meaning of (33) in terms of the original definition of the operator $\partial^2/\partial w^2$ (see §12(6)), we find that (33) is equivalent to

$$\frac{\partial^2 e^{-\tilde{\varphi}/2}}{\partial u\, \partial v} = 0, \qquad \frac{\partial^2 e^{-\tilde{\varphi}/2}}{\partial u^2} = \frac{\partial^2 e^{-\tilde{\varphi}/2}}{\partial v^2}.$$

It follows easily from these equations that

$$e^{-\tilde{\varphi}/2} = a(u^2 + v^2) + \text{a linear function of } u \text{ and } v, \tag{34}$$

which in complex notation takes the (anticipated) form

$$e^{-\tilde{\varphi}/2} = aw\bar{w} + bw + \bar{b}\bar{w} + c,$$

where a, c are real. Hence in terms of the new co-ordinates w, $\bar{w}$, our metric is given by

$$dl^2 = \frac{dw\, d\bar{w}}{(aw\bar{w} + bw + \bar{b}\bar{w} + c)^2}. \tag{35}$$

From the first of the formulae (29) (with $\tilde{\varphi}$ replacing φ), and (34), it follows that the Gaussian curvature is $K = 4(ac - b\bar{b})$. By means of linear-fractional transformations (which the reader may like to construct), the formula (35) can be brought into the forms:

(i) $\dfrac{4R^4\,dz\,d\bar{z}}{(1 + |z|^2)^2}$ if $K = 4(ac - b\bar{b}) > 0$;

(ii) $dz\,d\bar{z}$ if $K = 4(ac - b\bar{b}) = 0$;

(iii) $\dfrac{4R^4\,dz\,d\bar{z}}{(1 - |z|^2)^2}$ if $K = 4(ac - b\bar{b}) < 0$,

which are the familiar forms of the metrics of the sphere, Euclidean plane, and hyperbolic plane respectively. □

13.4. Exercises

1. Suppose the metric on a surface has the form

$$dl^2 = dx^2 + f(x)\,dy^2,$$

where $f(x)$ is a positive (real-valued) function. Prove that this metric can be brought into conformal form $dl^2 = g(u, v)(du^2 + dv^2)$.

2. Prove that a 2-dimensional pseudo-Riemannian metric (of type (1, 1)) with real analytic coefficients, takes the form

$$dl^2 = \lambda(t, x)(dt^2 - dx^2)$$

after a suitable co-ordinate change.

§14. Transformation Groups as Surfaces in N-Dimensional Space

14.1. Co-ordinates in a Neighbourhood of the Identity

Consider the group $GL(n, \mathbb{R})$ of invertible matrices A, i.e.

$$A = (a^i_j), \qquad \det(a^i_j) \neq 0. \tag{1}$$

Condition (1) defines a region in the space $M(n, \mathbb{R})$ of all $n \times n$ real matrices. If we regard $M(n, \mathbb{R})$ as a vector space (under matrix addition, and multiplication of matrices by scalars), then from this point of view the general linear group is a region of the vector space $\mathbb{R}^{n^2} = M(n, \mathbb{R})$. There is a natural system of co-ordinates for this space, namely the entries a^i_j of the general

$$K = \frac{\det(b_{ij})}{\det(g_{ij})} \qquad (14)$$

13.2 Surfaces of Constant Curvature

Are there surfaces in Euclidean 3-space whose induced metric are hyperbolic (i.e. Lobachevskian)?

... there is a one-to-one metric-preserving map onto, say, the Poincaré ~~model~~ of the hyperbolic plane.

(%% % % 9 2 ! = " ! % 1!
-256- - -* ! - $ " 7 3 \ " ! "
211 ! ! & 9 7 3 ! J 9 ! ! 7 1 J ! " < " 1"

affirmative: there are surfaces in Euclidean 3-space which are, as they say "locally isometric" to the hyperbolic plane. (However there is no such surface that is globally isometric to the hyperbolic plane; i.e. from which there is a one-to-one metric-preserving map onto, say, the Poincaré model of the hyperbolic plane.) An example is provided by the following hornshaped surface of revolution (to which the name "pseudo-sphere" was first applied):

$$x = \operatorname{sech} u \cos v, \qquad y = \operatorname{sech} u \sin v, \qquad z = u - \tanh u, \qquad u \geqq 0,$$

where x, y, z are Euclidean co-ordinates for $\mathbb{R}^3$. The induced metric is easily calculated to be given by

$$dl^2 = (\tanh^2 u)\, du^2 + (\operatorname{sech}^2 u)\, dv^2,$$

which by a change of local co-ordinates can be brought into one of the usual forms for the Lobachevskian metric (we omit the verification of this). It is also easy to calculate that the Gaussian curvature $K \equiv -1$ (cf. the first of the remarks at the end of §10).

To return to our theme, suppose we are given a surface in Euclidean 3-space whose metric (in terms of certain local co-ordinates) has complex conformal form $dl^2 = g(z, \bar{z})\, dz\, d\bar{z}$. (By 13.1.1 the metrics of many surfaces in Euclidean 3-space can (locally) be brought into this form. By the preceding remarks there are such surfaces locally isometric to the Lobachevskian plane.) Since $g(z, \bar{z}) > 0$, we can define a new function $\varphi(z, \bar{z})$ unambiguously by $g(z, \bar{z}) = e^{\varphi}$. In terms of φ, the formulae (11) and (17) for the Gaussian curvature become

$$K = -\tfrac{1}{2} e^{-\varphi} \Delta\varphi, \qquad K = -2e^{-\varphi} \frac{\partial^2 \varphi}{\partial z\, \partial \bar{z}}. \tag{29}$$

If K is constant, then in the following form these equations are known as "Liouville's equations":

$$\Delta\varphi = -2Ke^{\varphi}, \qquad \frac{\partial^2 \varphi}{\partial z\, \partial \bar{z}} = -\frac{K}{2} e^{\varphi}. \tag{30}$$

13.3.1. Theorem. *A surface in Euclidean 3-space with metric $dl^2 = g(z, \bar{z})\, dz\, d\bar{z}$, and with constant Gaussian curvature K is locally isometric to*:

(i) *the sphere if $K > 0$;*
(ii) *the Euclidean plane if $K = 0$;*
(iii) *the Lobachevskian plane if $K < 0$.*

PROOF. From (29), with K assumed constant, we have

$$0 = \frac{\partial}{\partial z}\left(-\frac{K}{2}\right) = \frac{\partial}{\partial z}\left(e^{-\varphi} \frac{\partial^2 \varphi}{\partial z\, \partial \bar{z}}\right) = e^{-\varphi}\left(\frac{\partial^3 \varphi}{\partial z^2\, \partial \bar{z}} - \frac{\partial \varphi}{\partial z} \frac{\partial^2 \varphi}{\partial z\, \partial \bar{z}}\right)$$

$$= e^{-\varphi} \frac{\partial}{\partial \bar{z}}\left(\frac{\partial^2 \varphi}{\partial z^2} - \frac{1}{2}\left(\frac{\partial \varphi}{\partial z}\right)^2\right),$$

so that the function $\partial^2\varphi/\partial z^2 - \frac{1}{2}(\partial\varphi/\partial z)^2 = \psi(z)$ say, is analytic. Under a complex analytic co-ordinate change $z = f(w)$ the metric takes the form (see Lemma 12.1.1)

$$dl^2 = g(z, \bar{z})\left|\frac{df}{dw}\right|^2 dw\,d\bar{w} = \tilde{g}(w, \bar{w})\,dw\,d\bar{w}.$$

If we then define $\tilde{\varphi}(w, \bar{w})$ by $\tilde{g}(w, \bar{w}) = e^{\tilde{\varphi}}$, it follows that

$$\tilde{\varphi}(w, \bar{w}) = \varphi(z, \bar{z}) + \ln\frac{df}{dw} + \ln\frac{d\bar{f}}{d\bar{w}}. \tag{31}$$

Of course since $\tilde{\varphi}$ was defined completely analogously to φ, the function $\partial^2\tilde{\varphi}/\partial w^2 - \frac{1}{2}(\partial\tilde{\varphi}/\partial w)^2 = \tilde{\psi}(w)$ say, will also be analytic (as a function of w). From this and (31) (and a little computation), we obtain

$$\tilde{\psi}(w) = \psi(z)(f')^2 + \frac{f'''}{f'} - \frac{3}{2}\left(\frac{f''}{f'}\right)^2,$$

where $f' = df/dw$. We wish to choose the function f so that $\tilde{\psi}(w)$ is identically zero, i.e. we seek an analytic function f satisfying the differential equation

$$\frac{f'''}{f'} - \frac{3}{2}\left(\frac{f''}{f'}\right)^2 = -\psi(f(w))(f')^2. \tag{32}$$

It can be shown using the theory of differential equations that (32) has an analytic solution; we shall not give the proof. (In the theory of functions of a complex variable, the left-hand side of (32) is known as the "Schwarz derivative.")

With f chosen to satisfy (32), we have $\tilde{\psi}(w) \equiv 0$, whence

$$\frac{\partial^2 e^{-\tilde{\varphi}/2}}{\partial w^2} = -\tfrac{1}{2}e^{-\tilde{\varphi}/2}\left(\frac{\partial^2\tilde{\varphi}}{\partial w^2} - \frac{1}{2}\left(\frac{\partial\tilde{\varphi}}{\partial w}\right)^2\right) = 0. \tag{33}$$

If we put $w = u + iv$, and analyse the meaning of (33) in terms of the original definition of the operator $\partial^2/\partial w^2$ (see §12(6)), we find that (33) is equivalent to

$$\frac{\partial^2 e^{-\tilde{\varphi}/2}}{\partial u\,\partial v} = 0, \qquad \frac{\partial^2 e^{-\tilde{\varphi}/2}}{\partial u^2} = \frac{\partial^2 e^{-\tilde{\varphi}/2}}{\partial v^2}.$$

It follows easily from these equations that

$$e^{-\tilde{\varphi}/2} = a(u^2 + v^2) + \text{a linear function of } u \text{ and } v, \tag{34}$$

which in complex notation takes the (anticipated) form

$$e^{-\tilde{\varphi}/2} = aw\bar{w} + bw + \bar{b}\bar{w} + c,$$

where a, c are real. Hence in terms of the new co-ordinates w, $\bar{w}$, our metric is given by

$$dl^2 = \frac{dw\,d\bar{w}}{(aw\bar{w} + bw + \bar{b}\bar{w} + c)^2}. \tag{35}$$

From the first of the formulae (29) (with $\tilde{\varphi}$ replacing φ), and (34), it follows that the Gaussian curvature is $K = 4(ac - b\bar{b})$. By means of linear-fractional transformations (which the reader may like to construct), the formula (35) can be brought into the forms:

$$\text{(i)}\ \frac{4R^4\,dz\,d\bar{z}}{(1+|z|^2)^2} \quad \text{if } K = 4(ac - b\bar{b}) > 0;$$

$$\text{(ii)}\ dz\,d\bar{z} \qquad \text{if } K = 4(ac - b\bar{b}) = 0;$$

$$\text{(iii)}\ \frac{4R^4\,dz\,d\bar{z}}{(1-|z|^2)^2} \quad \text{if } K = 4(ac - b\bar{b}) < 0,$$

which are the familiar forms of the metrics of the sphere, Euclidean plane, and hyperbolic plane respectively. □

1. Suppose the metric on a surface has the form

$$dl^2 = dx^2 + f(x)\,dy^2,$$

where $f(x)$ is a positive (real-valued) function. Prove that this metric can be brought into conformal form $dl^2 = g(u, v)(du^2 + dv^2)$.

2. Prove that a 2-dimensional pseudo-Riemannian metric (of type (1, 1)) with real analytic coefficients, takes the form

$$dl^2 = \lambda(t, x)(dt^2 - dx^2)$$

after a suitable co-ordinate change.

§14. Transformation Groups as Surfaces in N-Dimensional Space

14.1. Co-ordinates in a Neighbourhood of the Identity

Consider the group $GL(n, \mathbb{R})$ of invertible matrices A, i.e.

$$A = (a^i_j), \qquad \det(a^i_j) \neq 0. \tag{1}$$

Condition (1) defines a region in the space $M(n, \mathbb{R})$ of all $n \times n$ real matrices. If we regard $M(n, \mathbb{R})$ as a vector space (under matrix addition, and multiplication of matrices by scalars), then from this point of view the general linear group is a region of the vector space $\mathbb{R}^{n^2} = M(n, \mathbb{R})$. There is a natural system of co-ordinates for this space, namely the entries a^i_j of the general so that the eigenvector (ξ^i) is a (non-zero) solution of the linear system of equations

$$T_{kj}\xi^j = \lambda g_{ki}\xi^i, \qquad k = 1, \dots, n. \tag{11}$$

It is clear that the trace tr $T^i_j = T^i_i = g^{ik}T_{ik}$, and determinant det T^i_j of the linear operator $T^i_j = g^{ik}T_{kj}$, are metrical invariants of the form T_{ij}, i.e. they are invariant under co-ordinate changes, but of course depend on the metric g_{ij}. As the following example will recall to the reader, we have met these invariants before, albeit in a slightly different guise.

19.2.4. Example. In Chapter 2 we associated with (each point of) a surface $r = r(u, v)$; $r = (x, y, z)$, $x^1 = u$, $x^2 = v$, in Euclidean 3-space, two quadratic forms:

(i) the induced metric $g_{ij}\,dx^i\,dx^j$, or tensor g_{ij};
(ii) the second fundamental form $b_{ij}\,dx^i\,dx^j$, or tensor b_{ij}.

(Here the summation is from 1 to 2, since the surface is 2-dimensional.)

In §8 we obtained the following formulae expressing the Gaussian and mean curvatures of the surface in terms of these two tensors:

$$\text{Gaussian curvature } K = \frac{\det(b_{ij})}{\det(g_{ij})};$$

$$\text{mean curvature } H = b^i_i = g^{ij}b_{ij}.$$

Thus we see that, in our present terminology, the mean curvature is just the trace of the tensor b_{ij} relative to the metric g_{ij}, while since

$$K = (\det(g_{ij}))^{-1}\det(b_{ij}) = \det(g^{ik}b_{kj}) = \det(b^i_j),$$

the Gaussian curvature is the second of the above-mentioned metrical invariants of the second fundamental form b_{ij}.

19.3. The Operator $*$

The presence of a metric g_{ij} allows us to derive from any skew-symmetric tensor T of type $(0, k)$ a skew-symmetric tensor $*T$ of type $(0, n-k)$, defined as follows.

19.3.1. Definition. Given a skew-symmetric tensor T of type $(0, k)$, with components $T_{i_1 \dots i_k}$, we define the skew-symmetric tensor $*T$ of type $(0, n-k)$ by the formula

$$(*T)_{i_{k+1}\dots i_n} = \frac{1}{k!}\sqrt{|g|}\;\varepsilon_{i_1\dots i_n}T^{i_1\dots i_k}, \tag{12}$$

(%/B ' % ' 9

coincides (to within a constant factor) with the expression (24) for the energy-momentum tensor of an electromagnetic field.

In the case of so-called "empty" space, i.e. in the absence of matter, we have $T_{ik} \equiv 0$, so that the gravitational field equations take the form $R_{ik} - \frac{1}{2}Rg_{ik} = 0$, or more simply $R_{ik} = 0$ (this was noted in §30.3(iii)). To see how the latter equations are arrived at, note first that (36) may be rewritten as

$$R_k^\alpha - \tfrac{1}{2}R\delta_k^\alpha = \frac{8\pi G}{c^4} T_k^\alpha.$$

On contracting the indices α and k this yields $R - 2R = (8\pi G/c^4)T$, where $T = T_\alpha^\alpha$, whence

$$R = -\frac{8\pi G}{c^4} T.$$

Substituting for R from this into the original equations (36) for the general gravitational field we obtain

$$R_{ik} = \frac{8\pi G}{c^4}(T_{ik} - \tfrac{1}{2}g_{ik}T).$$

Thus if $T_{ik} = 0$, then $R_{ik} = 0$, as claimed.

It does not follow from the equations $R_{ik} \equiv 0$ that empty space-time is flat: the vanishing of the Ricci tensor does not in general entail the vanishing of the Riemann curvature tensor. (Recall that on the other hand if our space were 3-dimensional then $R_{jkl}^i \equiv 0$ would follow from $R_{ik} \equiv 0$, since in this case the Riemann curvature tensor is expressible in terms of the Ricci tensor (see §30.3(ii)).

From Theorem 37.4.1 (or, more precisely, its proof) we obtain the following consequence for 2-dimensional spaces.

37.4.2. Theorem. *Let g_{ij}, $i, j = 1, 2$, be a Riemannian metric on a 2-dimensional space, and let K denote as usual the Gaussian curvature of the space. Then the integral $S[g] = \int K\,dS$, where $dS = \sqrt{g}\,dx^1 \wedge dx^2$, is invariant under smooth local perturbations of the metric.*

PROOF. From Theorem 30.3.3 and its proof we obtain: $K = R/2$, $R_{ij} = \frac{1}{2}Rg_{ij}$, whence $R_{ij} - \frac{1}{2}Rg_{ij} \equiv 0$. Hence from Theorem 37.4.1 (whose proof was, in essence, independent of the number of dimensions and the fact that the metric was pseudo-Riemannian), we have

$$\frac{1}{\sqrt{g}}\frac{\delta S}{\delta g^{ij}} = R_{ij} - \tfrac{1}{2}Rg_{ij} \equiv 0,$$

which yields the desired conclusion. ☐

Since a closed surface in Euclidean $\mathbb{R}^3$ is by definition compact (and without boundary), we deduce immediately the following celebrated result of Gauss and Bonnet.

37.4.3. Corollary (Gauss–Bonnet). *The integral over a closed surface in 3-dimensional Euclidean space of the Gaussian curvature of the surface, is not changed by smooth deformations of the surface*:

$$\int K\,dS = \text{const.}$$

The value of this constant, and its significance, will be discussed in Part II.

37.5. Soap Films

Consider a smooth hypersurface V^{n-1} in Euclidean $\mathbb{R}^n$ with Euclidean coordinates $x^1, \ldots, x^n$, which we shall assume to be given in the graphical form $x^n = f(x^1, \ldots, x^{n-1})$, where the domain of definition of the function f is a bounded region D of $\mathbb{R}^{n-1}$. In this subsection our concern will be with the area functional $S[f]$ defined on the space of all functions f with the fixed domain D. Thus

$$S[f] = \int_D \sqrt{\det A}\, d^{n-1}x,$$

where $A = (g_{ij}(x))$, $x \in D$, is the induced Riemannian metric on the surface V^{n-1} defined by f, and $d^{n-1}x = dx^1 \wedge \cdots \wedge dx^{n-1}$.

We shall now express $\sqrt{\det A}$ explicitly in terms of the function f. We might for this purpose appeal directly to formula (31) of §7.4 (or rather to its generalization to surfaces of $(n-1)$ dimensions). Alternatively we may proceed as follows. Denote by $d\tau^{n-1}$ the form representing the $(n-1)$-dimensional volume element of V^{n-1}; thus $S[f] = \int_D d\tau^{n-1}$. For each point P of V^{n-1}, let $\alpha(P)$ denote the angle between $n(P)$, the unit normal to V^{n-1} at P, and $e_n = (0, \ldots, 0, 1)$. Then as Figure 39 suggests (at least in the case $n = 3$), we have

$$S[f] = \int_D d\tau^{n-1} = \int_D \frac{d^{n-1}x}{\cos\alpha(P)}.$$

Now since $n(P)$ is given by (cf. the formula for the unit normal in the case $n = 3$ given in §8.3(23)):

$$n(P) = \frac{1}{\sqrt{1 + \sum_{i=1}^{n-1} (f_{x^i})^2}}(-f_{x^1}, \ldots, -f_{x^{n-1}}, 1),$$

$M \to \mathbb{R}^{2n}$, are no longer everywhere dense in the space of all smooth maps $M \to \mathbb{R}^{2n}$. In general no further reduction of the dimension is possible: we invite the reader to prove that a non-orientable, closed 2-manifold is not embeddable in $\mathbb{R}^3$ (see §2.1). However in particular cases, i.e. for more restricted classes of manifolds, the dimension can be further reduced; for instance, it can be shown on the basis of the known classification of compact, orientable, 2-dimensional manifolds, that any such manifold can be embedded in $\mathbb{R}^3$.

11.2. The Construction of Morse Functions as Height Functions

With the aid of an embedding $M \to \mathbb{R}^N$, we shall now give a different proof of the existence of Morse functions on a compact smooth manifold M. We shall show that Morse functions can be found in a rather narrow class of functions on manifolds, called "height functions", which we shall now define.

Let M be smoothly embedded in $\mathbb{R}^N$, and let (in distinction to the previous subsection) $\xi_l(t)$ denote a (parametrized) straight line through the origin of $\mathbb{R}^N$ with direction vector l. Define a function h_l on M by setting $h_l(x)$ equal to t_x where t_x is that value of the parameter t at the point of orthogonal projection $\xi_l(t_x)$ of $x \in M$ onto the line $\xi_l(t)$. (Thus if t is distance (positive or negative) on $\xi_l(t)$ from the origin, then $h_l(x)$ is the distance of $x \in M$ from the origin (or "height above the origin") in the direction l. Such functions h_l are called *height functions* on $M \subset \mathbb{R}^N$.

The reader will easily verify the following two properties of height functions:

(i) The set of height functions on M is (neglecting the particular parametrizations of the $\xi_l(t)$) in one-to-one correspondence with the set of pairs of diametrically opposite points of the (unit) sphere S^{N-1}, or, equivalently, the points of $\mathbb{R}P^{N-1}$;
(ii) A point x_0 of M is a critical point of a height function h_l if and only if the vector l is orthogonal to the manifold M at the point x_0 (i.e. $l \perp T_{x_0}M$).

Our next task is to discover conditions under which a critical point $x_0 \in M$ of a height function h_l is non-degenerate. We shall at this point restrict our considerations to manifolds M embedded in $\mathbb{R}^{m+1}$, where $m = \dim M$, i.e. to hypersurfaces in $\mathbb{R}^{m+1}$ (but see the "Important Remark" below). Recall (from §26.2 of Part I) that for hypersurfaces $M \subset \mathbb{R}^{m+1}$ the *Gauss map* $r\colon M \to S^m \to \mathbb{R}P^m$ is defined by $r(x) = n(x)$, where $n(x)$ is the unit normal vector to M at the point x (translated back to the origin, i.e. with its tail at the origin).

11.2.1. Lemma. *A point x_0 of the hypersurface $M \subset \mathbb{R}^{m+1}$ is a non-degenerate critical point of a height function h_l if and only if it is a regular* (*i.e. non-critical*) *point of the Gauss map $r\colon M \to \mathbb{R}P^m$* (*and of course also $l \perp T_{x_0}M$*).

Proof. By means of a suitable orthogonal change of co-ordinates on $\mathbb{R}^{m+1}$ we can arrange that the x^{m+1}-axis is parallel to l (so that the other m-axes are perpendicular to l). The hyperplane $\mathbb{R}^m(x^1, \ldots, x^m)$ can then be regarded as the tangent space to M at x_0, and in some sufficiently small neighbourhood of x_0 the manifold M will be given by an equation of the form $x^{m+1} = \varphi(x^1, \ldots, x^m)$, with $d\varphi|_{x_0} = 0$, and $x^1, \ldots, x^m$ will serve as local co-ordinates. Then on that neighbourhood the "height" $h_l(x)$ is just the function $\varphi(x^1, \ldots, x^m) = x^{m+1}$. By defining in terms of $x^1, \ldots, x^{m+1}$, as in the proof of Theorem 26.2.2 of Part I, suitable local co-ordinates $y^1, \ldots, y^m$ on the sphere S^m in a neighbourhood of the image point $r(x_0)$, and repeating the argument given there (with $m+1$ in place of 3) leading to the formula $K\, d\sigma = r^*(\Omega)$, where K is the Gaussian curvature of M (which may be taken to be defined by the equation below), and $d\sigma$, Ω are the (induced) volume elements on M and S^m, respectively, we obtain the following equations:

$$\left(\frac{\partial^2 h_l(x_0)}{\partial x^\alpha\, \partial x^\beta}\right) = \left(\frac{\partial^2 \varphi(x_0)}{\partial x^\alpha\, \partial x^\beta}\right) = \left(\left.\frac{\partial y^\alpha}{\partial x^\beta}\right|_{x_0}\right);$$

$$\det\left(\frac{\partial^2 h_l(x_0)}{\partial x^\alpha\, \partial x^\beta}\right) = K,$$

where here K is the Gaussian curvature of M at x_0, and $y^\alpha = r^\alpha(x^1, \ldots, x^m)$, $1 \le \alpha \le m$, is the Gauss map expressed in terms of the local co-ordinates $x^1, \ldots, x^m$; $y^1, \ldots, y^m$. It is immediate from the first of the above equations that the condition that the Gauss map r be regular at x_0, namely $\det(\partial y^\alpha/\partial x^\beta|_{x_0}) \ne 0$, is equivalent to the defining condition for non-degeneracy of the critical point x_0 of h_l, namely $\det(\partial^2 h_l(x_0)/\partial x^\alpha\, \partial x^\beta) \ne 0$. This completes the proof of the lemma. □

11.2.2. Theorem. *A height function h_l on a hypersurface $M \subset \mathbb{R}^{m+1}$ ($m = \dim M$) is a Morse function precisely if the point $\{\pm l\}$ of $\mathbb{R}P^m$ is a regular value of the Gauss map r: $M \to \mathbb{R}P^m$. It follows that the Morse functions are everywhere dense in the set of height functions on M.*

Proof. The first statement is immediate from the lemma. The second follows from Sard's theorem, which tells us that the regular values of the Gauss map are everywhere dense in $\mathbb{R}P^m$. □

Important Remark. This theorem is valid without the restriction that M be a hypersurface in $\mathbb{R}^m$, i.e. it holds quite generally for any smooth embedding $M \subset \mathbb{R}^q$ ($q \ge m+1$). We now sketch an argument allowing us to deduce this general result from Lemma 11.2.1. Thus suppose $M \subset \mathbb{R}^q$ with $q > m+1$, where $m = \dim M$. We shall now define a $(q-1)$-dimensional manifold N, as the boundary of a so-called "tubular neighbourhood" of the manifold M. To this end consider the set of $(q-m)$-dimensional discs D_x^{q-m} in $\mathbb{R}^q$ (i.e. balls) orthogonal to the submanifold M, of radius $\varepsilon > 0$, and with centres at the points x of M. For sufficiently small $\varepsilon > 0$, the union of these discs is a q-

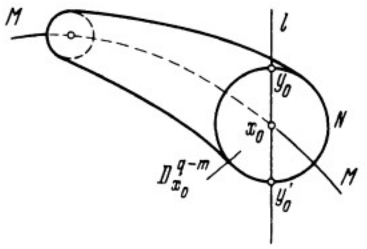

Figure 27

dimensional submanifold of $\mathbb{R}^q$ (a "tubular neighbourhood" of M), whose boundary we denote by N (see Corollary 11.3.3 below). Since N has dimension $q-1$, it can be mapped via the Gauss map r to S^{q-1}.

Now let $h_l(x)$ be any height function defined for points x in M or N (i.e. on $M \cup N$). It is intuitively clear that with each critical point $x_0 \in \mathrm{M}$ of the function $h_l(x)$ there are associated exactly two critical points y_0 and y_0' of h_l restricted to N, namely the two points of intersection with N of the straight line parallel to l passing through x_0 and orthogonal to M at x_0 (see Figure 27).

It may be shown that a critical point $x_0 \in M$, of the function h_l restricted to M, is non-degenerate precisely if the points y_0, y_0' are non-degenerate for h_l restricted to N. (They are always either both degenerate or both non-degenerate.) Hence if h_l is a Morse function on N, then it is also a Morse function when restricted to M. The existence and everywhere denseness (in the set of all height functions on N) of Morse functions on N, guaranteed by Theorem 11.2.2, therefore implies the analogous conclusion for M. We have thus shown that the restriction that M be a hypersurface in $\mathbb{R}^{m+1}$ was inessential.

11.3. Focal Points

There exist yet other simple methods of obtaining a plentiful supply of Morse functions on a smooth manifold. Without going into great detail, we describe one such method.

Consider a smooth m-manifold M smoothly embedded as a submanifold of $\mathbb{R}^q$. With each point $p \in \mathbb{R}^q$, we associate a smooth function L_p on the submanifold M, defined by $L_p(x) = |p-x|^2$, where $x \in M$ and $|p-x|$ is the Euclidean distance between the points $p, x \in \mathbb{R}^q$. We shall show that for almost all points $p \in \mathbb{R}^q$ (i.e. for all points except those in a set of measure zero) the function L_p is a Morse function on M. (Clearly the set of functions of the form $L_p(x)$ is different from the set of height functions $h_l(x)$.)

For the proof we first define the "focal points" for $M \subset \mathbb{R}^q$; our ultimate aim will then be to show that the set of focal points, which has measure zero,

(' 9 4 ! < " ! :31 !

over the respective regions are equal in absolute value (which is not surprising if f is one-to-one, i.e. if f is a co-ordinate change).

14.2. The Degree of a Vector Field on a Hypersurface

Let $\xi=(\xi^\alpha(x))$, $\alpha=1,\dots,n$, denote a smooth, non-vanishing vector field defined on a region U of n-dimensional Euclidean space $\mathbb{R}^n$ with Euclidean co-ordinates $x^1,\dots,x^n$. Since $\xi(x)\neq 0$ at all points of U, the vector field ξ gives rise to a unit vector field $n(x)=\xi(x)/|\xi(x)|$ on U, which leads in turn to the *spherical* (*Gauss*) *map* $f\colon U\to S^{n-1}$, where for each point $x\in U$, $f(x)$ is the tip of the unit vector $n(x)$ when its tail is at the origin. (Thus $f(x)$ is a point on the unit $(n-1)$-sphere, as required.) If now Q is any hypersurface entirely within U, then the degree of the restriction map $f|_Q\colon Q\to S^{n-1}$, is called the *degree of the vector field* ξ *on the hypersurface* Q.

Consider the following closed $(n-1)$-form Ω on S^{n-1} (or, if you like, on $\mathbb{R}^n\backslash\{0\}$):

$$\Omega=\frac{1}{\gamma_n}\,\frac{\sum_{i=1}^{n}(-1)^{i+1}x^i\,dx^1\wedge\cdots\wedge\widehat{dx^i}\wedge\cdots\wedge dx^n}{((x^1)^2+\cdots+(x^n)^2)^{n/2}}. \tag{3}$$

Here the hatted symbols are to be omitted, and γ_n is the normalizing constant chosen so that $\int_{S^{n-1}}\Omega=1$. (It is not difficult to verify that the form $\gamma_n\Omega$ is just the volume element on the unit sphere S^{n-1}, whence γ_n is the volume of S^{n-1}.) For instance in the plane $\mathbb{R}^2\backslash\{0\}$ with Euclidean co-ordinates x, y, we have

$$\Omega=\frac{1}{2\pi}\left(\frac{x\,dy-y\,dx}{x^2+y^2}\right),$$

or, in polar co-ordinates, $\Omega=d\varphi/2\pi$. In $\mathbb{R}^3\backslash\{0\}$ with Euclidean co-ordinates x, y, z, we have

$$\Omega=\frac{1}{4\pi}\left(\frac{x\,dy\wedge dz-y\,dx\wedge dz+z\,dy\wedge dx}{(x^2+y^2+z^2)^{3/2}}\right),$$

or, in spherical co-ordinates, $\Omega=(1/4\pi)|\sin\theta|\,d\theta\,d\varphi$.

From Theorem 14.1.1 we deduce the following

14.2.1. Corollary. *The degree of a non-vanishing vector field* $\xi(x)$ *on a closed hypersurface* Q *in Euclidean n-space, is equal to the integral* $\int_Q f^*\Omega$, *where* $f\colon Q\to S^{n-1}$ *is the Gauss map determined by the vector field, and* Ω *is the* $(n-1)$*-form on* S^{n-1} *defined in* (3). *It follows that if* Q *is given locally by a system of equations*

$$x^\alpha=x^\alpha(u^1,\dots,u^{n-1}),\qquad \alpha=1,\dots,n,$$

(*where* $x^1,\dots,x^n$ *are Euclidean co-ordinates in* $\mathbb{R}^n$), *then*

$$\deg f = \deg_Q \xi = \frac{1}{\gamma_n}\int_Q \frac{1}{|\xi|^n} \det \begin{pmatrix} \xi^1 & \cdots & \xi^n \\ \dfrac{\partial \xi^1}{\partial u^1} & \cdots & \dfrac{\partial \xi^n}{\partial u^1} \\ \cdots & \cdots & \cdots \\ \dfrac{\partial \xi^1}{\partial u^{n-1}} & \cdots & \dfrac{\partial \xi^n}{\partial u^{n-1}} \end{pmatrix} du^1 \wedge \cdots \wedge du^{n-1}. \tag{4}$$

(The first statement is immediate from Theorem 14.1.1. The second follows easily from the definitions of Ω, of f (via $f(x)=(1/|\xi(x)|)\,(\xi^1(x), \ldots, \xi^n(x))$), and of $f^*\Omega$ (see §22.1 of Part I).)

In the case $n=2$, the formula (4) becomes:

$$\deg f = \frac{1}{2\pi}\oint \frac{dt}{|\xi|^2}\left(\xi^1 \frac{d\xi^2}{dt} - \xi^2 \frac{d\xi^1}{dt}\right),$$

where t is a parameter on the closed curve over which the integral is taken, and $\xi(t)=(\xi^1(t), \xi^2(t))$ is a non-vanishing vector field on the curve. In the case $n=3$, we have $\gamma_3=4\pi$ whence (4) becomes:

$$\deg f = \frac{1}{4\pi}\iint_Q \frac{du\,dv}{|\xi|^3} \det \begin{pmatrix} \xi^1 & \xi^2 & \xi^3 \\ \dfrac{\partial \xi^1}{\partial u} & \dfrac{\partial \xi^2}{\partial u} & \dfrac{\partial \xi^3}{\partial u} \\ \dfrac{\partial \xi^1}{\partial v} & \dfrac{\partial \xi^2}{\partial v} & \dfrac{\partial \xi^3}{\partial v} \end{pmatrix} \tag{5}$$

$$= \frac{1}{4\pi}\iint_Q \frac{du\,dv}{|\xi|^3}\left\langle \xi, \left[\frac{\partial \xi}{\partial u}, \frac{\partial \xi}{\partial v}\right]\right\rangle,$$

where $[\ ,\ ]$ denotes the vector (or cross) product.

A particular situation of interest is that where the vector field $\xi(x)$ is a unit field (i.e. $|\xi|=1$), and at every point of the closed manifold Q has the direction of the exterior normal to Q. We know (from §26.2 of Part I) that in this case

$$\gamma_n(f^*\Omega) = K\,d\sigma = K\sqrt{g}\,du^1 \wedge \cdots \wedge du^{n-1}, \tag{6}$$

where K is the Gaussian curvature of the hypersurface (defined as the product of the principal curvatures), and $d\sigma=\sqrt{g}\,du^1 \wedge \cdots \wedge du^{n-1}$ is the standard volume element on the hypersurface Q determined by the metric induced on Q by the Euclidean metric on the ambient space $\mathbb{R}^n$. (Recall that when $n=2$ we have $d\sigma=dl$, the element of length on the curve Q, and $K=k$, the curvature of the curve, while for $n=3$, K is the usual Gaussian curvature of a 2-dimensional surface, and $d\sigma=\sqrt{EG-F^2}\,du \wedge dv$ is the usual element of area (see §7 of Part I).

Combining (6) with the first statement of Corollary 14.2.1, we obtain immediately the following

14.2.2. Theorem. *The integral of the Gaussian curvature over a closed hypersurface in Euclidean n-space is equal to the degree of the Gauss map of the surface, multiplied by* γ_n *(the Euclidean volume of the unit* $(n-1)$*-sphere).*

14.3. The Whitney Number. The Gauss–Bonnet Formula

Our aim in this subsection is to discover the relationship between the degree of the Gauss map of a hypersurface in Euclidean n-space and certain striking geometrical features of the hypersurface (or at least of the way it is embedded in $\mathbb{R}^n$). We shall restrict attention to the most important cases $n=2, 3$.

The case $n=2$: *curves in* $\mathbb{R}^2$. Let $\gamma=(x(t), y(t))$ be a closed curve "in general position" in Euclidean $\mathbb{R}^2$; by this we mean that: for all t, $x(t+2\pi)=x(t)$, $y(t+2\pi)=y(t)$; the tangent vector $(\dot{x}, \dot{y})$ is non-zero for all t; and finally every self-intersection (if there are any) is double and has the property that the two tangent vectors at the point of intersection are linearly independent (as for instance in Figure 34).

To each point of self-intersection of the closed curve γ we attach a sign (± 1) in the following way. Fix on any point t_0 of the curve which is not a point of self-intersection. Denote by $[1, 2]$ an orienting frame on $\mathbb{R}^2$ (e.g. that determined by the given Euclidean co-ordinates x, y, in that order). We now trace out the curve γ once starting from the point t_0 in the direction of increase of the parameter; when any particular point of self-intersection is first encountered we label with the numeral 1 the tangent vector at that point to the branch we are on, and when we meet that point of self-intersection again we label the tangent vector to the second branch (on which we now find ourselves) with the numeral 2 (see Figure 34). Once our tour is completed, each point of self-intersection of γ has associated with it a frame whose orientation class of course coincides either with that of the prescribed frame $[1, 2]$, or its opposite; in the former case we attach the sign $+1$ to the point, and in the latter case the sign -1. We then define the *Whitney number* $W(\gamma)$ of the plane closed curve γ (in general position) to be the sum of the signs of all its points of self-intersection.

The following result links the degree of the Gauss map to the Whitney number.

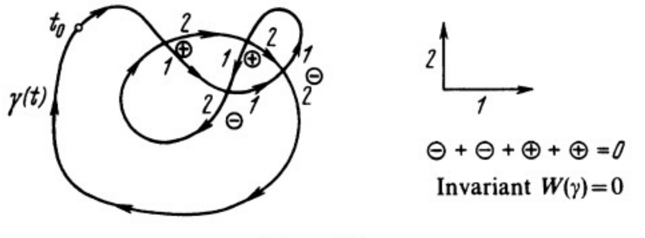

Figure 34

(' % '%9 @ 3 8 D 9 7!) < !

14.2.2. Theorem. *The integral of the Gaussian curvature over a closed hypersurface in Euclidean n-space is equal to the degree of the Gauss map of the surface, multiplied by γ_n (the Euclidean volume of the unit $(n-1)$-sphere).*

14.3. The Whitney Number. The Gauss–Bonnet Formula

Our aim in this subsection is to discover the relationship between the degree of the Gauss map of a hypersurface in Euclidean n-space and certain striking geometrical features of the hypersurface (or at least of the way it is embedded in $\mathbb{R}^n$). We shall restrict attention to the most important cases $n=2, 3$.

The case $n=2$: curves in $\mathbb{R}^2$. Let $\gamma=(x(t), y(t))$ be a closed curve "in general position" in Euclidean $\mathbb{R}^2$; by this we mean that: for all t, $x(t+2\pi)=x(t)$, $y(t+2\pi)=y(t)$; the tangent vector $(\dot{x}, \dot{y})$ is non-zero for all t; and finally every self-intersection (if there are any) is double and has the property that the two tangent vectors at the point of intersection are linearly independent (as for instance in Figure 34).

To each point of self-intersection of the closed curve γ we attach a sign (± 1) in the following way. Fix on any point t_0 of the curve which is not a point of self-intersection. Denote by $[1, 2]$ an orienting frame on $\mathbb{R}^2$ (e.g. that determined by the given Euclidean co-ordinates x, y, in that order). We now trace out the curve γ once starting from the point t_0 in the direction of increase of the parameter; when any particular point of self-intersection is first encountered we label with the numeral 1 the tangent vector at that point to the branch we are on, and when we meet that point of self-intersection again we label the tangent vector to the second branch (on which we now find ourselves) with the numeral 2 (see Figure 34). Once our tour is completed, each point of self-intersection of γ has associated with it a frame whose orientation class of course coincides either with that of the prescribed frame $[1, 2]$, or its opposite; in the former case we attach the sign $+1$ to the point, and in the latter case the sign -1. We then define the *Whitney number* $W(\gamma)$ of the plane closed curve γ (in general position) to be the sum of the signs of all its points of self-intersection.

The following result links the degree of the Gauss map to the Whitney number.

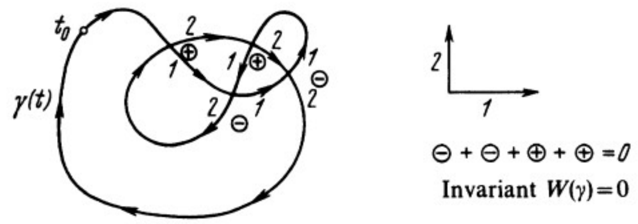

Figure 34

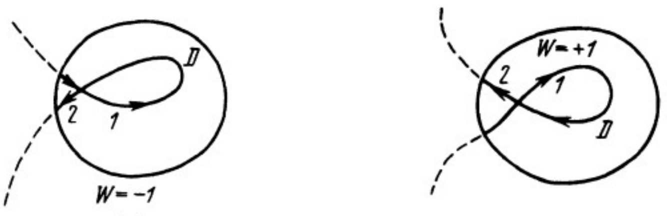

(a) (b)

Figure 35

14.3.1. Theorem. *Let γ be a non-singular, plane closed curve in general position. Then the parity of the number of self-intersections of γ (which is the same as the parity of the Whitney number of γ) is opposite to that of the degree of the Gauss map f of γ.*

PROOF. For a simple (i.e. non-self-intersecting) plane closed curve γ it is easy to see that $\deg f = 1$ (assuming the curve γ and S^1 traced in the same sense), while clearly $W(\gamma) = 0$; hence the theorem is true in this case. With this as our point of departure we shall prove the theorem by induction on the number of self-intersections. Suppose first that our curve γ has a loop with the properties that the "starting point" t_0 is not on the loop, and no points of γ are in its interior (see Figure 35). Enclose this loop in a region D which excludes all points of γ not on the loop (as in Figure 35); subsequent alterations of γ will be carried out entirely in the region D. The (direction-preserving) alterations in question are depicted in Figure 36(a) or (b) (depending on the sense in which the loop is traced). The operation of replacing γ by $\gamma_1 \cup \gamma_2$ and then removing γ_2, decreases the degree of f by 1 in case (a), and increases the degree by 1 in case (b); clearly the Whitney number is affected in the same way. Thus the inductive step is completed in the situation where γ has such a "minimal" loop.

Suppose now that γ has no "minimal" loops. It can be shown that there will still be a loop γ_2 say (see Figure 37) which does not have the point t_0 on it, but which intersects the remainder of the curve (denoted by γ_1 in Figure 37). If we now alter the curve γ appropriately within some sufficiently small neighbourhood of the point of self-intersection of our loop we shall arrive

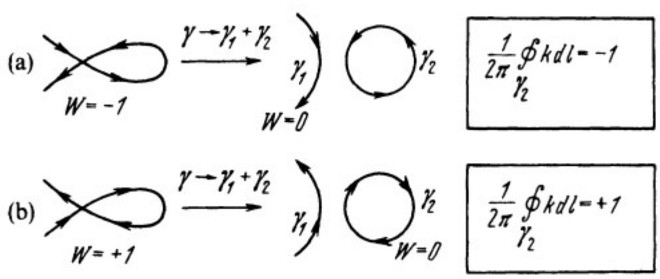

Figure 36

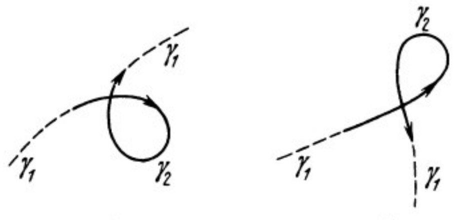

(a) (b)

Figure 37

again at the situation depicted in Figure 36(a) or (b), except that now the simple closed curve γ_2 of that figure will intersect γ_1. However since the number of such points of intersection will of course be even, the argument concerning parities goes through as before. This completes the proof of the theorem. □

Remark. It can be shown that under the above-described alteration of γ and subsequent removal of the simple closed component γ_2, the Whitney number and the degree of f change by the same amount (and not just modulo 2). This leads to the more precise result that *the Whitney number* $W(\gamma)$ *is equal to either* $\deg f-1$ *or* $\deg f+1$. Whether 1 is to be added or subtracted depends on the initial choice of the starting point t_0 (as illustrated in Figure 38).

The case $n=3$: *surfaces in* $\mathbb{R}^3$. Our aim is to express the degree of the Gauss map $f: Q\rightarrow S^2$, of a smooth, closed, oriented surface Q in $\mathbb{R}^3$, more directly in terms of the geometry of Q. Let $y_0\in S^2$ be a regular value of the map f. By applying a suitable orthogonal transformation we may clearly arrange for the point y_0 to be at the north pole of S^2, i.e. to have co-ordinates $(0, 0, 1)$, and, by means of a suitable, small deformation (i.e. homotopy), we may further arrange for the south pole $y_0^*=(0, 0, -1)$ to be also a regular value of f. (The simultaneous regularity of two diametrically opposite points of S^2 is equivalent to the regularity of their common image point in the real projective plane $\mathbb{R}P^2$ under the composite map

$$Q\xrightarrow{f}S^2\rightarrow\mathbb{R}P^2,$$

from Q to $\mathbb{R}P^2$.)

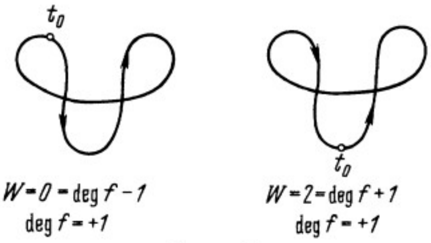

Figure 38

14.3.2. Lemma. *Let Q be a hypersurface in Euclidean 3-space, with f (the Gauss map of Q), y_0, y_0^* as above, and let φ be the height function on Q (i.e. for each $P \in Q$, $\varphi(P)$ is the z-co-ordinate of P). Then the set of critical points of the function φ coincides with the union $f^{-1}(y_0) \cup f^{-1}(y_0^*)$, and the critical points are all non-degenerate.*

Proof. In some neighbourhood of each critical point of $\varphi: Q \to \mathbb{R}$, the surface Q is defined by an equation of the form $z = \varphi(x, y)$, and the critical points in that neighbourhood are just those satisfying grad $\varphi = 0$. Now the gradient of $\varphi(x, y)$ is zero at precisely those points of Q where the direction of the z-axis is perpendicular to Q; but by definition of the Gauss map f of Q, the latter are exactly the points sent by f to the north or south poles of S^2. Hence the set of critical points of φ is $f^{-1}(y_0) \cup f^{-1}(y_0^*)$.

It is immediate from the proof of (6) above given in §26.2 of Part I, that at each point of $f^{-1}(y_0)$ the Jacobian of the Gauss map $f: Q \to S^2$ (in terms of suitable local co-ordinates on S^2) coincides with the determinant of the Hessian of the function $z = \varphi(x, y)$ (and hence with the Gaussian curvature). Since y_0 is a regular value of the map f it follows (from the definition (10.4.1) of non-degeneracy of critical points of a function) that the points of $f^{-1}(y_0)$ are indeed non-degenerate (critical) points of φ. (Alternatively this could have been inferred immediately from Lemma 11.2.1.) By applying the same argument with the z-axis reversed, we draw the same conclusion for the points in $f^{-1}(y_0^*)$, completing the proof of the lemma. □

In connexion with this proof note the obvious equality

$$\det\left(\frac{\partial^2 \varphi}{\partial u^i\, \partial u^j}\right) = (-1)^{n-1} \det\left(\frac{\partial^2(-\varphi)}{\partial u^i\, \partial u^j}\right), \tag{7}$$

where $u^1, \ldots, u^{n-1}$ are local co-ordinates in some neighbourhood of any point of the surface Q; this equality is crucial in the distinction arising between the cases of odd and even n. Since in our case $n-1=2$, it follows from (7) and the above proof that at every point of the set $f^{-1}(y_0) \cup f^{-1}(y_0^*)$ the Jacobian of the map f agrees in sign with the Gaussian curvature K (independently of the choice of the direction of the z-axis, i.e. of whether we work with φ or $-\varphi$). This, the above lemma, and the definition of the degree of a map, together yield immediately the following

14.3.3. Lemma. *With $f: Q \to S^2$ as above, we have*

$$2 \deg f = \sum_{P_j} (-1)^{\alpha(P_j)}, \tag{8}$$

where the summation is over the set of critical points P_j of the height function $z = \varphi$, and where $\alpha(P_j) = 0$ for those critical points where φ has a local maximum or minimum (where sgn $K = +1$*), and $\alpha(P_j) = 1$ for saddle points (where* sgn $K = -1$*).*

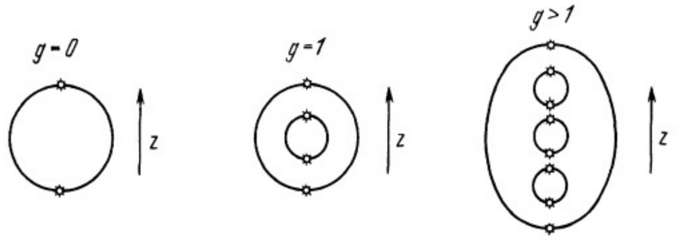

Figure 39

We shall now show that when Q is the sphere-with-g-handles, the number on the right-hand side of (8) is $2-2g$. It is easy to imagine this surface embedded in $\mathbb{R}^3$ in such a way that the height function φ has exactly one minimum point, one maximum point, and $2g$ saddle points (see Figure 39, where the critical points are indicated). For such an embedding we have by (8) together with Theorem 14.2.2 that

$$2 \deg f = \frac{1}{2\pi} \int_Q K \, d\sigma = 2-2g.$$

Of course other embeddings of the surface Q in $\mathbb{R}^3$ are possible. However at the conclusion of §37.4 of Part I we showed that the quantity $\int_Q K \, d\sigma$ is not altered by smooth variations in the metric on Q. Let $g_{ij}^{(0)}$ and $g_{ij}^{(1)}$ be any two Riemannian metrics on the surface Q, and consider the family of metrics

$$g_{ij}(t) = t g_{ij}^{(1)} + (1-t) g_{ij}^{(0)}, \qquad 0 \le t \le 1.$$

Clearly $g_{ij}(0) = g_{ij}^{(0)}$, $g_{ij}(1) = g_{ij}^{(1)}$, and $g_{ij}(t)$ is positive definite for all $t \in [0, 1]$. Hence the integral $\int_Q K \, d\sigma$ is the same for both metrics. We have thus proved (in more precise form than Corollary 37.4.3 of Part I) the following celebrated result.

14.3.4. Theorem (Gauss–Bonnet). *For the sphere-with-g-handles Q endowed with any Riemannian metric we have*

$$\frac{1}{2\pi} \int_Q K \, d\sigma = 2-2g.$$

14.4. The Index of a Singular Point of a Vector Field

In this subsection we shall study the Gauss map of a vector field in a neighbourhood of an "isolated singular point" of the vector field. We first need to define these terms. Thus let $\xi = \xi(x)$ be a vector field defined on some neighbourhood of a particular point x_0 of Euclidean space $\mathbb{R}^n$. In the conventional terminology, the point x_0 is called a *singular point of the field* ξ if $\xi(x_0) = 0$, and an *isolated* singular point of the field if it is a singular point but at all other points of some (small) neighbourhood of it $\xi(x)$ does not vanish. A singular point x_0 is said to be *non-degenerate* if

$$\det\left(\left.\frac{\partial\xi^\alpha}{\partial x^\beta}\right|_{x=x_0}\right)\neq 0.$$

14.4.1. Lemma. *A non-degenerate singular point of a vector-field is necessarily isolated.*

PROOF. Consider $\xi(x)$ as a map from $\mathbb{R}^n$ to $\mathbb{R}^n$. Since the derivative $\det(\partial\xi^\alpha/\partial x^\beta)\neq 0$ at the non-degenerate singular point x_0, the Inverse Function Theorem tells us that ξ is one-to-one on some neighbourhood of x_0. Hence x_0 is an isolated singular point, as claimed. □

By the *roots* of a non-degenerate singular point x_0 of a vector field ξ we shall mean the eigenvalues $\lambda_1, \ldots, \lambda_n$ of the matrix $(\partial\xi^\alpha/\partial x^\beta)_{x=x_0}$, and by the *index* of such a point the sign

$$\operatorname{sgn}\det\left(\left.\frac{\partial\xi^\alpha}{\partial x^\beta}\right|_{x=x_0}\right)=\operatorname{sgn}(\lambda_1\ldots\lambda_n).$$

Note that if the vector field ξ happens to be the gradient field of some function f, i.e. $\xi^\alpha=\partial f/\partial x^\alpha$, then the index of a non-degenerate singular point x_0 coincides with the sign of the determinant of the Hessian:

$$\operatorname{sgn}\det\left(\left.\frac{\partial\xi^\alpha}{\partial x^\beta}\right|_{x=x_0}\right)=\operatorname{sgn}\det\left(\left.\frac{\partial^2 f}{\partial x^\alpha\,\partial x^\beta}\right|_{x=x_0}\right)=(-1)^{i(x_0)},$$

where $i(x_0)$ denotes the number of negative squares occurring in the quadratic form $d^2f|_{x=x_0}$ when brought into canonical form.

Let $Q_\varepsilon\cong S^{n-1}$ be a sphere with centre an isolated singular point x_0 of a vector field ξ, and with radius $\varepsilon>0$ sufficiently small for the field ξ to be non-vanishing on Q_ε and its interior. We can then define, as in §14.2 above, the spherical Gauss map on Q_ε (relative to the field ξ):

$$f_{x_0}\colon Q_\varepsilon\to S^{n-1}.$$

14.4.2. Definition. The *index of an isolated singular point x_0 of a vector field ξ* is the degree of the Gauss map f_{x_0}:

$$\operatorname{ind}_{x_0}(\xi)=\deg f_{x_0}.$$

If the point x_0 is non-degenerate, then this definition of index is equivalent to the previous one; this is the import of the following result.

14.4.3. Theorem. *For a non-degenerate singular point x_0 of a vector field $\xi(x)$, we have*

$$\deg f_{x_0}=\operatorname{sgn}\det\left(\left.\frac{\partial\xi^\alpha}{\partial x^\beta}\right|_{x=x_0}\right),\tag{9}$$

where f_{x_0} is the Gauss map defined above.

Proof. In some neighbourhood of x_0 we have by Taylor's theorem that

$$\xi(x)=\xi^{(1)}(x)+\xi^{(2)}(x),$$

where $\xi^{(1)\beta}(x)=\partial\xi^\beta/\partial x^\gamma|_{x=x_0}(x^\gamma-x_0^\gamma)$, and $|\xi^{(2)}(x)|=o(|\xi^{(1)}(x)|)$. The homotopy $\xi(x,t)$ defined by

$$\xi(x,t)=\xi^{(1)}(x)+(1-t)\xi^{(2)}(x), \qquad 0\le t\le 1,$$

clearly has the properties that $\xi(x,0)=\xi(x)$, $\xi(x,1)=\xi^{(1)}(x)$, and in some sufficiently small neighbourhood of x_0, for all t, $0\le t\le 1$, $\xi(x,t)$ vanishes only at x_0. We have thus shown that in some neighbourhood of x_0 of the field ξ is smoothly homotopic to the linear vector field $\xi^{(1)}$ via fields for which x_0 is the only singular point (in the neighbourhood). Let ε be small enough for the sphere Q_ε with centre x_0 to be entirely contained in this neighbourhood. In the course of the above-defined deformation of ξ into $\xi^{(1)}$, the linear part of $\xi(x,t)$ remains fixed, and the map $f_{x_0}\colon Q_\varepsilon\to S^{n-1}$ undergoes a smooth homotopy; hence both sides of equation (9) remain constant throughout the homotopy, and it therefore suffices to verify (9) for the linear field $\xi^{(1)}$, and the corresponding map

$$f_{x_0}^{(1)}(x)=\frac{\xi^{(1)}(x)}{|\xi^{(1)}(x)|}.$$

Since $\xi^{(1)}$ is a non-singular linear transformation (from a neighbourhood of x_0 to a neighbourhood of the origin of $\mathbb{R}^n$), it follows that it is one-to-one, and that the map $f_{x_0}^{(1)}\colon Q_\varepsilon\to S^{n-1}$, is also one-to-one and without critical points. Hence each point y_0 on the sphere S^{n-1} is a regular value with exactly one preimage, and it is clear that the sign of the determinant of the linear transformation $\xi^{(1)}$ determines whether the orientation is preserved or reversed by $f_{x_0}^{(1)}$. This completes the proof. □

We now list the possible types of non-degenerate singular points in the simplest cases $n=2$ and 3.

(i) ($n=2$). The non-degenerate singular points of vector fields on the plane will be of one of the following types (note that in this case the index of a singular point is independent of the direction of the field):

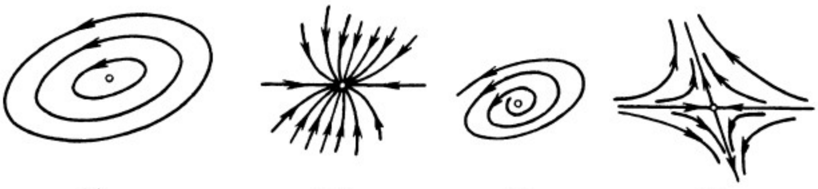

Figure 40

		Index
a centre (when both eigenvalues are purely imaginary)	Figure 40(a)	$+1$
a node (eigenvalues real and of the same sign)	Figure 40(b)	$+1$
a focal point (complex conjugate eigenvalues, not purely imaginary)	Figure 40(c)	$+1$
a saddle point (eigenvalues real and of opposite signs)	Figure 40(d)	-1

If the field happens to be the gradient of some two-variable function f then the possible singularities are restricted to the following types:

	Index
a local minimum point of f (Figure 40(b) with the arrows reversed—a "source")	$+1$
a saddle point of f (Figure 40(d))	-1
a local maximum point of f (Figure 40(b)—a "sink")	$+1$

(ii) ($n=3$). If the field is a gradient ($\xi^\alpha = \partial f/\partial x^\alpha$), a non-degenerate singular point is of one of the following types:

	Index
a local minimum point of f ("source")	$+1$
a saddle point of type 1 (when the form d^2f has only one negative square)	-1
a saddle point of type 2 (when the form d^2f has two negative squares)	$+1$
a local maximum of f ("sink")	-1

The classification of non-degenerate singular points of a general vector field in a region of $\mathbb{R}^3$ is as follows (note that either all three eigenvalues λ_i are real, or else one is real and the other two are complex conjugates):

	Index
a source (Re $\lambda_i \geq 0$, $i=1, 2, 3$)	$+1$
a saddle of type 1 (Re $\lambda_1 \geq 0$, Re $\lambda_2 \geq 0$, λ_3 real and negative)	-1
a saddle of type 2 (λ_1 real and positive, Re $\lambda_2 \leq 0$, Re $\lambda_3 \leq 0$)	$+1$
a sink (Re $\lambda_i \leq 0$, $i=1, 2, 3$)	-1

14.4.4. Theorem. *Let $\xi = \xi(x)$ be a vector field in $\mathbb{R}^n$ having only isolated singular points $x_1, \ldots, x_m$, and let Q be a closed oriented hypersurface in $\mathbb{R}^n$ avoiding the singular points of the vector field, and bounding a region D of $\mathbb{R}^n$. Then the degree of the vector field ξ on the surface Q, i.e. the degree of the Gauss map $Q \to S^{n-1}$ determined by the field, is equal to the sum of the indices of the singular points $x_{i_1}, \ldots, x_{i_k}$ lying in the region D.*

Proof. For each $j=1,\ldots,m$ let $Q_{j\varepsilon}$ be the sphere of radius $\varepsilon>0$ about the point x_j, choosing ε sufficiently small for the closed balls bounded by the $Q_{j\varepsilon}$ to miss the hypersurface Q and each other. The $\tilde{D}$ obtained from D by removing from it all open balls bounded by those spheres $Q_{j\varepsilon}$ in D, clearly has boundary

$$\partial\tilde{D}=Q\cup Q_{i_1\varepsilon}\cup\cdots\cup Q_{i_k\varepsilon}.$$

Consider now the form $f^*\Omega$ on $\tilde{D}$, where $f\colon\tilde{D}\to S^{n-1}$ is the Gauss map relative to ξ, and Ω is the form defined by the formula (3). Dimensional considerations yield immediately that $d\Omega=0$ on the sphere S^{n-1}, whence also $df^*\Omega=f^*(d\Omega)=0$ on S^{n-1}. Hence by the general Stokes formula (see §8.2) (and the additivity property of integrals) we have

$$0=\int_{\tilde{D}}df^*\Omega=\int_{\partial\tilde{D}}f^*\Omega=-\int_Q f^*\Omega+\sum_{q=1}^{k}\int_{Q_{i_q\varepsilon}}f^*\Omega,$$

where the difference in sign in the final expression is accounted for by the fact that in applying the general Stokes formula, the "external" component Q of the boundary $\partial\tilde{D}$ of $\tilde{D}$ is taken with orientation opposite to that on the boundaries of the $Q_{i_q\varepsilon}$. The theorem now follows from Definition 14.4.2 and Corollary 14.2.1. □

14.5. Transverse Surfaces of a Vector Field. The Poincaré–Bendixson Theorem

A situation of particular interest is that where the hypersurface Q is itself a sphere (of large radius) with the property that at no point of it is the vector field $\xi(x)$ tangential to it (or zero on it). We call a closed surface with the latter property a *transverse surface* to the vector field ξ. In this situation the following simple result holds.

14.5.1. Lemma. *The degree of a vector field ξ on a transverse hypersurface in $\mathbb{R}^n$ is (up to sign) equal to the (normalized) integral of the Gaussian curvature over the surface. (If the transverse surface is a sphere then this (normalized) integral is (in absolute value) unity.)*

Proof. A vector field which is transverse to a closed hypersurface $Q\subset\mathbb{R}^n$ is homotopic (in the class of fields on Q nowhere tangent to Q) to one or the other of the unit normal vector fields $\pm n(x)$ to Q, so that, degree being a homotopy invariant, we may assume our vector field on Q to be $\pm n(x)$. We know from Theorem 14.2.2 that the degree of the Gauss map (determined by $\pm n(x)$) is $\pm(1/\gamma_n)\int_Q K\,d\sigma$, where K is the Gaussian curvature on Q, $d\sigma$ is the volume element on Q, and γ_n is the volume of the unit $(n-1)$-sphere. If Q is a sphere then it is easy to calculate that $(1/\gamma_n)\int_Q K\,d\sigma=1$. This completes the proof of the lemma. □

they each have three components, say $A_a = A_a^0 e_0 + A_a^1 e_1 + A_a^2 e_2$, where e_0, e_1, e_2 form a canonical basis for L:

$$[e_0, e_1] = e_2, \qquad [e_1, e_2] = e_0, \qquad [e_2, e_0] = e_1, \tag{47}$$

chosen so that e_0 generates L_0, e_1, e_2 span L_1, and e_1, e_2 are of length 1 with respect to the scalar product $\langle\ ,\ \rangle_{L_1}$; thus

$$\langle e_0, e_0\rangle_{L_1} = 0; \qquad \langle e_1, e_1\rangle_{L_1} = \langle e_2, e_2\rangle_{L_1} = 1; \qquad \langle e_i, e_j\rangle_{L_1} = 0, \qquad i \neq j.$$

Regarding A as defining a trivial connexion on the principal G-bundle over $\mathbb{R}^2$, we deduce (as earlier) that $F_{ab} = 0$ (see e.g. Part I, §41.2), i.e.

$$\frac{\partial A_b^\beta}{\partial x^a} - \frac{\partial A_a^\beta}{\partial x^b} + [A_a, A_b]^\beta = 0, \qquad a, b = 1, 2; \quad \beta = 0, 1, 2. \tag{48}$$

Setting

$$\begin{aligned} &B_a = A_a^1 + iA_a^2, && \bar{B}_a = A_a^1 - iA_a^2, \\ &A_a^0 = if_a, && f_{ab} = \frac{\partial A_a^0}{\partial x^b} - \frac{\partial A_b^0}{\partial x^a}, \qquad a, b = 1, 2, \end{aligned} \tag{49}$$

we obtain from (48) by direct calculation (using (47)) that

$$f_{12} = \frac{i}{2}(B_1 \bar{B}_2 - B_2 \bar{B}_1), \tag{50}$$

and also

$$\frac{\partial B_1}{\partial x^2} - \frac{\partial B_2}{\partial x^1} = B_2 f_1 - B_1 f_2. \tag{51}$$

Defining a "covariant" differential operator $D = (D_1, D_2)$ in the usual way by (cf. §25.3 and Part I, §41.1)

$$D_a = \frac{\partial}{\partial x^a} + f_a,$$

(51) becomes

$$D_1 B_2 - D_2 B_1 = 0.$$

The Euler–Lagrange equations for the functional (45) turn out to have the form

$$\frac{\partial B_a}{\partial x^a} = 2f_a B_a, \qquad a = 1, 2. \tag{52}$$

Since the field $f_a = -iA_0^a$ is a gauge field (which, using (46), can be shown to have its transformation rule (under gauge transformations $g(x) \to e^{i\varphi(x)}g(x)$) of the purely gradient form $f_a \to f_a + \partial\varphi/\partial x^a$), and since $B = (B_a)$ can be shown (again via (46)) to transform according to the rule

$$B_a \to e^{i\varphi} B_a,$$

it follows that we have reduced our variational problem for n-fields to that of solving the equations (52) for the complex vector field (B_a) and the gauge field f_a, on whose stress tensor f_{ab} there is imposed the constraint

$$f_{12} = \frac{\partial f_1}{\partial x^2} - \frac{\partial f_2}{\partial x^1} = \frac{i}{2}(B_1 \bar{B}_2 - B_2 \bar{B}_1). \tag{53}$$

It can be shown that for any n-field n we have

$$n^*(\Omega) = \text{const.} \times f_{12}\, dx^1 \wedge dx^2, \tag{54}$$

where as before Ω is the $SO(3)$-invariant 2-form on S^2 given by the element of area on S^2, normalized so that $\int_{S^2} \Omega = 1$. (Thus

$$\Omega = \text{const.} \times \frac{dz \wedge d\bar{z}}{(1 + |z|^2)^2} \tag{55}$$

in terms of a suitable complex co-ordinate z *on* $S^2 \backslash \{\infty\}$ (cf. (41).) Hence the homotopy invariant d, the degree of the n-field, is also given (to within a constant factor) by the integral of the stress tensor:

$$\begin{aligned} d &= \int_{\mathbb{R}^2} n^*(\Omega) = \text{const.} \times \int_{\mathbb{R}^2} f_{12}\, dx^1 \wedge dx^2 \\ &= \text{const.} \times \oint_{\Gamma \cup \Gamma_\infty} (f_1\, dx^1 + f_2\, dx^2) = \lambda \int_{\mathbb{R}^2} (B_1 \bar{B}_2 - B_2 \bar{B}_1)\, dx^1 \wedge dx^2, \end{aligned} \tag{56}$$

where λ is a constant depending only on the degree d, and where to obtain the second equality we have used Stokes' formula (see Part I, §26.3), Γ_∞ denoting a circle in $\mathbb{R}^2$ of sufficiently large radius R and $\Gamma = \cup_i \Gamma_i$ consisting of appropriately oriented circles of small radius ε around the singular points x_i of the fields B or f. (Fields B, f with finitely many singular points in the "finite" part of S^2, i.e. in $\mathbb{R}^2$, must be admitted for consideration in order for the present formulation of the theory (of n-fields) to be valid, since in the present formalism the points x_i such that $n(x_i) = \infty$, will be singular for (B_a, f_a). A given map $n: S^2 \to S^2$ need not be globally covered by a map $g: S^2 \to S^3$, so that at one point (∞) of S^2 the corresponding cross-section (defining g) of the bundle $S^3 \to S^2$ may be many-valued, i.e. $g(x)$ may be many-valued at the points x_i in $n^{-1}(\infty)$, and consequently B or f will fail to be defined at these x_i.) (Note also that the form $f_1\, dx^1 + f_2\, dx^2$ appearing in (56) can be regarded as a connexion on the standard Hopf bundle $S^3 \to S^2$ with group $G \cong S^1$, and projection given by the natural map $SU(2) \to SU(2)/U(1)$; see §24.3, Example (a).)

We conclude the present discussion by finding an explicit expression for the B_a in terms of a holomorphic field n. Let w be the complex co-ordinate on $\mathbb{R}^2$ given by $w = x^1 + ix^2$; if the function $n = z(w)$ defined by a given n-field is holomorphic, then by (55) and Part I, Lemma 12.2.2,

$$n^*(\Omega) = \text{const.} \times \left|\frac{dz}{dw}\right|^2 \frac{dw \wedge d\bar{w}}{(1+|z(w)|^2)^2}. \tag{57}$$

Since

$$S = \int_{\mathbb{R}^2} \langle A, A\rangle_{L_1} d^2x = \int_{\mathbb{R}^2} (B_1\bar{B}_1 + B_2\bar{B}_2)\, dx^1 \wedge dx^2, \tag{58}$$

it follows (via 56) that

$$\begin{aligned} S + \frac{i}{\lambda}\int_{\mathbb{R}^2} n^*(\Omega) &= \int_{\mathbb{R}^2} (B_1\bar{B}_1 + B_2\bar{B}_2 + i(B_1\bar{B}_2 - B_2\bar{B}_1))\, dx^1 \wedge dx^2 \\ &= \int_{\mathbb{R}^2} |B_1 + iB_2|^2\, dx^1 \wedge dx^2 \geq 0. \end{aligned} \tag{59}$$

Since we are assuming $n = z(w)$ to be holomorphic, it follows (essentially from the result established earlier to the effect that the functional (58) attains the lower bound given by (59) precisely for the holomorphic n-fields of degree d) that

$$B_1 + iB_2 = 0. \tag{60}$$

Equations (53), (54), (57) and (60) together give

$$\begin{aligned} \left|\frac{dz}{dw}\right|^2 \frac{dw \wedge d\bar{w}}{(1+|z|^2)^2} &= \text{const.} \times (B_1\bar{B}_2 - B_2\bar{B}_1)\, dw \wedge d\bar{w} \\ &= \text{const.} \times B_1^2\, dw \wedge d\bar{w}, \end{aligned}$$

whence finally

$$B_1 = \frac{\text{const.}}{1+|z|^2}\frac{dz}{dw}. \tag{61}$$

We end this section with a proof of the following recent result: *The Lagrange–Euler equation $\delta S = 0$ for the extremals of the functional S given by* (40), *with the metric g_{ab} taken to be the Minkowski metric (so that the n-fields are defined on $\mathbb{R}_1^2$) rather than the Euclidean one, is equivalent to the "sine–Gordon equation"*. (The latter equation was derived in Part I, §30.4, as a necessary and sufficient condition for a surface of constant negative Gaussian curvature to be embeddable in Euclidean space $\mathbb{R}^3$.)

To prove this we first change from the usual Minkowski co-ordinates x, y of $\mathbb{R}_1^2$, in terms of which the metric has the form $ds^2 = dx^2 - dy^2$, to the co-ordinates $\eta = x + y$, $\xi = x - y$, in terms of which the metric is given by $ds^2 = d\eta\, d\xi$. If we write as before n^1, n^2, n^3 for the components of $n(x) \in \mathbb{R}^3 \supset S^2$, where $(n^1)^2 + (n^2)^2 + (n^3)^2 = 1$, the functional (40) (with g_{ab} now given by the Minkowski metric) becomes

$$S\{n\} = \int_{\mathbb{R}^2} \left(\sum_{\alpha=1}^{3} n_\xi^\alpha n_\eta^\alpha\right) d\xi\, d\eta. \tag{62}$$

2. Un hexágono regular tiene su centro en el polo y dos lados paralelos al eje polar; si la longitud de un lado es de 3 unidades, determina el par principal de coordenadas polares de cada uno de sus seis vértices.
3. Dos de los vértices de un triángulo equilátero son $A(0,0°)$ y $B(4,0°)$, encuentra el par principal de coordenadas polares del tercer vértice.
4. Determina la ecuación polar de la recta paralela al eje polar que está situada a 5 unidades por debajo del eje.
5. Demuestra por coordenadas polares que los siguientes puntos $A(-1,1)$, $B(3,1)$ y $C(1,4.46)$ son los vértices de un triángulo equilátero y determina su área.
6. Demuestra por coordenadas polares que los siguientes puntos $A(-5,0)$, $B(0,2)$ y $C(0,-2)$ son los vértices de un triángulo isósceles y determina su área.
7. Demuestra por medio de distancias que los puntos dados $A(3,30°)$, $B\left(\frac{3\sqrt{3}}{2},60\right)$ y $C(3,90°)$ son colineales.
8. Encuentra el área, perímetro y semiperímetro para un triángulo cuyos vértices son el polo y los puntos $Q(2,60°)$ y $R(1,135°)$.
9. Demuestra que las ecuaciones polares de las rectas que son perpendiculares y paralelas al eje polar se expresan en la forma $r = \pm p \sec \theta$ y $r = \pm p \csc \theta$, respectivamente, donde p es la distancia del polo a la recta.
10. Determina la ecuación polar de la recta que pasa por el punto $A(5,60°)$ y forma un ángulo de 120° con el eje polar.
11. Encuentra la ecuación polar de la recta que pasa por el punto $Q(4,120°)$ y por el polo.
12. Determina la ecuación polar de la recta que pasa por el punto $M\left(2,\frac{2\pi}{3}\right)$ y es perpendicular a la recta que une el polo con dicho punto.
13 Encuentra la ecuación de la recta que pasa por el punto $K(7,20°)$ y forma un ángulo de 140° con el eje polar.
14. Encuentra la ecuación de la recta que pasa por el punto $R(4,120°)$ y es perpendicular a la que une al polo con dicho punto.
15. Dos de los vértices de un paralelogramo son los puntos $A(3,-80°)$ y $B\left(5,\frac{3\pi}{14}\right)$; si el punto de intersección de sus diagonales es el polo, encuentra las coordenadas de los otros dos vértices del paralelogramo.

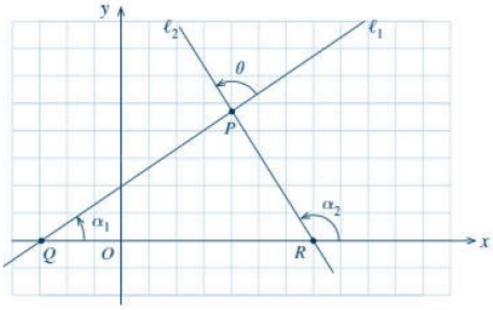
Ángulo entre dos rectas

Sean ℓ_1 y ℓ_2 dos rectas que se cortan en el punto P y que cortan al eje x en los puntos Q y R; las cuales forman con el eje x ángulos α_1 y α_2, de tal forma que sus pendientes son $m_1 = \tan \alpha_1$ y $m_2 = \tan \alpha_2$, donde α_1 y α_2 son diferentes de $\frac{\pi}{2}$.

Al cortarse, las rectas forman dos ángulos suplementarios, uno de ellos es el ángulo θ, cuya relación con las rectas se muestra en los siguientes casos.

Caso 1

Gráficamente, se tiene:



y
x
ℓ_1
ℓ_2
θ
P
α_1
α_2
Q
O
R

Los principios básicos de la geometría establecen que un ángulo exterior de un triángulo es igual a la suma de los dos ángulos interiores opuestos, es decir:

$$\alpha_2 = \alpha_1 + \theta$$

De tal forma, que el ángulo entre las rectas es:

$$\theta = \alpha_2 - \alpha_1$$

Al aplicar la fórmula trigonométrica: $\tan(\alpha_2 - \alpha_1) = \dfrac{\tan\alpha_2 - \tan\alpha_1}{1 + \tan\alpha_2 \tan\alpha_1}$, se tiene:

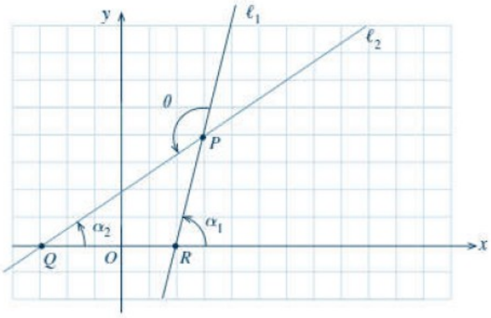
$$\tan\theta = \frac{\tan\alpha_2 - \tan\alpha_1}{1 \pm \tan\alpha_2 \tan\alpha_1}$$

Al sustituir $m_1 = \tan\alpha_1$ y $m_2 = \tan\alpha_2$ resulta:

$$\tan\theta = \frac{m_2 - m_1}{1 + m_2 m_1}, \text{ para } m_2 m_1 \neq -1.$$

Caso 2

Gráficamente, se tiene:



y
x
ℓ_1
ℓ_2
θ
P
α_2
α_1
Q
O
R

Por geometría elemental, se tiene que:

$$\begin{aligned} \theta &= \alpha_2 + (180^\circ - \alpha_1) \\ -180^\circ + \theta &= \alpha_2 - \alpha_1 \\ 180^\circ - \theta &= \alpha_1 - \alpha_2 \end{aligned}$$

Al aplicar la misma fórmula trigonométrica del caso anterior para las tangentes, resulta:

$$\tan(180^\circ - \theta) = \frac{\tan\alpha_1 - \tan\alpha_2}{1 + \tan\alpha_1 \tan\alpha_2}$$

Por la fórmula trigonométrica: $\tan(180^\circ - \theta) = -\tan\theta$, se tiene:

$$-\tan\theta = \frac{\tan\alpha_1 - \tan\alpha_2}{1 + \tan\alpha_1 \tan\alpha_2} \qquad \tan\theta = \frac{\tan\alpha_2 - \tan\alpha_1}{1 + \tan\alpha_1 \tan\alpha_2}$$

Al sustituir $m_1 = \tan\alpha_1$ y $m_2 = \tan\alpha_2$, resulta:

$$\tan\theta = \frac{m_2 - m_1}{1 + m_1 m_2}, \text{ para } m_1 m_2 \neq -1.$$

Teorema

Sean ℓ_1 y ℓ_2 dos rectas que tienen pendientes m_1 y m_2, respectivamente; si θ es el ángulo dirigido de ℓ_1 a ℓ_2, se establece que:

$$\tan\theta = \frac{m_2 - m_1}{1 + m_1 m_2}, \text{ para } m_1 m_2 \neq -1.$$

Para saber cuál de los dos ángulos se va determinar (Caso I o Caso II) se debe considerar que el ángulo se mide girando en el sentido contrario a las manecillas del reloj, por lo que la recta ℓ_1 será la que corresponde al **lado inicial** del ángulo y la recta ℓ_2 la que corresponde al **lado final**.

Deducción de las condiciones de paralelismo y perpendicularidad de dos rectas

Cuando dos rectas son paralelas, el ángulo que se forma entre ellas es de 0° o de 180°. Al aplicar la fórmula para determinar el ángulo de dos rectas, resulta:

Para $\theta = 0^\circ$

$$\begin{aligned} \tan\theta &= \frac{m_2 - m_1}{1 + m_1 m_2} \\ \tan 0^\circ &= \frac{m_2 - m_1}{1 + m_1 m_2} \\ 0 &= \frac{m_2 - m_1}{1 + m_1 m_2} \end{aligned}$$

$$m_2 - m_1 = 0$$

$$m_2 = m_1$$

Para $\theta = 180^\circ$

$$\begin{aligned} \tan\theta &= \frac{m_2 - m_1}{1 + m_1 m_2} \\ \tan 180^\circ &= \frac{m_2 - m_1}{1 + m_1 m_2} \\ 0 &= \frac{m_2 - m_1}{1 + m_1 m_2} \end{aligned}$$

$$m_2 - m_1 = 0$$

$$m_2 = m_1$$

Por el carácter simétrico o recíproco de la igualdad, se tiene que $m_1 = m_2$. Por consecuencia, se establece: **si dos rectas son paralelas, sus pendientes son iguales**.

Cuando dos rectas son perpendiculares, el ángulo que se forma entre ellas es de 90°, entonces, al aplicar la fórmula para determinar el ángulo de dos rectas, resulta:

$$\tan\theta = \frac{m_2 - m_1}{1 + m_1 m_2}$$

$$\tan 90^\circ = \frac{m_2 - m_1}{1 + m_1 m_2}$$

Como $\tan 90^\circ = \infty$, la ecuación anterior no apoya el principio que se desea demostrar, por lo que es necesario emplear la siguiente identidad:

$$\cot\theta = \frac{1}{\tan\theta}$$

Al sustituir en la expresión anterior, resulta:

$$\cot\theta = \frac{1}{\dfrac{m_2 - m_1}{1 + m_1 m_2}}$$

$$\cot 90^\circ = \frac{1 + m_1 m_2}{m_2 - \mathbf{m}_1}$$

$$0 = \frac{1 + m_1 m_2}{m_2 - m_1}$$

$$1 + m_1 m_2 = 0$$

$$m_1 m_2 = -1$$

Por consecuencia, se establece: **dos rectas son perpendiculares entre sí, cuando el producto de sus pendientes es igual a -1.**

También de la ecuación $m_1 m_2 = -1$, se tiene:

$$m_1 = -\frac{1}{m_2} \qquad m_2 = -\frac{1}{m_1}$$

Lo que da lugar al siguiente criterio equivalente: *dos rectas son perpendiculares si sus pendientes son recíprocas y de signos contrarios.*

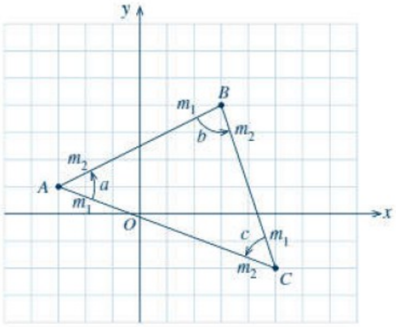
EJEMPLOS

Ejemplos

1 Determina los ángulos interiores del triángulo cuyos vértices son los puntos $A(-2,1)$, $B(3,4)$ y $C(5,-2)$ y comprueba los resultados.

Solución

Al elaborar la gráfica de los puntos dados, se tiene:



Se determinan las pendientes de los lados del triángulo, es decir:

$$m\,\overline{AB}=\frac{y_A-y_B}{x_A-x_B}=\frac{1-4}{-2-3}=\frac{-3}{-5}=\frac{3}{5}$$

$$m\,\overline{BC}=\frac{y_B-y_C}{x_B-x_C}=\frac{4+2}{3-5}=\frac{6}{-2}=-3$$

$$m\,\overline{AC}=\frac{y_A-y_C}{x_A-x_C}=\frac{1+2}{-2-5}=\frac{3}{-7}=-\frac{3}{7}$$

Al aplicar la fórmula $\tan\theta=\dfrac{m_2-m_1}{1+m_1m_2}$, resulta:

Para el $\sphericalangle a$

$$\tan a=\frac{m_{\overline{AB}}-m_{\overline{AC}}}{1+m_{\overline{AC}}m_{\overline{AB}}}$$

$$\tan a=\frac{\frac{3}{5}-\left(-\frac{3}{7}\right)}{1+\left(-\frac{3}{7}\right)\left(\frac{3}{5}\right)}$$

$$\tan a=\frac{\frac{21+15}{\cancel{35}}}{\frac{35-9}{\cancel{35}}}$$

$$\tan a=\frac{36}{26}=1.3846$$

$$\sphericalangle a=\arctan(1.3846)$$

$$\sphericalangle a=54°09'44''$$

Para el $\sphericalangle b$

$$\tan b=\frac{m_{\overline{BC}}-m_{\overline{AB}}}{1+m_{\overline{AB}}m_{\overline{BC}}}$$

$$\tan b=\frac{-3-\frac{3}{5}}{1+\left(\frac{3}{5}\right)(-3)}$$

$$\tan b=\frac{\frac{-18}{\cancel{5}}}{\frac{5-9}{\cancel{5}}}$$

$$\tan b=\frac{-18}{-4}=4.5$$

$$\sphericalangle \boldsymbol{b}=\arctan(4.5)$$

$$\sphericalangle b=77°28'16''$$

Para el $\sphericalangle c$

$$\tan c=\frac{m_{\overline{AC}}-m_{\overline{BC}}}{1+m_{\overline{BC}}m_{\overline{AC}}}$$

$$\tan c=\frac{-\frac{3}{7}-(-3)}{1+(-3)\left(-\frac{3}{7}\right)}$$

$$\tan c=\frac{\frac{-3+21}{\cancel{7}}}{\frac{7+9}{\cancel{7}}}$$

$$\tan c=\frac{18}{16}=1.125$$

$$\sphericalangle c=\arctan(1.125)$$

$$\sphericalangle c=48°21'59''$$

Como los ángulos interiores de todo triángulo suman 180°, se tiene una aproximación por redondeo:

$$\begin{aligned} \sphericalangle a + \sphericalangle b + \sphericalangle c &= 180^\circ \\ 54^\circ 09' 44'' + 77^\circ 28' 16'' + 48^\circ 21' 59'' &= 180^\circ \\ 179^\circ 59' 59'' &\approx 180^\circ \end{aligned}$$

2 ●●· Dos rectas se cortan formando un ángulo de 45°, la recta inicial pasa por los puntos $A(-2,1)$ y $B(9,7)$ y la recta final pasa por el punto $P(3,9)$ y por el punto Q, cuya abscisa es -2; determina la ordenada de Q.

Solución

De acuerdo con los datos dados, es necesario determinar las pendientes de las rectas inicial y final, dado que se conoce el ángulo entre las dos rectas, se tiene:

$$m_i = \frac{y_A - y_B}{x_A - x_B} = \frac{1-7}{-2-9} = \frac{-6}{-11} = \frac{6}{11}$$

$$m_f = \frac{y_P - y_Q}{x_P - x_Q} = \frac{9-y}{3+2} = \frac{9-y}{5}$$

Al sustituir en la fórmula del ángulo de dos rectas, resulta:

$$\tan\theta = \frac{m_f - m_i}{1 + m_i m_f}$$

$$\tan 45^\circ = \frac{\frac{9-y}{5} - \frac{6}{11}}{1 + \left(\frac{6}{11}\right)\left(\frac{9-y}{5}\right)}$$

$$\tan 45^\circ = \frac{\frac{11(9-y)-(5)(6)}{55}}{1 + \frac{54-6y}{55}}$$

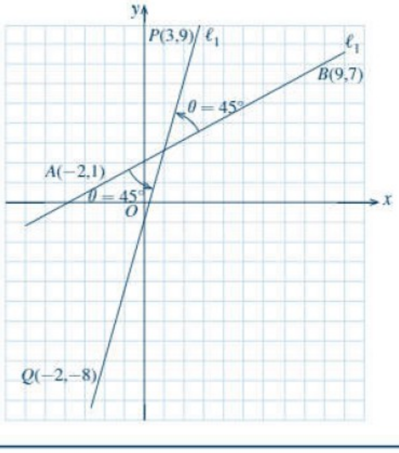
$$\tan 45^\circ = \frac{\frac{99-11y-30}{\cancel{55}}}{\frac{55+54-6y}{\cancel{55}}}$$

$$1 = \frac{69-11y}{109-6y}$$

$$\begin{aligned} 1(109-6y) &= 69-11y \\ 109-6y+11y &= 69 \\ 5y &= 69-109 \\ y &= \frac{-40}{5} \\ y &= -8 \end{aligned}$$

La ordenada del punto Q es -8.

Gráficamente, se tiene:



Posiciones relativas de dos rectas

A continuación discutiremos las condiciones analíticas de las posiciones relativas de dos rectas, cuyas ecuaciones se expresan en las formas generales $Ax + By + C = 0$ y $A'x + B'y + C' = 0$, bajo las cuales estas dos rectas son:

1. **Paralelas**. De la recta $Ax + By + C = 0$, su pendiente es $m = -\frac{A}{B}$, para $B \neq 0$; para la recta $A'x + B'y + C' = 0$, su pendiente es $m' = -\frac{A}{B}$, para $B' \neq 0$.

   Con base en el principio que establece que **si dos rectas son paralelas, sus pendientes son iguales**, se tiene que: $-\frac{A}{B} = -\frac{A'}{B'}$, o bien, $\frac{A}{B} = \frac{A'}{B'}$. Esta expresión puede escribirse como:

   $$AB' = A'B$$

   Al dividir la igualdad entre $A'B'$, resulta:

   $$\frac{A\cancel{B'}}{A'\cancel{B'}} = \frac{\cancel{A'}B}{\cancel{A'}B'}$$

   $$\frac{A}{A'} = \frac{B}{B'} \quad \Big\} \text{ Esto indica que los coeficientes de } x \text{ y } y \text{ deben ser proporcionales.}$$

   La expresión anterior sólo se aplica cuando $A' \neq 0$ y $B' \neq 0$. Si $A' = 0$, la recta es paralela al eje x, de esta forma, ambas rectas serán horizontales; cuando $B' = 0$, la recta es parelala al eje y, entonces, ambas rectas serán verticales.

   Entonces, la relación equivalente $AB' = A'B$ es verdadera para cualquier caso.

2. **Perpendiculares**. Con base en el principio que establece que **si dos rectas son perpendiculares entre sí, el producto de sus pendientes es igual a -1**, se tiene que:

   $$m = -\frac{A}{B} \qquad\qquad m' = -\frac{A'}{B'}$$

   De tal forma que:

   $$\left(-\frac{A}{B}\right)\left(-\frac{A'}{B'}\right) = -1$$

   Lo anterior da lugar a la relación $AA' + BB' = 0$, sea verdadera para cualquier caso, siempre que las rectas sean perpendiculares.

3. **Coinciden**. Cuando dos rectas tienen todos los puntos comunes y la misma pendiente, se dice que son coincidentes.

   Dadas las rectas $Ax + By + C = 0$ y $A'x + B'y + C = 0$, su intersección con el eje x, será el punto de abscisa, es decir:

   $$x = -\frac{C}{A} \quad x = -\frac{C'}{A'}$$

   Por lo anterior, se establece que $-\frac{C}{A} = -\frac{C'}{A'}$, lo que da lugar a la siguiente relación:

   $$\frac{A}{A'} = \frac{C}{C'}$$

Como las pendientes son iguales, se tiene que $-\frac{A}{B}=-\frac{A'}{B'}$, o la relación: $\frac{A}{A'}=\frac{B}{B'}$. Al relacionar ambos criterios, queda: $\frac{A}{A'}=\frac{B}{B'}=\frac{C}{C'}$, es decir, dos rectas son coincidentes, si sus coeficientes correspondientes son proporcionales.

Lo anterior es verdadero sólo si todos los coeficientes son diferentes de cero. Las relaciones equivalentes $A = kA'$, $B = kB'$ y $C = kC'$, para alguna constante k, caracterizan a dos rectas coincidentes cualquier caso.

4. **Se cortan en uno y solamente un punto**. Dos rectas no paralelas, por geometría, se cortan en uno y solamente en un punto; analíticamente, se deduce que sus pendientes no son iguales, por lo que sus coeficientes no son proporcionales, es decir:

$$\frac{A}{A'}\neq\frac{B}{B'},\ \text{o bien, } AB'-A'B\neq 0.$$

EJEMPLOS

Ejemplos

1 La ecuación de una recta es $3x - 2y - 6 = 0$; determina la ecuación que representa a todas las rectas paralelas a la recta dada. A partir de esta última ecuación encuentra la ecuación de la recta paralela a la recta dada y que pasa por el punto $A(-3,5)$.

Solución

La ecuación de la recta que representa a todas las rectas paralelas a la ecuación $3x - 2y - 6 = 0$, es:

$$Ax + By + C = 0$$

La condición de paralelismo establece que:

$$\frac{A}{A'}=\frac{B}{B'}\ \text{es decir, } \frac{A}{3}=\frac{B}{-2}$$

$$B=-\frac{2A}{3}$$

Al sustituir en la ecuación $Ax + By + C = 0$, se tiene:

$$Ax+\left(-\frac{2A}{3}\right)y+C=0$$

$$3Ax - 2Ay + 3C = 0$$

Al dividir entre A, resulta:

$$\frac{3\cancel{A}x}{\cancel{A}}-\frac{2\cancel{A}y}{\cancel{A}}+\frac{3C}{A}=0$$

Al hacer $k=\frac{3C}{A}$, se tiene:

$$3x-2y+\frac{3C}{A}=0$$
$$3x-2y+k=0$$

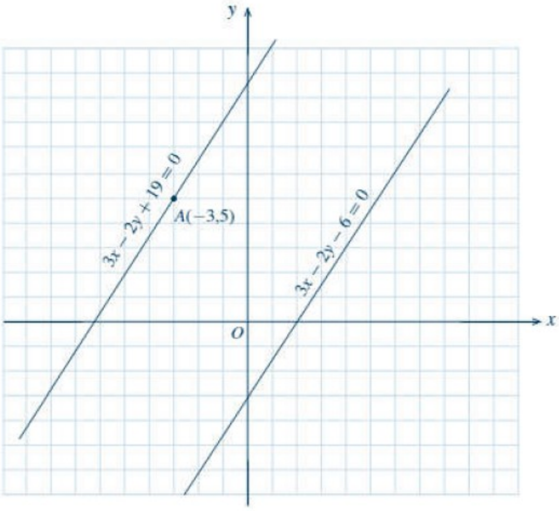
Ecuación que representa a todas las rectas paralelas a $3x - 2y - 6 = 0$

Específicamente, la recta paralela a la recta dada debe pasar por el punto $A(-3{,}5)$, es decir:

$$\begin{aligned} 3x-2y+k&=0\\ 3(-3)-2(5)+k&=0\\ -9-10+k&=0\\ k&=19 \end{aligned}$$

La ecuación de la recta que pasa por el punto $A(-3{,}5)$ y que es paralela a la recta dada es $3x-2y+19=0$.

Gráficamente, se tiene:



2 ●●• Demuestra que las rectas $3x-15y-21=0$ y $x-5y-7=0$, son coincidentes.

Solución

La condición que establece la coincidencia, indica que dos rectas tienen todos los puntos comunes y la misma pendiente, es decir:

$$m_1=-\frac{A}{B}=-\frac{3}{-15}=\frac{1}{5} \qquad m_2=-\frac{A}{B}=-\frac{1}{-5}=\frac{1}{5}$$

Como las pendientes son iguales, se debe cumplir la siguiente relación:

$$\frac{A}{A'}=\frac{B}{B'}$$

Al sustituir los coeficientes de las ecuaciones en la relación, se tiene:

$$\frac{3}{1}=\frac{-15}{-5}$$
$$3=3$$

La intersección de las rectas dadas con el eje x son:

$$x_1 = -\frac{C}{A} = -\frac{-21}{3} = 7 \qquad x_2 = -\frac{-7}{1} = 7$$

Como ambas rectas tienen el mismo punto en común, se debe cumplir la siguiente relación:

$$\frac{A}{A'} = \frac{C}{C'}$$

Al sustituir los coeficientes de las ecuaciones en la relación, se tiene

$$\frac{3}{1} = \frac{-21}{-7}$$
$$3 = 3$$

El principio de rectas coincidentes establece que:

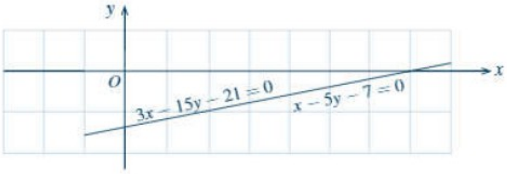
$$\frac{A}{A'} = \frac{B}{B'} = \frac{C}{C'}$$

Al sustituir los coeficientes de las ecuaciones en la relación, se tiene:

$$\frac{3}{1} = \frac{-15}{-5} = \frac{-21}{-7}$$
$$3 = 3 = 3$$

Por lo tanto, se demuestra que las dos rectas dadas son coincidentes.

Gráficamente, se tiene:



3 ●•·Demuestra que las rectas $3x + 4y - 12 = 0$ y $5x + 12y - 60 = 0$, se cortan en uno y solamente en un punto; determina las coordenadas del punto de intersección.

Solución

La condición que establece la intersección en uno y solamente un punto, indica que las dos rectas no tienen pendientes iguales y sus coeficientes no son proporcionales, es decir:

$$m_1 = -\frac{A}{B} = -\frac{3}{4} \quad m_2 = -\frac{A}{B} = -\frac{5}{12} \quad \therefore \quad \begin{matrix} m_1 \neq m_2 \\ -\frac{3}{4} \neq -\frac{5}{12} \end{matrix}$$

Como las pendientes no son iguales, se debe cumplir la siguiente relación:

$$\frac{A}{A'} \neq \frac{B}{B'} \qquad \text{o} \qquad AB' - A'B \neq 0$$

Al sustituir los coeficientes de las ecuaciones en la relación, se tiene:

$$\frac{3}{5} \neq \frac{4}{12} \qquad \text{o} \qquad (3)(12) - (5)(4) \neq 0$$

$$0.666\ldots \neq 0.333\ldots \qquad 16 \neq 0$$

Por lo anterior, se demuestra que las dos rectas dadas
se cortan en uno y solamente en un punto.

Al resolver el sistema de ecuaciones dadas, se tiene:

$$3x + 4y - 12 = 0 \quad \textbf{(1)}$$
$$5x + 12y - 60 = 0 \quad \textbf{(2)}$$

Al multiplicar la ecuación (**1**) por -3, resulta:

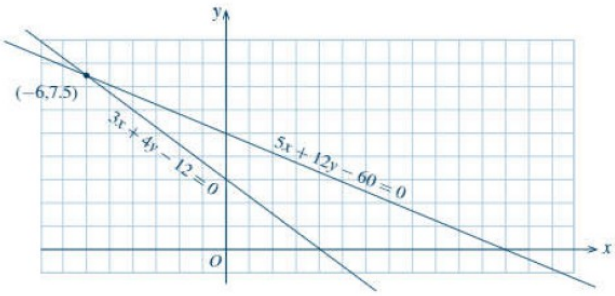
$$-3(3x + 4y - 12) = 0 \longrightarrow \begin{array}{r} -9x - \cancel{12y} + 36 = 0 \\ 5x + \cancel{12y} - 60 = 0 \\ \hline -4x - 24 = 0 \\ -4x = 24 \\ x = \dfrac{24}{-4} \\ x = -6 \end{array}$$

Al sustituir el valor de x en la ecuación (**1**):

$$\begin{array}{r} 5(-6) + 12y - 60 = 0 \\ -30 + 12y - 60 = 0 \\ 12y - 90 = 0 \\ 12y = 90 \\ y = \dfrac{90}{12} \\ y = 7.5 \end{array}$$

Las cordenadas del punto de intersección de las rectas dadas son $(-6{,}7.5)$.

Al elaborar la gráfica correspondiente, se tiene:



$\tan(\alpha_2 - \alpha_1) = \dfrac{\tan\alpha_2 - \tan\alpha_1}{1 + \tan\alpha_2 \tan\alpha_1}$, se tiene:

$$\tan\theta = \frac{\tan\alpha_2 - \tan\alpha_1}{1 \pm \tan\alpha_2 \tan\alpha_1}$$

Al substituir $m_1 = \tan\alpha_1$ y
$m_2 = \tan\alpha_2$
resulta:

$$\tan\theta = \frac{m_2 - m_1}{1 + m_2 m_1},$$ para

$m_2 m_1 \neq 1$.

Because the system of equations obtained by deleting all the equations for all the edges on the circuit from (1.6) is equivalent to the original system of equations (1.6), in virtue of the finite recursion principle a solution of (1.6) can always be extracted . $\square$

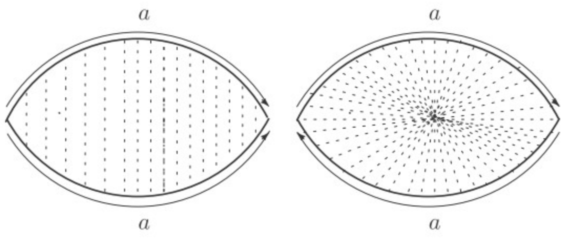
When $n = 2$, this theorem has a variety of applications. In [Liu5], some applications can be seen. Further, its extension on a nonAbelian group can also be done while the system of equations are not yet linear but quadratic.

I.2 Surfaces

In topology, a surface is a compact 2-dimensional manifold without boundary. In fact, it can be seen as what is obtained by identifying each pair of edges on a polygon of even edges pairwise.

For example, in Fig.1.3, two ends of each dot line are the same point. The left is a sphere, or the plane when the infinity is seen as a point. The right is the projective plane. From the symmetry of the sphere, a surface can also seen as a sphere cutting off a polygon with pairwise edges identified.

The two surfaces in Fig.1.3 are formed by a polygon of two edges pairwise as a.



Sphere(Plane) Projective plane

Fig.1.3 Sphere and projective plane

Surface closed curve axiom A closed curve on a surface has one of the two possibilities: one side and two sides.

A curve with two sides is called a *double side curve* ; otherwise, a *single side curve* . As shown in Fig.1.3, any closed curve on a sphere is a double side curve(In fact, this is the Jordan curve axiom). However, it is different from the sphere for the projective plane. there are both a single(shown by a dot line) and a double side curve.

How do we justify whether a closed curve on a surface is of single side, or not?

In order to answer this question, the concept of contractibility of a curve has to be clarified. If a closed curve on a surface can be continuously contracted along one side into a point, then it is said to be *contractible*, or *homotopic* to 0.

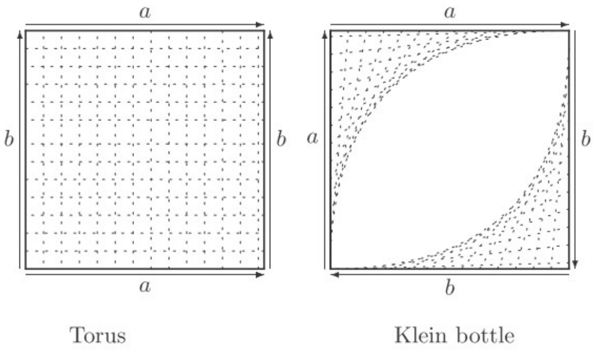


Fig.1.4 Torus and Klein bottle

It is seen that a single side curve is never homotopic to 0 and a double side curve is not always homotopic to 0. For example, in Fig.1.4, the left, *i.e.*, the torus, each of the dot lines is of double side but not contractible. The right, *i.e.*, the Klein bottle, all the dot lines are of single side , and hence, none of them is contractible.

A surface with all closed curves of double side is called *orientable*; otherwise, *nonorientable* .

For example, in Fig.1.3, the sphere is orientable and the projective plane is nonorientable. In Fig.1.4, the torus is orientable and the Klein bottle is nonorientable.

The maximum number of closed curves cutting along without destroying the continuity on a surface is called the *pregenus* of the surface.

In view of Jordan curve axiom, there is no such closed curve on the sphere. Thus, the pregenus of sphere is 0. On the projective plane, only one such curve is available (each of dot lines is such a closed curve in Fig.1.3) and hence the pregenus of projective plane is 1.

Similarly, the pregenera of torus and Klein bottle are both 2 as shown in Fig.1.4.

Theorem 1.5 The pregenus of an orientable surface is a nonnegative even number.

A formal proof can not be done until Chapter 5. Based on this theorem, the genus of an orientable surface can be defined to be half its pregenus, called the *orientable genus*. The genus of a nonorientable surface, called *nonorientable genus*, is its pregenus itself.

The sphere is written as aa^{-1} where a^{-1} is with the opposite direction of a on the boundary of the polygon. Thus, the projective plane, torus and Klein bottle are, respectively, aa, $aba^{-1}b^{-1}$ and $aabb$. In general,

$$\begin{aligned} O_p &= \prod_{i=1}^{p} a_i b_i a_i^{-1} b_i^{-1} \\ &= a_1 b_1 a_1^{-1} b_1^{-1} a_2 b_2 a_2^{-1} b_2^{-1} \cdots a_p b_p a_p^{-1} b_p^{-1} \end{aligned} \tag{1.8}$$

and

$$Q_q = \prod_{i=1}^{q} a_i a_i = a_1 a_1 a_2 a_2 \cdots a_q a_q \tag{1.9}$$

denote, respectively, a surface of orientable genus p and a surface of nonorientable genus q. Of course, O_0, Q_1, O_1 and Q_2 are, respectively, the sphere, projective plane, torus and Klein bottle.

It is easily checked that whenever an even polygon is with a pair of its edges in the same direction, the polygon represents a nonorientable surface. Thus, all O_p, $p \geq 0$, orientable and all Q_q, $q \geq 1$, are nonorientable.

Forms (1.8) and (1.9) are said to be *standard*.

If the *form* of a surface is defined by its orientability and its genus, then the operations 1–3 and their inverses shown as in Fig.1.5–7, do not change the surface form.

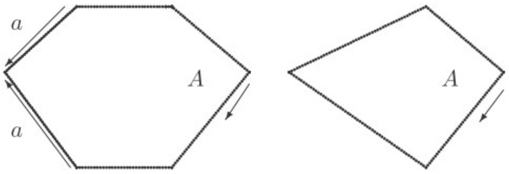

Fig.1.5 Operation 1: $Aaa^{-1} \Longleftrightarrow A$

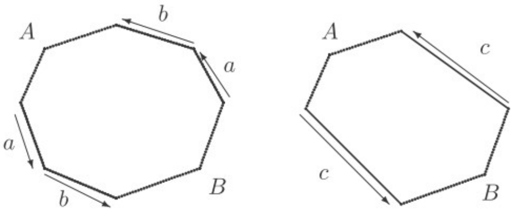

Fig.1.6 Operation 2: $AabBab \Longleftrightarrow AcBc$

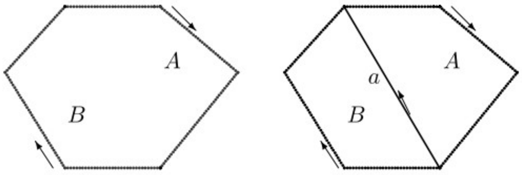

Fig.1.7 Operation 3: $AB \Longleftrightarrow (Aa)(a^{-1}B)$

In fact, what is determined under these operations is just a topological equivalence, denoted by $\sim_{\text{top}}$.

Notice that A and B are all linear order of letters and permitted to be empty as degenerate case in these operations.

The parentheses stand for cyclic order when more than one cyclic orders occur for distinguishing from one to another.

Relation 0 On a surface (A, B), if A is a surface itself then $(A, B) = ((A)x(B)x^{-1}) = ((A)(B))$.

Relation 1 $(AxByCx^{-1}Dy^{-1}) \sim_{\text{top}} ((ADCB)(xyx^{-1}y^{-1}))$.

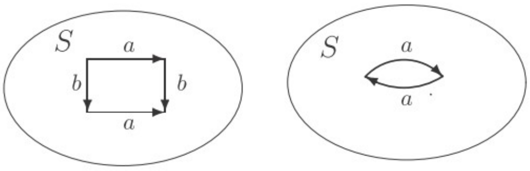
Relation 2 $(AxBx) \sim_{\text{top}} ((AB^{-1})(xx))$.

Relation 3 $(Axxyzy^{-1}z^{-1}) \sim_{\text{top}} ((A)(xx)(yy)(zz))$.

In the four relations, A, B, C, and D are permitted to be empty. $B^{-1} = b_s^{-1} \cdots b_3^{-1}b_2^{-1}b_1^{-1}$ is also called the inverse of $B = b_1b_2b_3 \cdots b_s$, $s \geq 1$. Parentheses are always omitted when unnecessary to distinguish cyclic or linear order.

On a surface S, the operation of cutting off a quadrangle $aba^{-1}b^{-1}$ and then identifying each pair of edges with the same letter is called a *handle* as shown in the left of Fig.1.8.

If the quadrangle $aba^{-1}b^{-1}$ is replaced by aa, then such an operation is called a *crosscap* as shown in the right of Fig.1.8.



Handle Crosscap

Fig.1.8 Handle and crosscap

The following theorem shows the result of doing a handle on an orientable surface.

Theorem 1.6 What is obtained by doing a handle on an orientable surface is still orientable with its genus 1 added.

Proof Suppose S is the surface obtained, then

$$\begin{aligned}S &\sim_{\text{top}} \prod_{i=1}^{p} a_i b_i a_i^{-1} b_i^{-1} x a_{p+1} b_{p+1} a_{p+1}^{-1} b_{p+1}^{-1} x^{-1} \text{ (Relation 0)}\\ &\sim_{\text{top}} \prod_{i=1}^{p} a_i b_i a_i^{-1} b_i^{-1} x x^{-1} a_{p+1} b_{p+1} a_{p+1}^{-1} b_{p+1}^{-1} \text{ (Relation 1)}\\ &\sim_{\text{top}} \prod_{i=1}^{p} a_i b_i a_i^{-1} b_i^{-1} a_{p+1} b_{p+1} a_{p+1}^{-1} b_{p+1}^{-1} \text{ (Operation 1)}\\ &= \prod_{i=1}^{p+1} a_i b_i a_i^{-1} b_i^{-1}.\end{aligned}$$

This is the theorem. □

In the above proof, x and x^{-1} are a line connecting the two boundaries to represent the surface as a polygon shown in Fig.1.8. This procedure can be seen as the degenerate case of operation 3.

In what follows, observe the result by doing a crosscap on an orientable surface.

Theorem 1.7 On an orientable surface of genus p, $p \geq 0$, what is obtained by doing a crosscap is nonorientable with its genus $2p+1$.

Proof Suppose N is the surface obtained, then

$$\begin{aligned}N &\sim_{\text{top}} \prod_{i=1}^{p} a_i b_i a_i^{-1} b_i^{-1} x a a x^{-1} \text{ (Relation 0)}\\ &\sim_{\text{top}} \prod_{i=1}^{p} a_i b_i a_i^{-1} b_i^{-1} x x^{-1} c_1 c_1 \text{ (Relation 2)}\\ &\sim_{\text{top}} \prod_{i=2}^{p} a_i b_i a_i^{-1} b_i^{-1} x x^{-1} c_1 c_1 c_2 c_2 c_3 c_3 \text{ (Relation 3)}\\ &\sim_{\text{top}} \prod_{i=1}^{2p+1} c_i c_i. \text{ (Relation 3 by } p-1 \text{ times).}\end{aligned}$$

This is the theorem. □

By doing a handle on a nonorientable surface, 2 more genus should be added with the same nonorientability.

Theorem 1.8 On a nonorientable surface, what is obtained by doing a handle is nonorientable with its genus 2 added.

Proof Suppose N is the obtained surface, then

$$\begin{aligned} N &\sim_{\text{top}} \prod_{i=1}^{q} a_i a_i x a b a^{-1} b^{-1} x^{-1} \text{ (Relation 0)} \\ &\sim_{\text{top}} \prod_{i=1}^{q} a_i a_i x x^{-1} a b a^{-1} b^{-1} \text{ (Relation 1)} \\ &\sim_{\text{top}} \prod_{i=1}^{q} a_i a_i a b a^{-1} b^{-1} \text{ (Operation 1)} \\ &\sim_{\text{top}} \prod_{i=1}^{q+2} c_i c_i. \text{ (Relation 3)}. \end{aligned}$$

This is the theorem. □

By doing a crosscap on a nonorientable surface, 1 more genus produced with the same nonorientability

Theorem 1.9 On a nonorientable surface, what is obtained by doing a crosscap is nonorientable with its genus 1 added.

Proof Suppose N is the obtained surface, then

$$\begin{aligned} N &\sim_{\text{top}} \prod_{i=1}^{q} a_i a_i x a a x^{-1} \text{ (Relation 0)} \\ &\sim_{\text{top}} \prod_{i=1}^{q} a_i a_i x x^{-1} a a \text{ (Relation 2)} \\ &\sim_{\text{top}} \prod_{i=1}^{q} a_i a_i a a \text{ (Operation 1)} \\ &\sim_{\text{top}} \prod_{i=1}^{q+1} a_i a_i. \text{ (Relation 3).} \end{aligned}$$

This is the theorem. □

I.3 Embedding

Let $G = (V, E)$, $V = \{v_1, v_2, \cdots, v_n\}$, be a graph. A point in the 3-dimensional space is represented by a real number t as the parameter, *e.g.*, $(x, y, z) = (t, t^2, t^3)$. Write the vertices as

$$v_i = (x_i, y_i, z_i) = (t_i, t_i^2, t_i^3)$$

such that $t_i \neq t_j$, $i \neq j$, $1 \leq i, j \leq n$, and an edge as

$$(u, v) = u + \lambda v, \ 1 \leq \lambda \leq 1,$$

i.e., the straight line segment between u and v. Because for any four vertices v_i, v_j, v_l and v_k,

$$\det \begin{pmatrix} x_i - x_j & x_i - x_l & x_i - x_k \\ y_i - y_j & y_i - y_l & y_i - y_k \\ z_i - z_j & z_i - z_l & z_i - z_k \end{pmatrix}$$

$$= \det \begin{pmatrix} t_i - t_j & t_i - t_l & t_i - t_k \\ t_i^2 - t_j^2 & t_i^2 - t_l^2 & t_i^2 - t_k^2 \\ t_i^3 - t_j^3 & t_i^3 - t_l^3 & t_i^3 - t_k^3 \end{pmatrix}$$

Nous venons de voir donc que l'aire se définit, de même que la longueur, par la donnée du produit scalaire (g_{ij}) de deux vecteurs tangents en chaque point.

Exercices. 1. Le tore T^2 dans l'espace euclidien à trois dimensions est une surface de révolution engendrée par un cercle qui tourne autour d'une droite contenue dans le plan du cercle. On demande d'écrire les équations paramétriques du tore et la métrique induite sur le tore.

2. Chercher la première forme fondamentale pour l'ellipsoïde de révolution

$$\frac{x^2}{a^2} + \frac{y^2 + z^2}{b^2} = 1.$$

3. Chercher la métrique induite sur la surface de révolution

$$r(u, \varphi) = \{\rho(u) \cos \varphi, \rho(u) \sin \varphi, z(u)\}.$$

Vérifier que ses méridiens $\{\varphi = \text{const}\}$ et parallèles $\{u = \text{const}\}$ forment un réseau orthogonal. Définir les bissectrices des angles formés par les méridiens et les parallèles.

4. Définir sur la sphère les loxodromies, c'est-à-dire les courbes qui coupent les méridiens sous un angle donné α. Chercher la longueur d'une loxodromie.

5. Soit $F(x, y, z)$ une fonction homogène différentiable (c'est-à-dire telle que $F(cx, cy, cz) = c^n F(x, y, z)$). Montrer que la métrique sur une surface conique $F(x, y, z) = 0$ est euclidienne partout sauf à l'origine des coordonnées.

§ 8. Deuxième forme fondamentale

1. Courbure des courbes sur la surface dans l'espace euclidien. Soit une surface dans l'espace euclidien à trois dimensions. Soit un point non singulier (x_0, y_0, z_0) de cette surface. Supposons d'abord que l'axe des z soit normal au plan tangent en (x_0, y_0, z_0) à la surface: dans ce cas les axes des x et des y sont parallèles à ce plan. Alors la surface se définit localement, dans le voisinage du point (x_0, y_0, z_0), par l'équation $z = f(x, y)$, $z_0 = f(x_0, y_0)$, où

$$\left.\frac{\partial f}{\partial x}\right|_{\substack{x=x_0\\ y=y_0}} = \left.\frac{\partial f}{\partial y}\right|_{\substack{x=x_0\\ y=y_0}} = 0, \text{ donc } \operatorname{grad} f|_{\substack{x=x_0\\ y=y_0}} = 0. \tag{1}$$

Considérons la différentielle seconde de la fonction $z = f(x, y)$, c'est-à-dire $d^2 f = f_{xx} dx^2 + 2 f_{xy}\, dx\, dy + f_{yy}\, dy^2$, et écrivons la matrice (appelée *hessienne)* $a_{ij} = f_{x^i x^j}$, où $x^1 = x$, $x^2 = y$. Etudions cette matrice de la forme quadratique dans le point (x_0, y_0, z_0) où $\operatorname{grad} f = 0$.

DÉFINITION 1. Par *courbures principales* de la surface $z = f(x, y)$ dans le point (x_0, y_0, z_0) où grad $f = 0$, on entend les valeurs propres de la matrice (a_{ij}). On appelle *courbure totale* ou *courbure de Gauss* le déterminant de la matrice (a_{ij}) dans ce point, et *courbure moyenne*, la trace de la matrice dans ce point: $\operatorname{Tr} a_{11} + a_{22} = k_1 + k_2$; k_1 et k_2 sont les valeurs propres; la courbure totale est $K = k_1 k_2 = \det(a_{ij}) = a_{11}a_{22} - a_{12}a_{21}$.

Il sera montré dans le chapitre 4 que la courbure totale de la surface ne dépend que des propriétés métriques intrinsèques de cette surface.

Nous avons défini la notion de courbure en coordonnées spéciales attachées au point en question, où l'axe des z est normal à la surface et les axes des x et y sont tangents à celle-ci en ce point, ou, localement, $z = f(x, y)$ et grad $f = 0$ en (x_0, y_0). Afin de définir ces grandeurs en coordonnées quelconques, rappelons les faits de la théorie de la courbure des courbes sur la surface.

Supposons que la surface soit définie sous forme paramétrique:

$$r = r(u, v). \tag{2}$$

On a alors $[r_u, r_v] = |[r_u, r_v]| m$, où m est le vecteur unité de la normale à la surface, $|m| = 1$. Considérons une courbe $r = r(u(t), v(t))$ sur la surface. On a $\dot{r} = r_u \dot{u} + r_v \dot{v}$, $\ddot{r} = (r_{uu}\dot{u}^2 + 2r_{uv}\dot{u}\dot{v} + r_{vv}\dot{v}^2) + (r_u \ddot{u} + r_v \ddot{v})$. Puisque $r_u \perp m$ et $r_v \perp m$, il vient

$$\langle \ddot{r}, m \rangle = \langle r_{uu}, m \rangle \dot{u}^2 + 2\langle r_{uv}, m \rangle \dot{u}\dot{v} + \langle r_{vv}, m \rangle \dot{v}^2 = \\ = b_{11}\dot{u}^2 + 2b_{12}\dot{u}\dot{v} + b_{22}\dot{v}^2. \tag{3}$$

CONCLUSION. *La projection normale du vecteur accélération* $\langle \ddot{r}, m \rangle$ *est la forme quadratique du vecteur vitesse* $(\dot{u}, \dot{v})$ *en coordonnées locales* $u = x^1$, $v = x^2$.

Posons $b_{11} = L$, $b_{12} = M$, $b_{22} = N$. Il vient

$$\langle \ddot{r}, m \rangle dt^2 = b_{ij}\, dx^i\, dx^j = L(du)^2 + 2M\, du\, dv + N(dv)^2.$$

DÉFINITION 2. La forme quadratique $\langle \ddot{r}, m \rangle dt^2$ est appelée *deuxième forme fondamentale* de la surface (2).

Supposons que la courbe $u(t)$, $v(t)$ soit rapportée au paramètre naturel $t = l$. En vertu des formules de Frenet on a pour la courbe $r = r(t) = r(u(t), v(t))$

$$\ddot{r} = \frac{d^2 r}{dl^2} = kn,$$

où n est la normale principale à la courbe, et k la courbure de cette courbe. On a donc $\langle \ddot{r}, m \rangle = k \langle n, m \rangle = k \cos\theta$, où θ est l'angle entre m et n, d'où l'on tire

$$k \cos\theta (dl)^2 = \langle \ddot{r}, m \rangle dl^2 = L(du)^2 + 2M\, du\, dv + N(dv)^2 = \\ = b_{ij}\, dx^i\, dx^j, \quad x^1 = u, \quad x^2 = v,$$

où $dl^2 = g_{ij}\, dx^i\, dx^j = E(du)^2 + 2F\, du\, dv + G(dv)^2$.

CONCLUSION. On a

$$k\cos\theta = \frac{b_{ij}dx^i\,dx^j}{g_{ij}dx^i\,dx^j}, \quad x^1 = u, \quad x^2 = v, \tag{4}$$

ce qui achève la démonstration du

THÉORÈME 1. *Le produit de la courbure, dans un point donné, d'une courbe sur une surface dans l'espace à trois dimensions par le cosinus de l'angle entre la normale à la surface et la normale principale à la courbe est égal au rapport de la deuxième et de la première formes fondamentales sur le vecteur tangent à la courbe dans ce point.*

COROLLAIRE. *Si la courbe est la section d'une surface par un plan normal, on a*

$$\cos\theta = 1$$

et

$$k = \frac{b_{ij}dx^i\,dx^j}{g_{ij}dx^i\,dx^j}. \tag{5}$$

2. Invariants d'un couple de formes quadratiques. On a donc, en tout point de la surface, un couple de formes quadratiques:

1) $$dl^2 = g_{ij}\,dx^i\,dx^j, \tag{6}$$

2) $$\langle \ddot{r}, m\rangle\, dt^2 = b_{ij}\,dx^i\,dx^j, \tag{7}$$

la forme dl^2 étant toujours positive.

Quels sont les invariants d'un couple de formes quadratiques connus de l'Algèbre?

Soit, sur le plan, un couple de formes quadratiques (dont une positive) de matrices

$$G = \begin{pmatrix} g_{11} & g_{12} \\ g_{21} & g_{22} \end{pmatrix}, \qquad Q = \begin{pmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \end{pmatrix} \tag{8}$$

($g_{21} = g_{12}$, $b_{21} = b_{12}$). Faisons l'équation

$$\det(Q - \lambda G) = 0, \tag{9}$$

ou, sous forme développée,

$$(b_{11} - \lambda g_{11})(b_{22} - \lambda g_{22}) - (b_{12} - \lambda g_{12})^2 = 0.$$

Les racines λ_1, λ_2 de cette équation sont appelées *valeurs propres du couple de formes quadratiques.*

Proposons-nous de résoudre les équations linéaires

$$\left.\begin{aligned} (b_{11} - \lambda_i g_{11})\xi_i^1 + (b_{12} - \lambda_i g_{12})\xi_i^2 = 0, \\ (b_{12} - \lambda_i g_{12})\xi_i^1 + (b_{22} - \lambda_i g_{22})\xi_i^2 = 0, \end{aligned}\right\} \tag{10}$$

où ξ_i^1, ξ_i^2 sont des inconnues.

Si λ_1, λ_2 sont les valeurs propres, le système (10) admet des solutions non triviales

$$f_1 = (\xi_1^1, \xi_1^2) \quad \text{et} \quad f_2 = (\xi_2^1, \xi_2^2).$$

Les directions des vecteurs f_1, f_2 sont dites *directions principales* du couple de formes quadratiques; f_1 correspond à λ_1 et f_2 à λ_2.

De même qu'auparavant, les produits scalaires $\langle e_i, e_j \rangle$ des vecteurs de base du plan sont désignés par g_{ij}, $i, j = 1, 2$ (la métrique riemannienne étant définie par la forme g_{ij}).

LEMME 1. *Si les valeurs propres du couple de formes quadratiques sont différentes, les directions principales sont orthogonales.*

Nous avons deux directions principales f_1, f_2,

$$f_1 = \xi_1^1 e_1 + \xi_1^2 e_2, \qquad f_2 = \xi_2^1 e_1 + \xi_2^2 e_2.$$

Par définition, leur orthogonalité signifie que

$$\langle f_1, f_2 \rangle = g_{ij} \xi_1^i \xi_2^j = 0.$$

Démonstration. Choisissons un couple de vecteurs plans d_1, d_2 tels que $\langle d_i, d_j \rangle = \delta_{ij}$. Cela est possible, parce que la forme quadratique de matrice g_{ij} est définie positive et qu'on peut l'exprimer comme une somme de carrés par une transformation linéaire. Etudions maintenant la deuxième forme quadratique par rapport à la nouvelle base d_1, d_2 en posant

$$e_i = a_i^j d_j, \qquad A = (a_i^j). \tag{11}$$

Dans cette nouvelle base d_1, d_2 les matrices $\overline{G}$ et $\overline{Q}$ de la première et de la deuxième forme quadratique vérifient les relations

1) $\overline{G} = (\langle d_i, d_j \rangle) = (\delta_{ij})$ ou $\overline{G} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$, donc $G = AA^{\mathrm{T}}$;

2) $Q = A\overline{Q}A^{\mathrm{T}}$.

Puisque $G = AA^{\mathrm{T}}$ et $Q = A\overline{Q}A^{\mathrm{T}}$, on a

$$\begin{gathered} Q - \lambda G = A(\overline{Q} - \lambda \cdot 1)A^{\mathrm{T}}, \\ \det(Q - \lambda G) = (\det A)^2 \det(\overline{Q} - \lambda \cdot 1). \end{gathered} \tag{12}$$

Remarquons que $\det A = \det A^{\mathrm{T}} = \sqrt{g} = \sqrt{\det G} \neq 0$. Aussi l'équation (9) est-elle équivalente à

$$\det(\overline{Q} - \lambda \cdot 1) = 0. \tag{13}$$

Les solutions de n'importe laquelle de ces deux équations aux valeurs propres λ_1 et λ_2 donnent les directions principales f_1 et f_2.

Si la base est d_1, d_2, le produit scalaire est euclidien. Il est défini par la matrice unité $\overline{G} = 1 = (\delta_{ij})$. On apprend dans le cours d'Algèbre que toute forme quadratique $\overline{Q}$ peut être ramenée, au moyen d'une rotation, à une forme définie par une matrice diagonale dont les vecteurs propres f_1, f_2 sont orthogonaux au sens euclidien usuel. Le lemme est démontré.

Ce lemme n'est qu'une variante du théorème sur la diagonalisation par rotation d'une forme quadratique dans le plan euclidien.

3. Propriétés de la deuxième forme fondamentale. Revenons maintenant aux deux formes fondamentales de la surface dans l'espace euclidien à trois dimensions:

$$g_{ij}\,dx^i\,dx^j = dl^2, \tag{14}$$

$$b_{ij}dx^i\,dx^j, \qquad x^1 = u, \qquad x^2 = v. \tag{15}$$

Le rapport de ces formes quadratiques est la courbure de la section normale.

DÉFINITION 3. Les valeurs propres de ce couple de formes quadratiques s'appellent *courbures principales de la surface* dans le point donné. Le produit des courbures principales est la *courbure de Gauss*, ou *courbure totale de la surface*, et leur somme, la *courbure moyenne* [*] *de la surface*.

Exemple. Supposons que la surface soit définie sous la forme $z = f(x, y)$ avec $f_x = f_y = 0$ dans un point donné (x_0, y_0) (l'axe des z étant normal au plan tangent à la surface en ce point). Soit $x = u$, $y = v$, $z = f(u, v)$. Dans le point x_0, y_0 on a pour la première et la deuxième forme fondamentale

$$\begin{aligned}
&\text{(I)} && g_{11} = 1,\ g_{22} = 1,\ g_{12} = g_{21} = 0 \quad (g_{ij} = \delta_{ij}),\\
&\text{(II)} && L\ = b_{11} = \langle r_{uu}, m\rangle = f_{xx}(x_0, y_0),\\
& && M = b_{12} = \langle r_{uv}, m\rangle = f_{xy}(x_0, y_0),\\
& && N\ = b_{22} = \langle r_{vv}, m\rangle = f_{yy}(x_0, y_0).
\end{aligned} \tag{16}$$

Le vecteur m se confond ici avec le vecteur unité porté par l'axe des z.

Ainsi donc, la deuxième forme fondamentale se présente dans le point considéré comme suit:

$$b_{ij}\,dx^i\,dx^j = f_{x^ix^j}\,dx^i\,dx^j = d^2f. \tag{17}$$

La courbure totale se confond dans ce cas avec le déterminant $\det\begin{pmatrix} f_{xx} & f_{xy} \\ f_{xy} & f_{yy}\end{pmatrix}$. Les valeurs propres se laissent déduire de l'équation $(f_{xx} - \lambda)(f_{yy} - \lambda) - (f_{xy})^2 = 0$, puisque $g_{ij} = \delta_{ij}$.

Le plan tangent à la surface dans ce point est parallèle au plan (x, y). On obtient les directions principales dans ce point par la résolution des équations

$$(f_{x^ix^j} - \lambda_1\delta_{ij})\xi_1^j = 0, \qquad i, j = 1, 2 \text{ pour } f_1, \tag{18}$$

$$(f_{x^ix^j} - \lambda_2\delta_{ij})\xi_2^j = 0, \qquad i, j = 1, 2 \text{ pour } f_2. \tag{19}$$

---

[*] Généralement, on entend par courbure moyenne la demi-somme des courbures principales.

Puisque $f_1 \perp f_2$, nous pouvons retenir les vecteurs unités des directions principales comme les nouveaux axes de coordonnées x', y', c'est-à-dire effectuer une rotation dans le plan (x, y), avec la seule condition que $\lambda_1 \neq \lambda_2$.

En ces nouvelles coordonnées (z, x', y') on a

$$z = f(x(x', y'),\ y(x', y')),$$

où $x = x' \cos\varphi + y' \sin\varphi$, $y = -x' \sin\varphi + y' \cos\varphi$, en désignant par φ l'angle de rotation.

En coordonnées nouvelles la deuxième forme fondamentale se présente (dans le point considéré seulement!) comme suit:

$$\lambda_1(dx')^2 + \lambda_2(dy')^2. \tag{20}$$

La courbure de la section normale dans le point donné sera alors

$$k = \frac{\lambda_1(dx')^2 + \lambda_2(dy')^2}{(dx')^2 + (dy')^2}. \tag{21}$$

Le vecteur tangent e à la section normale de la surface se présente dans le point donné comme $e = (\dot{x}', \dot{y}')$, avec

$$dx' = \dot{x}'\, dt, \qquad dy' = \dot{y}'\, dt,$$

aussi

$$\cos^2\alpha = \frac{(dx')^2}{(dx')^2 + (dy')^2}, \qquad \sin^2\alpha = \frac{(dy')^2}{(dx')^2 + (dy')^2}, \tag{22}$$

où α est l'angle que fait l'axe des x avec le vecteur tangent e à la section normale.

Nous constatons donc que dans notre système de coordonnées privilégiées $k = \lambda_1 \cos^2\alpha + \lambda_2 \sin^2\alpha$. Cette formule porte le nom de *formule d'Euler*. Remarquons qu'elle reste valable dans n'importe quel système de coordonnées.

THÉORÈME 2. *La courbure de la section normale dans un point donné est égale à*

$$k = \lambda_1 \cos^2\alpha + \lambda_2 \sin^2\alpha,$$

où λ_1, λ_2 sont les courbures principales dans le point considéré, et α l'angle sur la surface entre le vecteur tangent à la section normale et la direction principale correspondante.

Démonstration. La formule d'Euler vient d'être établie pour le cas où la surface est définie sous la forme $z = f(x, y)$ et $f_x = f_y = 0$ dans le point donné (x_0, y_0). Or, puisque le résultat obtenu ne dépend pas du système de coordonnées choisi, nous pouvons toujours choisir des coordonnées au point considéré de telle façon que l'axe des z soit normal à la surface dans ce point et que les axes des x et y soient tangents à la surface et orthogonaux entre eux (on peut même faire confondre ces axes et les directions principales). La surface se définit alors dans le voisinage du point considéré par l'expression

$$z = f(x, y), \qquad f_x = f_y = 0,$$

et même $f_{xy} = f_{yx} = 0$ (toujours dans le point considéré) si les axes se confondent avec les directions principales. On a alors en ce point $\lambda_1 = f_{xx}$, $\lambda_2 = f_{yy}$. Puisque la formule d'Euler a été établie justement dans ces coordonnées, le théorème est démontré.

Remarque. Quand on inverse le sens de l'axe des z, le signe des courbures principales se trouve inversé lui aussi.

La formule d'Euler donne lieu à un corollaire: si $\lambda_1 > \lambda_2$, alors λ_1 et λ_2 sont les courbures maximale et minimale des sections normales dans le point donné (en tenant compte du signe).

Citons quelques expressions utiles de la deuxième forme fondamentale.

Si la surface est définie par l'équation $z = f(x, y)$, les coefficients de la deuxième forme fondamentale s'écriront (avec $x = u$, $y = v$)

$$r_u = (1, 0, f_x), \qquad r_v = (0, 1, f_y),$$
$$[r_u, r_v] = (-f_x, -f_y, 1), \tag{23}$$

$$r_{uu} = (0, 0, f_{xx}), \quad r_{uv} = (0, 0, f_{xy}), \quad r_{vv} = (0, 0, f_{yy}),$$

$$m = \frac{[r_u, r_v]}{\|[r_u, r_v]\|} = \frac{(-f_x, -f_y, 1)}{\sqrt{1 + f_x^2 + f_y^2}},$$

$$L = b_{11} = \frac{f_{xx}}{\sqrt{1 + f_x^2 + f_y^2}}, \qquad M = b_{12} = b_{21} = \frac{f_{xy}}{\sqrt{1 + f_x^2 + f_y^2}},$$

$$N = b_{22} = \frac{f_{yy}}{\sqrt{1 + f_x^2 + f_y^2}}.$$

D'où nous déduisons

$$b_{ij}\, dx^i\, dx^j = \frac{1}{\sqrt{1 + f_{x^1}^2 + f_{x^2}^2}} (f_{x^i x^j}\, dx^i\, dx^j), \tag{24}$$
$$x^1 = u = x, \qquad x^2 = v = y.$$

Rappelons que nous avons établi les formules (7.15) pour les coefficients g_{ij}:

$$g_{11} = 1 + f_x^2, \qquad g_{12} = g_{21} = f_x f_y, \qquad g_{22} = 1 + f_y^2,$$
$$g = g_{11} g_{22} - g_{12}^2 = 1 + f_x^2 + f_y^2. \tag{25}$$

On a le

THÉORÈME 3. *La courbure totale de la surface est égale au rapport des déterminants de ses deuxième et première formes fondamentales:*

$$K = \frac{b_{11} b_{22} - b_{12}^2}{g_{11} g_{22} - g_{12}^2}. \tag{26}$$

En particulier, si la surface est définie sous la forme d'un graphique $z = f(x, y)$, *on a*

$$K = \frac{f_{xx}f_{yy} - f_{xy}^2}{(1 + f_x^2 + f_y^2)^2} \cdot$$

Démonstration. Nous avons déduit les valeurs propres λ_1 et λ_2 de l'équation (9)

$$\det(Q - \lambda G) = 0$$

dans laquelle $Q = (b_{ij}) = \begin{pmatrix} L & M \\ M & N \end{pmatrix}$ est la matrice de la deuxième forme fondamentale, $G = (g_{ij})$. Remarquons que $Q - \lambda G = (b_{ij} - \lambda g_{ij})$ et $\det(Q - \lambda G) = (b_{11} - \lambda g_{11}) = (b_{22} - \lambda g_{22}) - (b_{12} - \lambda g_{12})^2$. La matrice $G = (g_{ij})$ est définie positive, donc non dégénérée. Il vient donc

$$\det(Q - \lambda G) = \det G \det(G^{-1}Q - \lambda \cdot 1),$$

où $\det G \neq 0$. Les valeurs propres λ_1 et λ_2 sont solutions de l'équation $\det(G^{-1}Q - \lambda \cdot 1) = 0$. Rappelons un fait connu de l'Algèbre: le produit de toutes les valeurs propres d'une matrice est égal à son déterminant; plus exactement, on a $\det A = \lambda_1\lambda_2$ pour les matrices du second ordre. En posant $A = G^{-1}Q$, nous voyons que

$$\lambda_1\lambda_2 = \det(G^{-1}Q) = \frac{\det Q}{\det G} = K. \tag{27}$$

Il s'ensuit que la courbure totale est égale au rapport des déterminants des matrices de la deuxième et de la première formes fondamentales.

Ensuite, si la surface est définie par $z = f(x, y)$, les coefficients b_{ij} et g_{ij} sont donnés par les formules (23) et (7.15). En calculant les déterminants et en faisant leurs rapports, nous aboutissons à la formule de la courbure totale.

COROLLAIRE. *Si la surface est définie par le graphique* $z = f(x, y)$, *le signe de la courbure totale* K *est le même que celui du déterminant* $f_{xx}f_{yy} - f_{xy}^2$, *parce que*

$$K = \frac{f_{xx}f_{yy} - f_{xy}^2}{(1 + f_x^2 + f_y^2)^2} \cdot$$

Exemple. Soit une surface définie par $z = f(x, y)$, où la fonction $f(x, y)$ vérifie l'équation de Laplace $f_{xx} + f_{yy} = 0$. On a alors $f_{xx}f_{yy} - f_{xy}^2 \leqslant 0$, car $f_{xx} = -f_{yy}$. Aussi la courbure totale K est-elle inférieure à zéro chaque fois que l'une au moins des deux dérivées f_{xx}, f_{xy} est non nulle.

Précisons la signification géométrique de la courbure totale. Plaçons dans le point considéré de la surface un repère orthonormé (x, y, z) tel que l'axe des z soit normal à la surface. La surface se définira alors localement par $z = f(x, y)$, où $f_x = f_y = 0$ dans le point en question.

On a dans le point donné $g_{ij} = \delta_{ij}$, parce que $g_{11} = 1 + f_x^2$, $g_{12} = f_x f_y$, $g_{22} = 1 + f_y^2$. Il vient ensuite $L = b_{11} = f_{xx}$, $M = b_{12} = f_{xy}$, $N = b_{22} = f_{yy}$. Considérons les trois cas suivants.

1) $K > 0$, $\lambda_1 > 0$, $\lambda_2 > 0$ (la fonction $f(x, y)$ admet un minimum pour $x = x_0$, $y = y_0$, fig. 10, *a*).

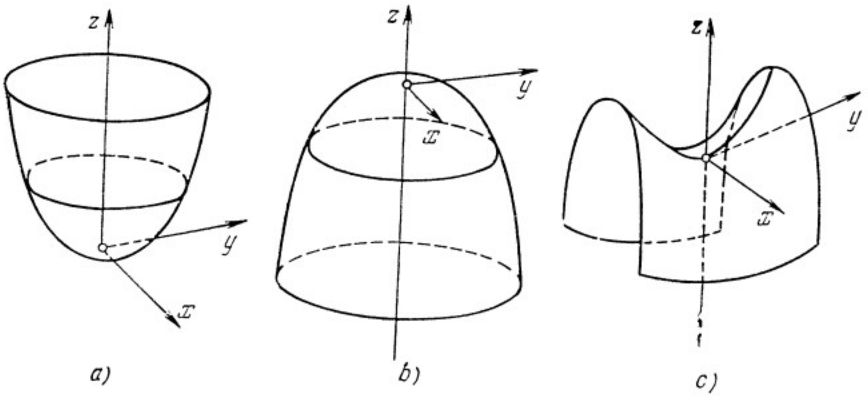

Fig. 10.

2) $K > 0$, $\lambda_1 < 0$, $\lambda_2 < 0$ (la fonction admet un maximum pour $x = x_0$, $y = y_0$, fig. 10, *b*).

3) $K < 0$, donc $\lambda_1 > 0$, $\lambda_2 < 0$ ou inversement: la fonction passe par un « point selle » ou « col » (fig. 10, *c*).

CONCLUSION. *Pour* $K > 0$ *la surface est localement située d'un même côté du plan tangent dans le voisinage du point donné. Pour* $K < 0$ *la surface coupe toujours le plan tangent aussi près que l'on veut du point de contact.*

Si la courbure totale est partout positive, il s'agit d'une surface *strictement convexe*.

Exercices. 1. Chercher la surface dont toutes les normales viennent concourir en un point.

2. Calculer la deuxième forme fondamentale sur la surface de révolution

$$r(u, \varphi) = \{x(u),\ \rho(u)\cos\varphi,\ \rho(u)\sin\varphi\}, \qquad \rho(u) > 0.$$

3. Calculer les courbures totale et moyenne de la surface d'équation

$$z = f(x) + g(y).$$

4. Montrer que si la surface plongée dans l'espace euclidien à trois dimensions a ses courbures totale et moyenne identiquement nulles, il s'agit d'un plan.

5. Montrer que la courbure moyenne H de la surface $z = f(x, y)$ est

$$H = \operatorname{div}\left(\frac{\operatorname{grad} f}{\sqrt{1 + |\operatorname{grad} f|^2}}\right).$$

6. Soit S une surface formée par des droites tangentes à la courbe donnée de courbure $k(l)$. Montrer que si la courbure $k(l)$ se conserve le long de la courbe, la surface S conserve sa métrique.

7. Si la métrique d'une surface est

$$dl^2 = A^2 du^2 + B^2 dv^2, \qquad A = A(u, v), \qquad B = B(u, v),$$

la courbure totale est

$$K = -\frac{1}{AB}\left[\left(\frac{A_v}{B}\right)_v + \left(\frac{B_u}{A}\right)_u\right].$$

8. Montrer que les seules surfaces de révolution admettant une courbure moyenne nulle sont le plan et la caténoïde engendrée par la rotation de la courbe $\left(\frac{\operatorname{ch}(at + b)}{a}, t\right)$.

§ 9. Métrique de la sphère

La sphère $S^2 \subset \mathbf{R}^3$ de rayon R centrée à l'origine des coordonnées a pour équation

$$x^2 + y^2 + z^2 = R^2. \tag{1}$$

En coordonnées sphériques r, θ, φ cette sphère a pour équation $r = R$, avec θ et φ quelconques. Aussi les paramètres (θ, φ) peuvent-ils servir de coordonnées locales sur la sphère, sauf en ses pôles Nord et Sud (en lesquels on a $\theta = 0$, $\theta = \pi$; ce sont les points singuliers du système de coordonnées sphériques; voir § 1). On sait (voir § 3, n° 1) que la métrique euclidienne $dx^2 + dy^2 + dz^2$ s'écrit en coordonnées sphériques comme suit:

$$dx^2 + dy^2 + dz^2 = dr^2 + r^2(d\theta^2 + \sin^2\theta\, d\varphi^2). \tag{2}$$

Sur la surface $r = R$ la différentielle dr s'annule, si bien qu'on a pour la métrique de la sphère dans les coordonnées (θ, φ)

$$dl^2 = R^2(d\theta^2 + \sin^2\theta\, d\varphi^2). \tag{3}$$

Ici $0 \leqslant \varphi \leqslant 2\pi$, $0 \leqslant \theta \leqslant \pi$ (fig. 11). Dans un petit voisinage du point 0 on a $\sin\theta \sim \theta$, ce qui fait que $\frac{1}{R^2} dl^2$ est approximativement égal à la métrique euclidienne $d\theta^2 + \theta^2(d\varphi)^2$ (en coordonnées polaires θ, φ). Considérons la projection stéréographique de la sphère sur le plan (voir fig. 12 où l'on montre la section plane de la sphère). Ici (θ, φ) sont les coordonnées sur la sphère et (r, φ) les coordonnées polaires sur le plan. On remarque sur la figure 12 que $\varphi = \varphi$, $r = R \operatorname{cotg} \frac{\theta}{2}$. En utilisant ces formules de changement de coordonnées, nous pouvons transcrire la métrique (3) dans les coordonnées (r, φ) (ou dans les coordonnées x, y):

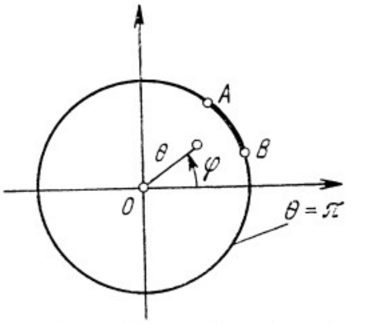

Fig. 11. La distance des points A et B mesurée le long du cercle de rayon $\theta = \pi$ est égale à zéro, c'est-à-dire que la frontière du cercle se réduit à un point; on obtient donc une sphère à deux dimensions.

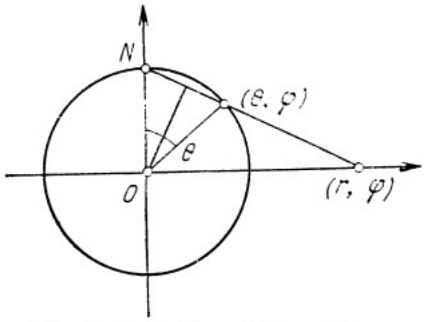

Fig. 12. Projection stéréographique $(\theta, \varphi) \to (r, \varphi)$.

$$dl^2 = \frac{4R^4}{(R^2 + r^2)^2}(dr^2 + r^2 d\varphi^2) = \frac{4R^4}{(R^2 + x^2 + y^2)^2}(dx^2 + dy^2). \quad (4)$$

Il est clair qu'on obtient la métrique de la sphère en multipliant la métrique du plan euclidien par la fonction $\frac{4R^4}{(R^2 + x^2 + y^2)^2}$, soit

$$dl^2_{\text{sphère}} = \frac{4R^4}{(R^2+x^2+y^2)^2} dl^2_{\text{plan}}. \quad (5)$$

Exemple. Proposons-nous de chercher la longueur du cercle et l'aire du disque de rayon ρ sur une sphère. Supposons que le disque soit centré au pôle Nord (noté N) de la sphère (point $\theta = 0$, fig. 13). Le rayon ρ du cercle est alors $\rho = R\theta_0$. Le cercle

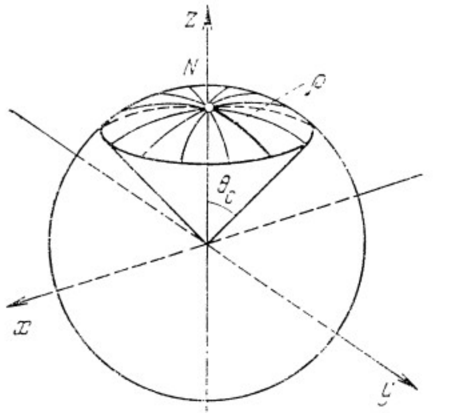

Fig. 13. Le disque de rayon ρ sur la sphère.

a alors pour équation $\theta = \rho/R$, $0 \leqslant \varphi \leqslant 2\pi$. Le disque de rayon ρ est le domaine $\theta \leqslant \rho/R$, $0 \leqslant \varphi \leqslant 2\pi$. Sur la courbe $\theta = \rho/R = \text{const}$ nous avons

$$dl^2 = R^2(d\theta^2 + \sin^2\theta\, d\varphi^2) = R^2 \sin^2 \frac{\rho}{R}\,(d\varphi)^2,$$

aussi la longueur l_ρ est-elle

$$l_\rho = \int_0^{2\pi} R \sin\left(\frac{\rho}{R}\right) d\varphi = 2\pi R \sin\left(\frac{\rho}{R}\right)\cdot \tag{6}$$

Nous voyons que pour $\rho = R\pi/2$ la longueur est maximale (c'est l'équateur), et pour $\rho = \pi$ elle est minimale (le pôle Sud). De la formule (6) il ressort que le rapport de la longueur du cercle l_ρ au rayon ρ sur la sphère est toujours plus petit que 2π:

$$\frac{l_\rho}{\rho} = 2\pi \frac{\sin(\rho/R)}{\rho/R} < 2\pi \text{ pour } \rho > 0.$$

Cherchons maintenant l'aire σ_ρ du disque de rayon ρ. Il ressort de la représentation (3) de dl^2 que $\sqrt{g} = R^2|\sin\theta|$. L'aire cherchée est donc

$$\sigma_\rho = \iint\limits_{0 \leqslant \theta \leqslant \rho/R} R^2 |\sin\theta|\, d\theta\, d\varphi = R^2 \int_0^{\rho/R} \sin\theta\, d\theta \int_0^{2\pi} d\varphi =$$

$$= 2\pi R^2 \left(1 - \cos\frac{\rho}{R}\right), \qquad \rho \leqslant \frac{\pi}{R}\cdot \tag{7}$$

Pour $\rho = \pi R$ notre disque va envahir la sphère tout entière, si bien que l'aire de la sphère est égale à $4\pi R^2$.

Si le rayon ρ est faible, on a $\sin\frac{\rho}{R} \approx \frac{\rho}{R}$ et $1 - \cos\frac{\rho}{R} \approx \frac{\rho^2}{2R^2}$. Il vient donc

$$l_\rho = 2\pi R \sin\frac{\rho}{R} \approx 2\pi\rho,$$

$$\sigma_\rho = 2\pi R^2\left(1 - \cos\frac{\rho}{R}\right) \approx \pi\rho^2,$$

ce qui signifie que, lorsque les rayons sont faibles, les longueurs et les aires s'expriment sensiblement par les mêmes formules qu'en géométrie euclidienne.

Cherchons maintenant les courbures totale et moyenne de la sphère de rayon R. Notons que les sections normales de la sphère sont des cercles de rayon R (appelés grands cercles de la sphère). Aussi toute section normale a-t-elle une courbure constante égale à R^{-1} (voir § 5, n° 1). Ainsi donc, les deux valeurs propres de la deuxième forme fondamentale sont égales entre elles et à R^{-1}. Il s'ensuit que la courbure totale de la sphère est égale à $1/R^2$, et sa courbure moyenne, à $2/R$.

Passons au groupe des déplacements conservant la métrique de la sphère. Toute rotation de l'espace effectuée autour de l'origine des coordonnées applique la sphère de rayon R dans elle-même. Cette rotation définie par une matrice orthogonale conserve la métrique riemannienne sur la sphère. Ainsi donc, les déplacements de la sphère S^2 sont définis par des matrices orthogonales. Rappelons (§ 4, n° 3) que le groupe des matrices orthogonales se note $O(3)$ et s'appelle groupe orthogonal. Toute rotation se laisse définir à l'aide de trois paramètres. Donc, la métrique de la sphère admet un ensemble de déplacements au moins tridimensionnel (triparamétrique).

Remarque importante. Nous avons vu que toutes les transformations de la sphère définies par des matrices orthogonales sont des déplacements. Aussi le groupe $O(3)$ est-il au moins un *sous-groupe* du groupe des déplacements de la sphère S^2. Nous n'avons pas encore démontré que le groupe $O(3)$ est le groupe des déplacements. C'est pourtant ce qui a lieu. Toute transformation conservant la métrique sur S^2 est une transformation linéaire et orthogonale dans $\mathbf{R}^3$. Or, la démonstration rigoureuse de cette assertion est fondée sur la notion de géodésique; nous reviendrons sur cette question dans le chapitre 4.

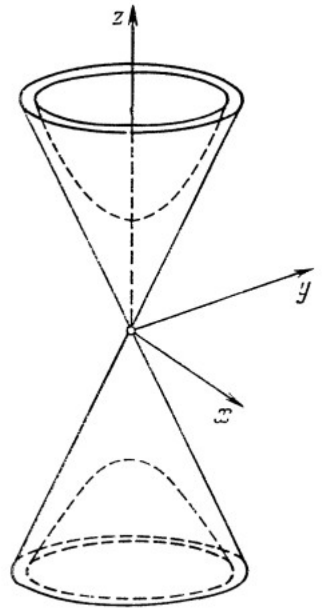

Fig. 14.

§ 10. Surfaces spatiales dans l'espace pseudo-euclidien

1. Pseudosphère. Considérons un espace pseudo-euclidien à trois dimensions muni de coordonnées (t, x, y) dans lesquelles la métrique pseudo-euclidienne s'écrit

$$(dl^2) = (dt)^2 - (dx)^2 - (dy)^2. \qquad (1)$$

La pseudosphère de rayon R se définit dans l'espace $\mathbf{R}^3_1$ par l'équation

$$t^2 - x^2 - y^2 = R^2. \qquad (2)$$

C'est un hyperboloïde à deux nappes dans l'espace à trois dimensions (fig. 14). Contenue tout entière à l'intérieur du cône de lumière $t^2 - x^2 -$

$- y^2 = 0$, la pseudosphère se définit en coordonnées pseudosphériques ρ, χ, φ (voir (3.11), (3.12)) par les équations

$$\rho = R \text{ (nappe supérieure)},$$
$$\rho = - R \text{ (nappe inférieure)}.$$

Nous ne considérerons que la nappe supérieure de l'hyperboloïde. Rappelons que la métrique $dt^2 - dx^2 - dy^2$ exprimée en coordonnées pseudosphériques ρ, χ, φ a pour équation (3.12):

$$dl^2 = - \rho^2(d\chi^2 + \operatorname{sh}^2\chi\, d\varphi^2) + d\rho^2. \tag{3}$$

Aussi a-t-on pour l'hyperboloïde, où $d\rho = 0$,

$$-dl^2 = R^2(d\chi^2 + \operatorname{sh}^2\chi\, d\varphi^2). \tag{4}$$

Ainsi donc, la métrique induite par la métrique pseudo-euclidienne (donc indéfinie) sur la surface de la pseudosphère est définie négative.

Cela revient à dire que la pseudosphère $t^2 - x^2 - y^2 = R^2$ dans $\mathbf{R}_1^3$ est une hypersurface spatiale: en effet, les vecteurs tangents à cette surface sont toujours spatiaux (avec $dl^2 < 0$).

DÉFINITION 1. La métrique (4) porte le nom de *métrique lobatchevskienne*.

Par analogie avec le paragraphe précédent, on peut construire la projection stéréographique de la pseudosphère sur le plan (x, y). La pseudosphère a pour centre l'origine des coordonnées O, son pôle Nord est le point de coordonnées $(R, 0, 0)$, et son pôle Sud, le point de coordonnées $(- R, 0, 0)$. La nappe supérieure de la pseudosphère aura comme image le disque ouvert $x^2 + y^2 < R^2$ (fig. 15).

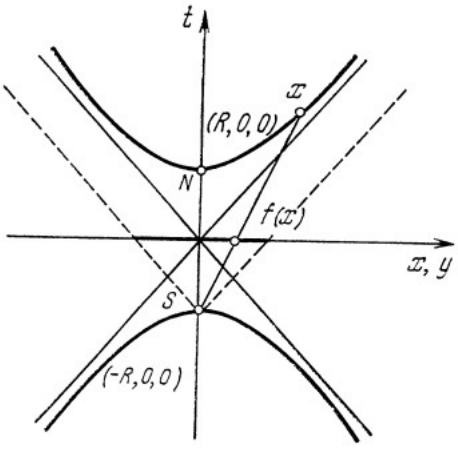

Fig. 15.

Soient t, x, y les coordonnées d'un point P sur la pseudosphère (avec $t > 0$), et u, v les coordonnées du point $f(P)$, où f est la projection stéréographique. Cherchons à expliciter la relation entre ces coordonnées. En regardant la figure 15, on s'assure que

$$\frac{x}{u} = \frac{t+R}{R}, \qquad \frac{y}{v} = \frac{t+R}{R},$$

d'où $x = u\left(1 + \frac{t}{R}\right)$, $y = v\left(1 + \frac{t}{R}\right)$. En portant ces expressions de x et y dans l'équation de la surface $t^2 - x^2 - y^2 = 0$, on obtient

$$t = -R\left(1 + \frac{2R^2}{u^2 + v^2 - R^2}\right), \tag{5}$$

d'où

$$x = \frac{2R^2u}{R^2 - u^2 - v^2}, \qquad y = \frac{2R^2v}{R^2 - u^2 - v^2}. \tag{6}$$

Les formules (5) et (6) sont les relations cherchées pour la projection stéréographique. Leur connaissance permet d'exprimer la métrique (4) sur la pseudosphère en coordonnées (u, v). Par calcul direct on obtient

$$-dl^2 = -(dt^2 - dx^2 - dy^2) = \frac{4R^2}{(u^2 + v^2 - R^2)^2}(du^2 + dv^2). \tag{7}$$

On voit qu'ici encore, la métrique de la pseudosphère est proportionnelle en coordonnées u, v à la métrique du plan euclidien (comme dans le cas de la sphère S^2). La métrique (7) sur le disque $u^2 + v^2 < R^2$ affectée du signe négatif s'appelle *métrique de Poincaré* de la géométrie de Lobatchevski. En introduisant des coordonnées polaires (r, φ) sur le disque $u^2 + v^2 < R^2$, la métrique lobatchevskienne s'écrira

$$dl^2 = \frac{4R^2}{(R^2 - r^2)^2}(dr^2 + r^2 d\varphi^2). \tag{8}$$

L'analogie avec la métrique de la sphère S^2 est évidente (voir (9.4)).

Résumons les différents types de métriques de la sphère S^2 et du plan lobatchevskien L^2 dans un tableau (en posant $R = 1$):

S^2	L^2
$d\theta^2 + \sin^2\theta\,(d\varphi)^2$	$d\chi^2 + \text{sh}^2\chi\,(d\varphi)^2$
$4\dfrac{dx^2 + dy^2}{(1 + x^2 + y^2)^2}$	$4\dfrac{dx^2 + dy^2}{(1 - x^2 - y^2)^2}$, $x^2 + y^2 < 1$

Nous donnerons maintenant une autre notation de la métrique lobatchevskienne. Elle sera basée sur un fait bien connu de la Théorie des fonctions d'une variable complexe: il existe une transformation homographique du plan complexe par laquelle le demi-plan supérieur se transforme en un disque unité. Indiquons à titre d'exemple la transformation $z = (1 + iw)/(1 - iw)$ (fig. 16). En posant $z = u + iv$, $w = x + iy$, nous intro-

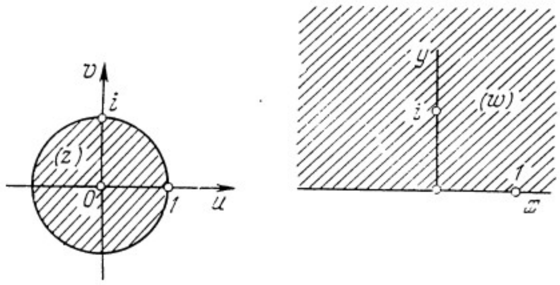

Fig. 16.

duisons sur le disque unité un nouveau système de coordonnées (x, y) avec $y > 0$. Le calcul direct montre que la métrique lobatchevskienne se présente dans les coordonnées (x, y) comme suit:

$$dl^2 = \frac{dx^2 + dy^2}{y^2}, \qquad y > 0. \tag{9}$$

La métrique (9) est dite *métrique de Klein* de la géométrie de Lobatchevski.

Cherchons le groupe des déplacements du plan lobatchevskien. Puisque toute transformation pseudo-orthogonale de l'espace $\mathbf{R}_1^3$ (voir § 6, n° 2) conserve la forme $t^2 - x^2 - y^2$, la pseudosphère $t^2 - x^2 - y^2 = R^2$ revient à elle-même. Or, si la transformation appartient au groupe $O(1, 2)$, il se peut que les nappes supérieure et inférieure de la pseudosphère soient permutées: le groupe des déplacements du plan lobatchevskien contient donc le groupe des transformations orthochrones appartenant à $O(1, 2)$. Nous verrons dans le chapitre 4 que ces groupes se confondent. Ainsi donc, le plan lobatchevskien admet, au même titre que la sphère et le plan euclidien, un ensemble de déplacements triparamétrique.

2. Courbure des surfaces spatiales dans $\mathbf{R}_1^3$. Nous dirons qu'une surface dans $\mathbf{R}_1^3$ est spatiale si tel est tout vecteur tangent à cette surface. En d'autres termes, la métrique minkowskienne $dl^2 = dt^2 - dx^2 - dy^2$ induit sur la surface une métrique définie négative.

Dans le cas où la surface est définie sous forme d'un graphique de fonction $t = f(x, y)$, la métrique de la surface se présente comme suit:

$$\begin{gathered} -dl^2 = -(dt^2 - dx^2 - dy^2) = \\ = (1 - f_x^2)\,dx^2 - 2f_x f_y\,dx\,dy + (1 - f_y^2)\,dy^2 = g_{ij}\,dx^i\,dx^j, \\ x^1 = x, \ x^2 = y. \end{gathered}$$

On a $\det g_{ij} = 1 - f_x^2 - f_y^2$; pour que la surface soit spatiale, il faut qu'il y ait $\det g_{ij} = 1 - f_x^2 - f_y^2 > 0$. Le vecteur unité de la normale à la surface est

$$m = \frac{(1, f_x, f_y)}{\sqrt{1 - f_x^2 - f_y^2}}$$

(vecteur spatial). La deuxième forme fondamentale de la surface a pour équation

$$b_{ij} = \left\langle \frac{\partial^2 r}{\partial x^i \, \partial x^j}, m \right\rangle, \qquad i, j = 1, 2.$$

Introduisons la courbure totale K de la surface spatiale en posant

$$K = -\frac{\det b_{ij}}{\det g_{ij}}. \tag{10}$$

Pour les surfaces d'équation $t = f(x, y)$, $1 - f_x^2 - f_y^2 > 0$, il vient par analogie avec le § 8

$$K = \frac{f_{xy}^2 - f_{xx} f_{yy}}{(1 - f_x^2 - f_y^2)^2}. \tag{11}$$

En particulier, pour l'hyperboloïde $t^2 - x^2 - y^2 = 1$ (géométrie de Lobatchevski) on a $K \equiv -1$.

Remarques. 1. Dans le chapitre 4 nous calculerons la courbure du plan lobatchevskien en ne tenant compte que de sa géométrie intrinsèque. Ce calcul nous donnera encore $K \equiv -1$, ce qui explique le choix du signe dans la définition (10).

2. De même que dans le § 8, nous constatons que les surfaces spatiales de courbure totale **négative** $K < 0$ dans l'espace $\mathbf{R}_1^3$ sont convexes.

§ 11. Le langage des nombres complexes en géométrie

1. Coordonnées complexes et réelles. Dans bien des cas, le langage des nombres complexes offre des avantages certains en géométrie. L'utilisation de ce langage repose sur quelques faits élémentaires que nous exposerons dans le texte qui suit.

Soit un espace linéaire $\mathbf{C}^n$ de dimension n sur le corps des nombres complexes $\mathbf{C}$ avec la base $e_1, \ldots, e_n$. Chaque vecteur $\xi \in \mathbf{C}^n$ se présente comme suit:

$$\xi = z^k e_k, \qquad z^k = x^k + i y^k, \tag{1}$$

où z^k sont les coordonnées complexes.

L'espace $\mathbf{C}^n$ peut être regardé comme un espace linéaire $\mathbf{R}^{2n}$ de dimension $2n$ sur le corps des nombres réels. La base dans $\mathbf{R}^{2n}$ se définit comme suit:

$$e_1, \ldots, e_n, \qquad i e_1, \ldots, i e_n. \tag{2}$$

C'est la formule de Gauss-Ostrogradski dans l'espace euclidien à trois dimensions.

b) Soient $k = 2$, U un domaine sur la surface $x^i = x^i(z^1, z^2)$, $i = 1, 2, 3$, et Γ le bord de ce domaine (une courbe). On a

$$\oint_\Gamma T_\alpha dx^\alpha = \iiint_U \left[\left(\frac{\partial T_1}{\partial x^2} - \frac{\partial T_2}{\partial x^1} \right) dx^1 \wedge dx^2 + \right.$$

$$\left. + \left(\frac{\partial T_1}{\partial x^3} - \frac{\partial T_3}{\partial x^1} \right) dx^1 \wedge dx^3 + \left(\frac{\partial T_2}{\partial x^3} - \frac{\partial T_3}{\partial x^2} \right) dx^2 \wedge dx^3 \right]. \quad (37)$$

Dans le cas euclidien, où l'on n'a pas à distinguer les vecteurs et les covecteurs et lorsqu'on peut associer à un tenseur alterné (T_{ij}) un vecteur $T = (T^i)$, on retrouve la formule de Stokes:

$$\oint_\Gamma T_\alpha dx^\alpha = \iint_U \langle \text{rot } T, n \rangle \sqrt{|g|} dz^1 \wedge dz^2, \quad (38)$$

où rot T est le vecteur associé au tenseur alterné $(\text{rot } T)_{\alpha\beta} = \frac{\partial T_\alpha}{\partial x^\beta} - \frac{\partial T_\beta}{\partial x^\alpha}$.

On constate donc que dans tous les cas envisagés la formule générale de Stokesse réduit, au moyen du théorème 1, à des formules intégrales différentes connues du cours d'Analyse, ce qui achève la démonstration pour l'espace à trois dimensions.

Notons en conclusion que l'énoncé de la formule générale de Stokes n'implique pas nécessairement que le bord Γ soit constitué d'un seul morceau. Si Γ se compose de plusieurs morceaux (fig. 31), les intégrales prises sur les morceaux différents interviendront avec leur signe + ou — ; le seul problème consiste à choisir correctement le signe. Nous l'avons déjà vu dans le cas trivial de $k = 1$, lorsque le bord Γ du segment de courbe est formé de deux points: un point (extrémité) de signe + et un point (origine) de signe — . Il y a lieu de remarquer ici que le choix du signe dans l'expression $\iint_\Gamma \langle T, n \rangle \sqrt{|g|} dz^1 \wedge dz^2$ (ou, comme l'on dit, de l'« orientation » du bord Γ) est défini par le sens de la normale unité n.

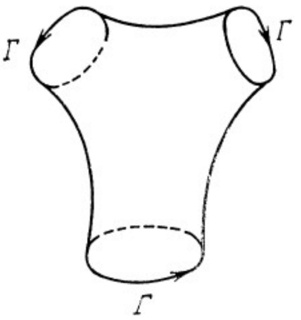

Fig. 31.

Citons une application importante de la formule générale de Stokes.

Considérons l'espace à quatre dimensions $x^0 = ct,\ x^1, x^2, x^3$ muni de la métrique $g_{ij} = \begin{pmatrix} +1 & & & 0 \\ & -1 & & \\ & & -1 & \\ 0 & & & -1 \end{pmatrix}$, où c est la vitesse de la lumière et t le temps.

Soit $F_{ik} = - F_{ki}$ le tenseur du champ électromagnétique, $i, k = 0, 1, 2, 3$. Les propriétés de ce tenseur seront étudiées en laissant le temps $x^0 = ct$ inchangé et en faisant varier seules les coordonnées spatiales x^i, $i = 1, 2, 3$:

$$x'^0 = x^0, \qquad x'^i = x'^i(x^1, x^2, x^3).$$

Dans ce cas le tenseur (F_{ik}) se définit dans l'espace à quatre dimensions par le covecteur du champ électrique $E_\alpha = F_{0\alpha}$, $\alpha = 1, 2, 3$, et le tenseur du champ magnétique $H_{\alpha\beta} = - H_{\beta\alpha} = F_{\alpha\beta}$, $\alpha, \beta = 1, 2, 3$. Si les coordonnées x^1, x^2, x^3 sont euclidiennes, le champ magnétique se définit par le vecteur du champ magnétique (§ 21)

$$H^1 = H_{23}, \qquad H^2 = - H_{13}, \qquad H^3 = H_{12}.$$

Dans le langage des formes différentielles, on a (voir § 25)

$d(F_{ij} dx^i \wedge dx^j) = 0$ (premier couple d'équations de Maxwell),

ou, sous forme euclidienne à trois dimensions,

$$\text{a)} \qquad \operatorname{div} \mathbf{H} = \frac{\partial H^i}{\partial x^i} = 0;$$

$$\text{b)} \qquad \operatorname{rot} \mathbf{E} + \frac{1}{c} \frac{\partial \mathbf{H}}{\partial t} = 0.$$

De l'équation a) et de la formule de Gauss-Ostrogradski on déduit (Γ étant le bord d'un domaine U)

$$\iiint_U \operatorname{div} \mathbf{H}\, dx^1 \wedge dx^2 \wedge dx^3 = \iint_\Gamma \langle \mathbf{H} \cdot n \rangle d\sigma = 0$$

(« le flux du champ magnétique à travers une surface fermée est toujours égal à zéro »).

De l'équation b) et de la formule de Stokes on déduit

$$\iint_U \langle \operatorname{rot} \mathbf{E}, n \rangle d\sigma = \oint_\Gamma E_\alpha\, dx^\alpha$$

(Γ étant le bord du domaine U sur la surface),

$$-\iint_U \left\langle \frac{1}{c}\frac{\partial \mathbf{H}}{\partial t}, n \right\rangle d\sigma = \oint_\Gamma E_\alpha \, dx^\alpha$$

(« la dérivée par rapport au temps du flux du champ magnétique à travers une surface est égale à la circulation du champ électrique le long du bord de la surface »).

Le deuxième couple d'équations de Maxwell (voir § 25) se présente comme suit :

$$\sum_{k=1}^{3} \frac{\partial F_{ik}}{\partial x^k} - \frac{1}{c}\frac{\partial F_{0i}}{\partial t} = \frac{4\pi}{c} j_{(4)i},$$

où $j_{(4)} = (c\rho, j_1, j_2, j_3)$, ρ est la densité de la charge, $\mathbf{j} = (j_1, j_2, j_3)$ le vecteur courant tridimensionnel (la divergence de dimension quatre du tenseur F_{ik} pour la métrique $\begin{pmatrix} +1 & & & 0 \\ & -1 & & \\ & & -1 & \\ 0 & & & -1 \end{pmatrix}$ est égale au produit du vecteur courant de dimension quatre par $4\pi/c$).

Sous forme tridimensionnelle, on a

a) $\operatorname{div} \mathbf{E} = 4\pi\rho$;

b) $\operatorname{rot} \mathbf{H} + \dfrac{1}{c}\dfrac{\partial \mathbf{E}}{\partial t} = \dfrac{4\pi}{c}\mathbf{j}$.

De a) et de la formule de Gauss-Ostrogradski on déduit

$$\iiint_U 4\pi\rho \, dx^1 \wedge dx^2 \wedge dx^3 = \iint_\Gamma \langle \mathbf{E}, n \rangle d\sigma$$

(« le flux du champ électrique à travers le bord d'un domaine est égal — à 4π près — à la charge totale dans ce domaine »).

De b) et de la formule de Stokes on déduit

$$-\frac{1}{c}\iint_U \frac{\partial \mathrm{E}}{\partial t} n \, d\sigma + \iint_U \frac{4\pi}{c} \mathbf{j} n \, d\sigma = \oint_\Gamma H_\alpha \, dx^\alpha,$$

où Γ est le bord du domaine U sur la surface (« le courant total à travers une surface diminué de la dérivée du flux du champ électrique à travers cette surface est égal à la circulation du champ magnétique le long du bord de la surface »).

Nous voyons que le premier et le deuxième couple d'équations de Maxwell revêtent ici des significations géométriques différentes. Le premier couple d'équations de Maxwell n'implique aucune métrique particulière dans l'espace, tandis que le deuxième couple n'existe pas en dehors de la métrique. La forme usuelle de ces équations est étroitement liée aux coordonnées euclidiennes.

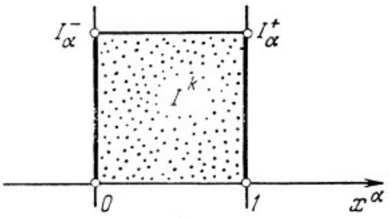

Fig. 32.

4. Démonstration de la formule générale de Stokes pour le cube. Nous venons de montrer que les formules intégrales classiques de Green et de Gauss-Ostrogradski sont des cas particuliers de la formule générale de Stokes. Dans ce n°, nous nous appliquerons à démontrer la formule générale de Stokes pour le cas où l'intégration s'étend à un cube de dimension k.

Le *cube singulier* σ dans l'espace $\mathbf{R}^n$ est une application différentiable

$$\sigma : I^k \to \mathbf{R}^n, \qquad n \geqslant k,$$

où I^k est un cube cartésien de dimension k:

$$I^k = \{(x^1, \ldots, x^k) | \, 0 \leqslant x^\alpha \leqslant 1\}.$$

Les équations $x^\alpha = 0$ et $x^\alpha = 1$ définissent deux faces à $(k-1)$ dimensions I_α^- et I_α^+ respectivement (fig. 32). Désignons par ∂I^k le bord du cube I^k, en sorte que $\partial I^k = \bigcup\limits_\alpha (I_\alpha^+ \cup I_\alpha^-)$. Soit φ^{k-1} une $(k-1)$-forme dans $\mathbf{R}^n$, et soit $d\varphi^{k-1}$ sa différentielle extérieure; soit enfin $\sigma : I^k \to \mathbf{R}^n$ le cube singulier.

THÉORÈME 4. *On a l'égalité*

$$\int\limits_{\sigma(\partial I^k)} \varphi^{k-1} = \int\limits_{\sigma(I^k)} d\varphi^{k-1}$$

(l'orientation du bord ∂I^k étant induite par l'orientation naturelle du cube I^k, compte tenu du sens de la normale extérieure).

Remarque. Dans cette formule, on entend par l'intégrale $\int\limits_{\sigma(\partial I^k)} \varphi$ la somme prise pour toutes les faces du cube.

Démonstration. Considérons la forme $\omega = \sigma^*(\varphi)$; les opérations σ^* et d étant permutables, on a $d\omega = d\sigma^*(\varphi) = \sigma^*(d\varphi)$, ce qui veut dire qu'il suffit de démontrer la proposition avancée sous la forme

$$\int\limits_{\partial I^k} \omega = \int\limits_{I^k} d\omega.$$

Nous nous sommes servi du fait qu'on a par définition

$$\int\limits_{\sigma(I^k)} d\varphi = \int\limits_{I^k} \sigma^*(d\varphi) \qquad \text{et} \qquad \int\limits_{\sigma(\partial I^k)} \varphi = \int\limits_{\partial I^k} \sigma^*(\varphi).$$

Soit $\omega = a_\alpha(x^1, \ldots, x^k)\, dx^1 \wedge \ldots \wedge \widehat{dx^\alpha} \wedge \ldots \wedge dx^k$, où $a_\alpha(x^1, \ldots, x^k)$ sont des fonctions différentiables; la différentielle dx^α est omise. Il vient alors

$$d\omega = \sum_\alpha \frac{\partial a_\alpha}{\partial x^\alpha}\, dx^\alpha \wedge dx^1 \wedge \ \ldots \wedge \widehat{dx^\alpha} \wedge \ldots \wedge dx^k = \sum_\alpha (-\, 1)^{\alpha-1} \frac{\partial a_\alpha}{\partial x^\alpha}\, d^k x,$$

où $d^k x = dx^1 \wedge \ldots \wedge dx^k$. Pour simplifier le raisonnement qui va suivre, mettons les fonctions $a_\alpha(x^1, \ldots, x^k)$ sous la forme de produits:

$$a_\alpha(x^1, \ldots, x^k) = \prod_{q=1}^{k} b_\alpha^q(x^q),$$

ou les fonctions b_α^q sont des fonctions différentiables d'une variable unique x^q. (Rappelons un théorème démontré dans le cours d'Analyse: toute fonction différentiable se laisse uniformément approcher par des combinaisons linéaires de produits de fonctions différentiables d'une même variable; il va sans dire que la démonstration de ce théorème n'a pas sa place ici.)

Explicitons $\int\limits_{I^k} d\omega$:

$$\int\limits_{I^k} d\omega = \int\limits_{I^k} \Bigl(\sum_\alpha (-\, 1)^{\alpha-1} \frac{\partial a_\alpha}{\partial x^\alpha} \Bigr)\, d^k x =$$

$$= \int\limits_{I^k} \Bigl(\sum_\alpha (-\, 1)^{\alpha-1} \frac{\partial}{\partial x^\alpha} \Bigl(\prod_{q=1}^{k} b_\alpha^q(x^q) \Bigr) \Bigr)\, d^k x =$$

$$= \int\limits_{I^k} \Bigl(\sum_\alpha (-\, 1)^{\alpha-1}\, b_\alpha^1(x^1) \ldots \frac{\partial b_\alpha^\alpha(x^\alpha)}{\partial x^\alpha} \ldots\ b_\alpha^k(x^k) \Bigr)\, d^k x =$$

$$= \sum_\alpha \int\limits_{(x^1)} \cdots \int\limits_{(\hat{x}^\alpha)} \cdots \int\limits_{(x^k)} ((-\, 1)^{\alpha-1} b_\alpha(x^1) \ldots b_\alpha^{\alpha-1}(x^{\alpha-1}) b_\alpha^{\alpha+1}(x^{\alpha+1}) \ldots$$

$$\ldots b_\alpha^k(x^k) \Bigl[(-\, 1)^{\alpha-1} \int\limits_{(x^\alpha)} \frac{\partial b_\alpha^\alpha(x^\alpha)}{\partial x^\alpha}\, dx^\alpha \Bigr]\, dx^1 \wedge \ldots \wedge \widehat{dx^\alpha} \wedge \ldots \wedge dx^k =$$

$$= \sum_\alpha \int\limits_{(x^1)} \cdots \int\limits_{(\hat{x}^\alpha)} \cdots \int\limits_{(x^k)} (b_\alpha^1(x^1) \ldots \hat{b}_\alpha^\alpha(x^\alpha) \ldots$$

$$\ldots b_\alpha^k(x^k)[b_\alpha^\alpha(1) - b_\alpha^\alpha(0)])\, dx^1 \wedge \ldots \wedge \widehat{dx^\alpha} \wedge \ldots \wedge dx^k =$$

$$= \sum_\alpha \int_{(x^1)} \cdots \int_{(\hat{x}^\alpha)} \cdots \int_{(x^k)} (b_\alpha^1(x^1) \ldots b_\alpha^\alpha(1) \ldots b_\alpha^k(x^k) -$$

$$- b_\alpha^1(x^1) \ldots b_\alpha^\alpha(0) \ldots b_\alpha^k(x^k))\, dx^1 \wedge \ldots \wedge \widehat{dx^\alpha} \wedge \ldots \wedge dx^k =$$

$$= \sum_\alpha \int_{(x^1)} \cdots \int_{(\hat{x}^\alpha)} \cdots \int_{(x^k)} (a_\alpha(x^1, \ldots, x^k)|_{x^\alpha = 1} -$$

$$- a_\alpha(x^1, \ldots, x^k)|_{x^\alpha = 0}\, dx^1 \wedge \ldots \wedge \widehat{dx^\alpha} \wedge \ldots \wedge dx^k = \int_{\partial I^k} \omega.$$

Le théorème est démontré.

Exercices. 1. Calculer le volume des groupes $SO(3, \mathbf{R})$ et $SU(2)$ pour la métrique de Killing.

2. Soit X^i un champ de vecteurs dans l'espace de Minkowski $\mathbf{R}_1^4$. Définissons l'intégrale de ce champ de vecteurs sur l'hypersurface à trois dimensions (le «flux» du champ de vecteurs à travers l'hypersurface) comme l'intégrale d'une 3-forme $X^i dS_i$ avec

$$dS_i = \frac{1}{6} \sqrt{|g|}\, \varepsilon_{jkli}\, dx^j \wedge dx^k \wedge dx^l$$

et ε_{jkli}, tenseur antisymétrique de rang 4. Déduire de la formule générale de Stokes l'égalité suivante:

$$\int_{\partial V} X^i\, dS_i = \int_V \frac{\partial X^i}{\partial x^i}\, dV.$$

3. Soient U un domaine borné à bord différentiable dans l'espace muni de la métrique riemannienne g_{ij} et Ω_U^p l'espace des formes différentiables qui s'annulent en dehors de U. Définissons le produit scalaire dans Ω_U^p en posant

$$\langle \omega_1, \omega_2 \rangle = \int_U \omega_1 \wedge * \omega_2$$

pour les p-formes ω_1, ω_2 de Ω_U^p.

2) Montrer que Ω_U^p muni du produit scalaire est un espace euclidien (voir § 19, exercice 2).

b) L'opérateur $*$ est orthogonal:

$$\langle * \omega_1, * \omega_2 \rangle = \langle \omega_1, \omega_2 \rangle.$$

c) Les opérateurs $\delta = (-1)^{np+n+1} * d *$ et d sont adjoints entre eux, en sorte que

$$\langle d\omega_1, \omega_2 \rangle = \langle \omega_1, \delta\omega_2 \rangle.$$

d) Le carré de l'opérateur δ est nul, $\delta\delta = 0$.

e) Soit $\Delta = d\delta + \delta d$. Montrer que l'opérateur Δ est autoadjoint dans $\Omega^p_U : \langle \Delta\omega_1, \omega_2 \rangle = \langle \omega_1, \Delta\omega_2 \rangle$. Vérifier que les relations de commutativité suivantes ont lieu:

$$\Delta d = d\Delta, \qquad \Delta\delta = \delta\Delta, \qquad \Delta * = * \Delta.$$

§ 27. Formes différentielles dans les espaces complexes

1. Opérateurs d′ et d″. Soit D un domaine dans l'espace complexe $\mathbf{C}^n$ muni de coordonnées complexes $z^1, \ldots, z^n$. On peut y distinguer un domaine «décomplexifié» $D^{\mathbf{R}}$ muni de coordonnées réelles $x^1, \ldots, x^n, \; y^1, \ldots, y^n$ dans lequel

$$z^k = x^k + iy^k, \qquad k = 1, \ldots, n. \tag{1}$$

La base dans l'espace tangent à $D^{\mathbf{R}}$ (en un point quelconque) est constituée par les vecteurs $\frac{\partial}{\partial x^1}, \ldots, \frac{\partial}{\partial x^n}, \; \frac{\partial}{\partial y^1}, \ldots, \frac{\partial}{\partial y^n}$. Considérons les vecteurs tangents complexes, c'est-à-dire les combinaisons linéaires

$$\sum_{k=1}^{n} a^k \frac{\partial}{\partial x^k} + \sum_{k=1}^{n} b^k \frac{\partial}{\partial y^k} \tag{2}$$

à coefficients complexes. Il est commode d'introduire dans l'espace des vecteurs de cette espèce une base complexe $\frac{\partial}{\partial z^k}, \frac{\partial}{\partial \bar{z}^k}$ en posant

$$\frac{\partial}{\partial z^k} = \frac{1}{2}\left(\frac{\partial}{\partial x^k} - i\,\frac{\partial}{\partial y^k}\right), \quad \frac{\partial}{\partial \bar{z}^k} = \frac{1}{2}\left(\frac{\partial}{\partial x^k} + i\,\frac{\partial}{\partial y^k}\right), \quad k = 1, \ldots, n. \tag{3}$$

Afin de faciliter la compréhension des formules qui seront établies par la suite, nous adopterons une convention d'écriture qui consiste à surligner toujours les indices tensoriels correspondant aux coordonnées surlignées, exception faite pour les lettres qui étaient surlignées auparavant. C'est ainsi que la notation $a_{k\bar{l}} z^k \bar{z}^l$ implique la sommation pour les deux indices (voir aussi les formules (4), (7), (9), etc. ci-après).

Tout vecteur complexe ξ peut donc se présenter comme suit:

$$\xi = \xi^k \frac{\partial}{\partial z^k} + \xi^{\bar{k}} \frac{\partial}{\partial \bar{z}^k}, \qquad \xi = (\xi^k, \; \xi^{\bar{k}})\,; \tag{4}$$

CHAPITRE 3

DEGRÉ DE L'APPLICATION. INDICE D'INTERSECTION. APPLICATIONS DE CES NOTIONS

§ 12. Notion d'homotopie

1. Définition de l'homotopie. Possibilité de l'approximation différentiable. Soient deux variétés différentiables N, M (par exemple de classe C^∞) et une application différentiable $f: N \to M$.

DÉFINITION 1. On entend par *homotopie* (ou *déformation*) *différentiable* (resp. *différentiable par morceaux*, *continue*) d'une application f, une application différentiable (resp. différentiable par morceaux, continue) du cylindre

$$F: N \times I \to M \qquad (I = [0, 1])$$

telle que, pour tout $x \in N$, $F(x, 0) = f(x)$. On dit que les applications $f_t: N \to M$, $f_t(x) = F(x, t)$ sont *homotopes* à l'application initiale $f = f_0$; quant à l'application du cylindre F dans son ensemble, elle est appelée *homotopie* ou « opération d'homotopie ».

L'ensemble des applications homotopes à f forme une classe d'applications homotopes deux à deux, ou classe d'homotopie. Il va sans dire que les classes d'homotopie différentiable existent pour tout degré de différentiabilité l. En particulier, pour $l = 0$ on a une classe d'applications continues et continûment homotopes. D'autre part, le théorème selon lequel toute application continue peut être approchée par une application différentiable donne lieu à quelques propriétés élémentaires de l'homotopie:

1) toute application continue se laisse approcher par une application différentiable de classe quelconque (C^∞ entre autres) qui est voisine de l'application donnée et homotope à celle-ci;

2) deux applications continues sont différentiablement homotopes chaque fois qu'elles sont continûment homotopes.

Examinons ces propriétés plus en détail.

THÉORÈME 1. *Soient deux variétés différentiables compactes M, N et deux applications continues f, g: $M \to N$. Alors, étant donnée une métrique riemannienne quelconque sur N, il existe un $\varepsilon > 0$ tel que la condition $\rho(f, g) < \varepsilon$ implique l'homotopie de f et g (ρ est la distance des deux applications, voir plus haut).*

Démonstration. Munissons M d'une métrique riemannienne et désignons par ρ_0 la distance définie par cette métrique. Puisque N est une variété compacte, il existe un $\varepsilon > 0$ tel que pour $p, q \in N$ et $\rho_0(p, q) < \varepsilon$ les points p et q peuvent être reliés par une seule géodésique réalisant le plus court chemin de p à q (voir Première partie, § 29). Soient maintenant

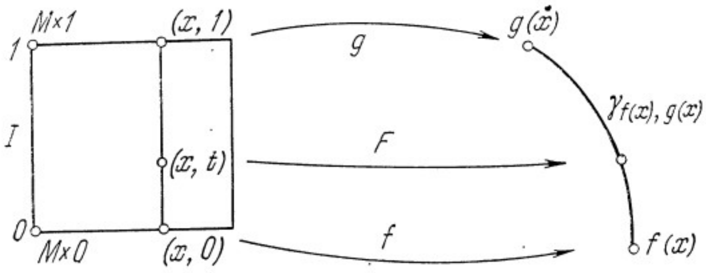

Fig. 28.

deux applications continues $f, g: M \to N$ telles que $\rho\,(f, g) < \varepsilon$. Faisons l'homotopie de $F: M \times I \to N$ avec $F(x, 0) = f(x)$, $F(x, 1) = g(x)$. A cet effet, définissons la valeur que prend $F(x, t)$ en un point quelconque $(x, t) \in M \times I$. Considérons deux points $f(x)$, $g(x) \in N$. Puisque $\rho_0(f(x), g(x)) < \varepsilon$, le plus court chemin entre ces points sera réalisé par une géodésique unique $\gamma_{f(x), g(x)}(\tau)$. Puisque nous connaissons non seulement x mais aussi t, nous pouvons diviser le segment de la géodésique $\gamma_{f(x), g(x)}$ entre $f(x)$ et $g(x)$ dans le rapport $t: (1 - t)$ et identifier le point de division au point $(x, t) \in M \times I$ (fig. 28).

Le fait que l'application $F(x, t)$ ainsi construite est continue résulte du théorème selon lequel les solutions dépendent continûment des conditions initiales; ce théorème s'applique à tout système d'équations différentielles ordinaires, ce qui est précisément le cas pour les équations des géodésiques. Le théorème est démontré.

THÉORÈME 2. *Soit f une application continue quelconque d'une variété différentiable M dans une variété différentiable N. Cette application est homotope alors à une application différentiable $g: M \to N$.*

Démonstration. Nous avons montré plus haut que toute application continue $f: M \to N$ admet toujours une application différentiable aussi voisine que l'on veut. L'assertion du théorème résulte du théorème précédent.

Exercice. Montrer que si l'application f est déjà différentiable sur une certaine sous-variété $X \subset M$, on peut toujours l'approcher par une application différentiable g de telle sorte que les restrictions de g et de f à X soient identiques.

THÉORÈME 3. *Deux applications différentiables* f, $g: M \to N$ *continûment homotopes sont différentiablement homotopes.*

Ce théorème résulte de l'existence d'une approximation différentiable pour toute application continue (en l'occurrence, l'homotopie initiale $F: M \times I \to N$), ainsi que des théorèmes 1 et 2.

On démontre par analogie l'assertion suivante: *toute application continue d'une variété différentiable M dans une variété différentiable de dimension suffisamment grande est homotope à un plongement différentiable. Si l'application donnée est différentiable, il peut en être de même pour l'homotopie en question.*

DÉFINITION 2. Nous disons que deux plongements différentiables f, $g: M \to N$ sont (différentiablement) *isotopes* s'ils sont liés par une homotopie différentiable $F: M \times I \to N$ telle que l'application $f_t: M \to N$ définie par l'égalité $f_t(x) = F(x, t)$ reste un plongement différentiable pour tout $t \in [0, 1]$.

THÉORÈME 4. *Deux plongements différentiables quelconques f, g d'une variété différentiable M de dimension n dans un espace euclidien* $\mathbf{R}^q$ *de dimension q suffisamment élevée (plus exactement* $q \geqslant 2n + 2$*) sont isotopes.*

Démonstration. Si la dimension q est suffisamment grande, deux plongements f, g admettent toujours une homotopie continue (donc aussi différentiable) $F: M \times I \to \mathbf{R}^q$ (par exemple ils peuvent être tous les deux homotopes à une application ponctuelle). Ceci étant, on peut transformer l'homotopie différentiable $F: M \times I \to N$ en un plongement par une déformation différentiable (la déformation étant fixe sur les « bases » $M \times 0$ et $M \times 1$ du cylindre), ce qui nous conduit justement à l'isotopie de f et g.

Grâce aux théorèmes démontrés, nous cesserons désormais de faire la distinction entre homotopie continue et homotopie différentiable. Dans le texte qui suit, nous considérerons des classes d'homotopie continue, différentiable par morceaux ou continûment différentiable de classe C^∞, suivant le cas.

La classe d'homotopie d'une application f se note $[f]$; l'ensemble des classes d'homotopie des applications $N \to M$ se note $[N; M]$.

2. Homotopies relatives. Dans le texte qui suit, nous rencontrerons des homotopies et des classes d'homotopie auxquelles on a imposé certaines contraintes. Citons-en quelques-unes:

a) Soient deux variétés N et M dont chacune présente un point de base $x_0 \in N$ et $y_0 \in M$. On demande que x_0 se transforme en y_0 par toute application $f: N \to M$ (de même que par toute homotopie). On dit alors que la classe d'applications (classe d'homotopie) est *liée en un point*.

b) Soient deux variétés à bord N et M de bords $\Gamma = \partial N$ et $\Delta = \partial M$. On demande que le bord Γ se transforme en le bord Δ par toute application $f: N \to M$ et par toute homotopie. Une telle classe d'applications est dite *relative* (relativement aux bords).

c) Soient deux variétés N, M non compactes (ouvertes). On demande que l'image réciproque d'un point quelconque par l'application $f: N \to M$ soit compacte. La même condition est demandée pour les homotopies $F: N \times I \to M$. Une telle classe d'applications (d'homotopie) est dite *propre.*

d) La classe la plus générale d'applications relatives est la suivante. Soit, dans chacune des variétés N et M, un ensemble de base $A \subset N$ et $B \subset M$. On demande que B soit l'image de A par toute application f et par toute homotopie F. L'ensemble des classes d'homotopie correspondantes se note $[(N, A); (M, B)]$.

§ 13. Degré de l'application

1. Définition du degré. Dans ce paragraphe, nous examinerons surtout les classes d'homotopie des applications de deux fermés orientés N et M de même dimension n, particulièrement lorsque M est une sphère. Soit une application différentiable $f: N \to M$. Choisissons un point $y_0 \in M$ et supposons que f soit une application régulière pour $y_0 \in M$. Cela revient à dire que l'image réciproque de y_0 est constituée par un nombre fini de points x_i $(i = 1, \ldots, m)$ de la variété N aux coordonnées locales (x_i^β) dans le voisinage des x_i et (y_0^α) dans le voisinage de y_0, les jacobiens det $\left(\dfrac{\partial y_0^\alpha}{\partial x_i^\beta}\right)$ étant non nuls, $i = 1, \ldots, m$. Rappelons que les variétés N et M sont munies d'une orientation, c'est-à-dire que tous les jacobiens de passage des coordonnées locales d'un voisinage à celles d'un autre sont positifs.

DÉFINITION 1. Le *degré* d'une application différentiable $f: N \to M$ de deux variétés fermées orientées connexes en un point régulier par rapport à une valeur régulière $y_0 \in M$ est la quantité

$$\deg f = \sum_{f(x_i) = y_0} \operatorname{sgn} \det\left(\frac{\partial y_0^\alpha}{\partial x_i^\beta}\right)$$

(les signes des jacobiens des applications étant bien déterminés dans tous les x_i).

On a le théorème important que voici:

THÉORÈME 1. *Le degré d'une application est indépendant de la valeur régulière choisie y_0 et est invariant par toute homotopie.*

Démonstration. Montrons d'abord que le degré ne dépend pas du choix de la valeur régulière. Ce résultat est immédiat pour toute valeur régulière voisine de y_0, car les images réciproques sont au même nombre et de même signe.

Soient y_0 et y_1 deux valeurs régulières de l'application f. Relions-les par un chemin différentiable non croisé sur la variété M à tangente non dégénérée: ce chemin représente une variété à une dimension γ. En vertu du

(/ /$ < 211 ! ! 1 P

cations $M \to \mathbf{R}^{2n}$. Dans le cas général, on en reste là. C'est ainsi qu'une variété fermée non orientable à deux dimensions ne peut pas être plongée dans $\mathbf{R}^3$ (vérifier!).

Il y a cependant des cas où l'on peut faire mieux: en particulier, toute variété orientable à deux dimensions peut se réaliser dans $\mathbf{R}^3$, ce qui ressort de la classification des variétés pareilles.

2. Fonctions de Morse comme fonctions de la hauteur. Le plongement $M \to \mathbf{R}^N$ peut fournir une nouvelle démonstration de l'existence des fonctions de Morse sur des variétés compactes différentiables. Nous montrerons en effet que les fonctions de Morse peuvent être recherchées dans une classe assez restreinte de fonctions sur M, dites «fonctions de la hauteur».

Etant donné un plongement différentiable de M dans $\mathbf{R}^N$ et une droite $\xi_l(t)$ parallèle à un vecteur l et passant par l'origine des coordonnées dans $\mathbf{R}^N$, considérons une fonction $h_l(x)$ (*fonction de la hauteur*) dont la valeur en $x \in M$ est égale à la projection orthogonale de x sur $\xi_l(t)$ (on suppose que $\xi(t)$ est la droite numérique réelle).

La fonction de la hauteur $h_l(x)$ possède quelques propriétés évidentes (d'ailleurs faciles à vérifier):

1) L'ensemble des fonctions de la hauteur correspond biunivoquement aux couples de points diamétralement opposés de la sphère S^{N-1} ou aux points de l'espace projectif $\mathbf{R}P^{N-1}$.

2) Le point $x_0 \in M$ est un point critique de la fonction de la hauteur $h_l(x)$ si et seulement si le vecteur l est orthogonal à M en x_0 (c'est-à-dire si $l \perp T_{x_0}M$).

Voyons dans quelles conditions le point critique $x_0 \in M$ est un point non dégénéré pour $h_l(x)$. Plaçons-nous dans le cas particulier où M est plongé dans $\mathbf{R}^{m+1}$ avec $m = \dim M$ (à la façon d'une hypersurface).

Rappelons que pour toute hypersurface $M \subset \mathbf{R}^{m+1}$ il existe une application gaussienne $r\colon M \to S^m \to \mathbf{R}P^m$ telle que $r(x) = n(x)$, où $n(x) \perp T_xM$ est le vecteur unité de la normale à M en x (le vecteur $n(x)$ étant transporté par parallélisme à l'origine des coordonnées $0 \in \mathbf{R}^{m+1}$).

LEMME 1. *Le point* $x_0 \in M \subset \mathbf{R}^{m+1}$ *est un point critique non dégénéré pour la fonction de la hauteur* $h_l(x)$ *si et seulement si* x_0 *est en même temps un point régulier de l'application gaussienne* $r\colon M \to \mathbf{R}P^m$, *avec* $l \perp T_{x_0}M$.

Démonstration. Orientons l'axe de coordonnée x^{m+1} parallèlement au vecteur l, et les axes de coordonnées $x^1, \ldots, x^m$ perpendiculairement à l; le plan $\mathbf{R}^m(x^1, \ldots, x^m)$ sera alors tangent à M en x_0. Dans le voisinage du point $x_0 \in M$, la variété M admet pour équation $x^{m+1} = \varphi(x^1, \ldots$ $\ldots, x^m)$, avec $d\varphi\,|_{x_0} = 0$. Dans un voisinage suffisamment petit U de x_0, on peut admettre que $(x^1, \ldots, x^m)$ soient des coordonnées locales introduites sur l'hypersurface M, tandis que la «hauteur» $h_l(x)$ soit précisément $x^{m+1} =$ $= \varphi(x^1, \ldots, x^m)$. Des coordonnées analogues $y^1, \ldots, y^m$ seront introduites sur la sphère dans le voisinage du point l. Un calcul analogue à celui qui a été entrepris pour déduire la formule $K d\sigma = f^*\Omega$ montre qu'on a dans le point x_0, en coordonnées locales $(x^1, \ldots, x^m)$ et $(y^1, \ldots, y^m)$, l'égalité

$$\left(\frac{\partial^2 h_l(x_0)}{\partial x^\alpha \partial x^\beta}\right) = \left(\frac{\partial^2 \varphi(x_0)}{\partial x^\alpha \partial x^\beta}\right) = \left(\frac{\partial y^\alpha}{\partial x^\beta}\bigg|_{x_0}\right);$$

$$\det\left(\frac{\partial^2 h_l(x_0)}{\partial x^\alpha \partial x^\beta}\right) = K.$$

Ici K est la courbure totale de l'hypersurface au point x_0, et $y^\alpha = r^\alpha(x^1, \ldots$ $\ldots, x^m)$, $1 \leqslant \alpha \leqslant m$, est l'application gaussienne transcrite au moyen des coordonnées (x) et (y). Ainsi donc, si l'on veut que l'application gaussienne r admette x_0 comme point régulier, $\det\left(\frac{\partial y^\alpha}{\partial x^\beta}\bigg|_{x_0}\right) \neq 0$, il faut et il suffit que la hessienne de la fonction de la hauteur $h_l(x_0)$ soit non dégénérée, $\det\left(\frac{\partial^2 h_l(x_0)}{\partial x^\alpha \partial x^\beta}\right) \neq 0$. Le lemme est démontré.

Remarque importante. Etant donné un plongement $M \subset \mathbf{R}^q$, où $q > m + 1$ ($m = \dim M$), il existe une variété différentiable N à $q - 1$ dimensions qui constitue la frontière du «voisinage tubulaire» de M. Considérons en effet l'ensemble des disques D^{q-m}_x de dimension $q - m$ orthogonaux à M, de centre en des points $x \in M$ et de rayon $\varepsilon > 0$ suffisamment petit. La réunion de ces boules (avec $\varepsilon > 0$ petit) forme une variété q-dimensionnelle appelée quelquefois voisinage tubulaire de M; c'est sa frontière (bord) qu'on désigne par N. L'image de cette sous-variété (plongée dans $\mathbf{R}^q$ pour ε petit) par l'application gaussienne r est une sphère S^{q-1}. Soit $h_l(x)$ une fonction de la hauteur sur M et sur N. Il est facile de voir (vérifier!) que, pour tout point critique $x_0 \in M$ de la fonction $h_l(x)$, on a exactement deux points critiques y_0, y_0' sur N: ce sont les points où N vient couper la droite l qui passe par x_0 et qui est orthogonale à M (fig. 27).

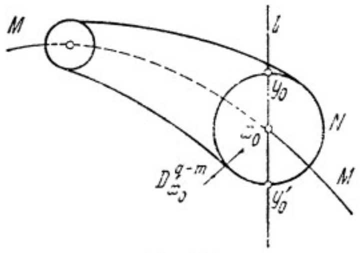

Fig. 27.

On vérifie sans peine ensuite que le point critique $x_0 \in M$ de la fonction $h_l(x)$ est non dégénéré si et seulement si les points y_0, y_0' sont non dégénérés pour $h_l(x)$ (les points y_0 et y_0' sont tous les deux dégénérés ou non). Si donc $h_l(x)$ est une fonction de Morse sur N, elle l'est aussi sur M. Il s'ensuit que toute proposition selon laquelle les fonctions de Morse existent et sont partout denses dans l'ensemble des fonctions de la hauteur sur N est toujours vraie pour M. Cela prouve qu'on ne diminue pas la généralité en se bornant à considérer, dans le lemme ci-dessus, une hypersurface $M \subset \mathbf{R}^{m+1}$.

THÉORÈME 2. *La fonction de la hauteur* $h_l(x)$ *sur l'hypersurface* $M \subset \mathbf{R}^{m+1}$, $m = \dim M$, *est une fonction de Morse si et seulement si le point* $(\pm l) \in \mathbf{R}P^m$ *est une valeur régulière de l'application gaussienne* $r: M \to \mathbf{R}P^m$. *En particulier, presque toutes les fonctions de la hauteur* $h_l(x)$ *sont des fonctions de Morse.*

Démonstration. La première assertion du théorème découle du lemme 1. La seconde résulte du lemme de Sard: en effet, les valeurs régulières de l'application gaussienne $r: M \to \mathbf{R}P^m$ sont partout denses dans $\mathbf{R}P^m$. Le théorème est démontré.

Remarque. En vertu des observations supplémentaires faites ci-dessus au sujet de $M \subset \mathbf{R}^q$ pour $q > m + 1$, le théorème reste valable pour toute sous-variété différentiable dans $\mathbf{R}^q$ de codimension quelconque (donc pour tout $q - m > 0$).

3. Points focaux. Il y a beaucoup d'autres procédés qui permettent de construire sans peine de nombreuses fonctions de Morse sur des variétés différentiables. Sans entrer dans le détail, donnons la description d'un procédé.

Considérons une variété différentiable M et son plongement différentiable quelconque dans $\mathbf{R}^q$. Choisissons une fois pour toutes un point $p \in \mathbf{R}^q$ et associons à ce point une fonction différentiable L_p construite sur le plongement M^m en posant $L_p(x) = |p - x|^2$, où $x \in M$ et $|p - x|$ est la longueur du vecteur $p - x$. On montre que $L_p(x)$ est une fonction de Morse sur M pour presque tous les points $p \in \mathbf{R}^q$. L'ensemble des fonctions du type $L_p(x)$ ne se confond pas avec celui des fonctions de la hauteur $h_l(x)$.

On veut savoir pour quels points p la fonction $L_p(x)$ est une fonction de Morse. Désignons par N l'ensemble des couples (x, v) où $x \in M$ et $v \in \mathbf{R}^q$ est un vecteur orthogonal à M en x. Il est évident que N est une variété différentiable à q dimensions (vérifier!). Considérons une application différentiable $f: N \to \mathbf{R}^q$ qui à tout couple $(x, v) \in N$ fait correspondre l'extrémité d'un vecteur ayant son origine en x.

DÉFINITION 1. On dit que le point $p \in \mathbf{R}^q$ est un *point focal de multiplicité* $\mu > 0$ pour M si $p = f(x, v)$ et le jacobien de f en (x, v) est de rang $q - \mu$.

En vertu du lemme de Sard, on ne trouve presque pas de point focal pour le plongement $M \subset \mathbf{R}^q$ parmi les points $p \in \mathbf{R}^q$; en particulier, les points focaux $p \in \mathbf{R}^q$ forment un ensemble de mesure nulle.

Considérons à présent la «deuxième forme fondamentale du plongement $M \subset \mathbf{R}^q$». Supposons que la variété M soit (localement) définie dans $\mathbf{R}^q$ sous forme paramétrique $x = x(u^1, \ldots, u^m)$, où u^α, $1 \leqslant \alpha \leqslant m$, sont des coordonnées locales sur M; $x = (x^1, \ldots, x^q)$. Considérons un vecteur $\dfrac{\partial^2 x}{\partial u^i \partial u^j} = x_{ij}$; soit v la normale à M en $x \in M$. Il existe alors le produit sca-

Actually, the Gaussian curvature (see § 1.4) of space, C_G, at the center of the star is larger than it is at other places. The quantity C_G is given by the formula (see eq. [1.8.13]):

$$C_G = (8\pi/3)(G\rho/c^2)\ . \tag{3.3.6}$$

Inasmuch as the density is a maximum at the center of the star, C_G is also a maximum there. Of course, we should not assume on the basis of equation (3.3.6) that space is Euclidean outside the star (where $\rho = 0$), when the gravitational field near the star is strong. Formula (3.3.6) gives only the mean curvature of space averaged over all two-dimensional directions; and this mean curvature actually is zero. However, beyond the star, the Riemannian space curvature (see § 1.4) is nonzero; and, depending on the two-dimensional direction, it may be positive or negative. At the center of the star, all directions are equivalent; there the curvature for any orientation is given by formula (3.3.6), and it is always positive.

The gravitational field obtained by joining the star's interior and exterior solutions has no physical singularities of the type exhibited on the Schwarzschild sphere; everywhere

$$1 \leq e^{\lambda} < \infty\ , \quad \text{and} \quad 0 < e^{\nu} < 1\ .$$

3.4 THE RADIAL MOTION OF LIGHT RAYS AND OF ULTRA-RELATIVISTIC PARTICLES

Consider now the radial motion, in a spherical gravitational field, of particles with the fundamental speed c; for example, photons and neutrinos. Since an observer can locally introduce coordinates for which $ds^2 = c^2dt^2 - dx^2 - dy^2 - dz^2$, and since the speed of light c is independent of reference frame, an equation of motion for a particle with zero rest mass is $ds = 0$ in any coordinate system. Because of spherical symmetry, a particle that starts out moving radially will always move radially. Along such a particle's trajectory θ and ϕ are constant, so the condition $ds = 0$ implies

$$dr/dt = ce^{(\nu-\lambda)/2}\ . \tag{3.4.1}$$

Everywhere inside the star $e^{(\nu-\lambda)/2} < 1$. Outside the star, in vacuum, $e^{(\nu-\lambda)/2} = 1 - 2GM/c^2r < 1$; and this quantity approaches unity as $r \to \infty$. It follows, for example, that for a neutrino emitted from the star's center, the radial coordinate r, as a function of the time t of a distant observer, must have the form shown in Figure 7. The dotted line in this diagram indicates the motion of the neutrino in the absence of a gravitational field.

In the future we will frequently consider the motion of bodies in the immediate vicinity of the gravitational radius of the central body (where the field is especially strong), and even in the limit $r \to r_g$. As noted in § 3.2, a static body cannot have dimensions $r \leq r_g$; and Bondi (1964) has demonstrated that the dimensions of a body in equilibrium cannot be smaller than (up to terms of first order in a). Expression (4.3.4) is identical with the one given by Landau and Lifshitz (1962) for a weak field. In reality, it is valid also in a strong field when $a \ll r_g$ (to first order in the dimensionless parameter a/r_g). The expression (4.3.4) for a stationary sphere was independently obtained by Gurovich (1965). For beautiful discussions of its relationship to Mach's Principle see Brill and Cohen (1966), and Cohen and Brill (1968).

In this solution for perturbations of the Schwarzschild field, only terms linear in a were retained in $h_{\mu\nu}$; terms proportional to a^2 and higher powers were neglected. Notice that the surfaces S_m and S_{hor} coincide in this case; they differ only by $O(a^2)$. Those aspects of the Kerr solution at $g_{00} = 0$ which depend on corrections to $g_{\mu\nu}$ which are linear in a are retained by this solution. In particular, here $C_{g_{00}} = 0 = 12/r_g{}^4 < \infty$.

Hartle and Thorne (1968) have derived the general solution for the exterior gravitational field of a slowly rotating, centrifugally deformed star with a precision of second order in the angular momentum $(a/r_g)^2$ and of first order in the quadrupole moment. Their solution has this curious property: it has no singularity at S_m or S_{hor} if and only if the quadrupole moment Q, the angular momentum K, and the star's mass M satisfy the algebraic identity

$$Q = K^2/M\,.$$

It is widely speculated that in order for the exact solution to have no real singularities at S_{hor}, every higher multipole moment must be linked to the angular momentum and mass by a relation similar to the above; and it is thought that the only exact solution with such a property (an absence of singularities at the event horizon) is probably the Kerr solution (cf. Hernandez 1967).

Can a solution with a "rotational" deviation from spherical symmetry be realized in nature for the entire domain down to $g_{00} = 0$?

Such a solution cannot be created by a stationary body for the same reason that it cannot in the case of a body with a quadrupole moment. However, for a nonstationary source we cannot apply the same reasoning as we did in § 4.2, because here in the "rotating" Kerr solution the invariant C is finite at $g_{00} = 0$ and at the event horizon, S_{hor}. It will be demonstrated later that a stationary solution with "rotational" perturbations and without a singularity at the event horizon can actually be realized, throughout the domain down to the horizon, as the asymptotic solution for the collapse of a rotating body.

4.4 THE SCHWARZSCHILD SPHERE IN AN EXTERNAL QUADRUPOLE FIELD

We conclude our discussion of nonspherical static fields with the following comments.

There exist solutions of the Einstein equations containing Schwarzschild surfaces S_m which do not differ qualitatively from the Schwarzschild surface for the spherical case. However, in these cases the deviations from spherical symmetry must be caused by external fields. For example, if we consider a spherical mass in an external quadrupole field (which increases with distance from the mass m), then an exact solution of the Einstein equations in vacuum has the form (the notation is the same as used in § 2 of this chapter)

$$\psi = \tfrac{1}{2} \ln [(\lambda - 1)/(\lambda + 1)] + \tfrac{1}{4} q(3\lambda^2 - 1)(3\mu^2 - 1) ,$$

$$\gamma = \tfrac{1}{2} \ln [(\lambda^2 - 1)/(\lambda^2 - \mu^2)] - 3q\lambda(1 - \mu^2)$$

$$- \tfrac{9}{16} q^2(\lambda^2 - 1)(1 - \mu^2)[9\mu^2\lambda^2 - \lambda^2 - \mu^2 + 1] .$$

The surface $g_{00} = 0$ is determined by the condition $\lambda = 1$. This surface is a Schwarzschild sphere deformed by an external field. The Gaussian curvature of the two-dimensional surface S_m (*not* the Gaussian curvature of the three-dimensional surface created by S_m as it moves through spacetime),

$$C_G{}^* = \frac{1}{4m^2} e^q[1 + 3q - 12q\mu^2 - 9q^2\mu^2 + 9q^2\mu^4] ,$$

is different for different μ and is always finite. The physical properties of this S_m are the same as those of the Schwarzschild sphere.

A constant external quadrupole field could be created by distant masses fastened on supports, which prevent them from falling inward. For a limited interval of time the same field could be created approximately also by freely moving distant masses, whose velocities under the influence of reciprocal gravitation are small initially. In this case the field would be almost static.

4.5 THE GRAVITATIONAL CONTRACTION OF A SLOWLY ROTATING BODY WITH SMALL DEVIATIONS FROM SPHERICAL SYMMETRY[6]

Let us briefly review the contraction of a uniform spherical dust cloud of radius r (see § 3.12). For a distant observer, the picture tends to "freeze" as $r \longrightarrow r_g$ because of time retardation. For this observer, the contracting ball will never have dimensions smaller than r_g. By contrast, an observer on the surface of the contracting ball reaches $R_0 = r_g$ in finite proper time. For him the contraction does not "freeze" at all, but continues through the Schwarzschild sphere into the T-region. The density of the matter in the ball, when $R_0 = r_g$ and the mass is large, has no singularity whatsoever. It can be estimated easily that

$$\rho_g \approx \frac{M}{\frac{4}{3}\pi r_g{}^3} \approx 2 \times 10^{16}(M_\odot/M)^2 \text{ g cm}^{-3} ,$$

where $M_\odot \approx 2 \times 11^{33}$ g is the mass of the Sun.

---

[6] We will not consider here large-scale magnetic and electric fields surrounding the contracting body. Such fields will be discussed later in § 13.6.

For $M = 10^8 M_\odot$, for example, $\rho_g \approx 2 \text{ g cm}^{-3}$. After the contracting ball passes its gravitational radius, light beams from its surface (see Fig. 25) cannot escape back out through the Schwarzschild sphere and *cannot* reach the distant observer.

If there are small initial perturbations in the density and velocity of the matter inside the body, then they will increase as the contraction proceeds; this was first investigated in detail by Lifshitz (1946) (see Vol. II). However, the surface of the contracting body will at some point cross a surface (event horizon) through which light rays cannot escape to infinity. Although this horizon will differ from the Schwarzschild surface due to the small perturbations, the difference will be so small that we need not make a distinction between the actual horizon and the Schwarzschild surface $r = r_g$. The moment when the star's surface crosses the Schwarzschild surface, $R_0 = r_g$, is in no way special so far as the dynamics of the body's matter are concerned; the density of the matter then is still far from infinite.

Thus, if the initial perturbations are sufficiently small, then at the moment when $R_0 = r_g$ they have not had enough time as yet to become large. The surface of the body in the frame of the comoving observer intersects the Schwarzschild sphere when the perturbations in its matter and in the field around it are still small.

Subsequently, the perturbations in the body increase. But, as demonstrated in § 3.12, an external observer does not receive any information whatsoever from under the Schwarzschild sphere. Consequently, the increasing perturbations inside S_m have no effect whatsoever on the spacetime domain near the Schwarzschild surface, nor on the external domain of the distant observer (R-region). The reader who is inclined to accept this without further explanation may skip the following paragraph. A more formal mathematical proof is included in the appendix to this section.

In fact, disturbances in the gravitational field propagate away from the body at the speed of light. It follows however, from Figure 25 that the trajectories of the rays which escape from the body in the T-region do not approach the Schwarzschild surface. Even trajectories that are fairly large perturbations of null rays do not reach it. This means that the disturbances in the vacuum near the Schwarzschild surface are always small, and that its properties remain unchanged. In particular, no information and no radiation pass through the Schwarzschild sphere to an external observer.[7] Consequently, even when there are disturbances in the collapsing body, the external observer has only a finite interval of the body's evolution accessible to him.

---

[7] Let us emphasize once more that, because of the small perturbations, the event horizon actually lies deeper than $g_{00} = 0$ (see § 4.3), so that the properties of the Schwarzschild surface are now smeared out over a narrow region (between the horizon and $g_{00} = 0$). However, that region is so very narrow that we shall simply call it the "Schwarzschild surface."

He can follow the development of the disturbances in the body and in its surrounding field, but only up to the moment when $R_0 = r_g$.

It should be clear by now that the external field of the collapsing body for a distant observer must become stationary in the limit $t \rightarrow \infty$; all $\partial/\partial t \rightarrow 0$. As a matter of fact, in the reference frame of an external observer, time-dependent perturbations that occur prior to the moment when the surface reaches the sphere r_g must spread out as gravitational waves, and

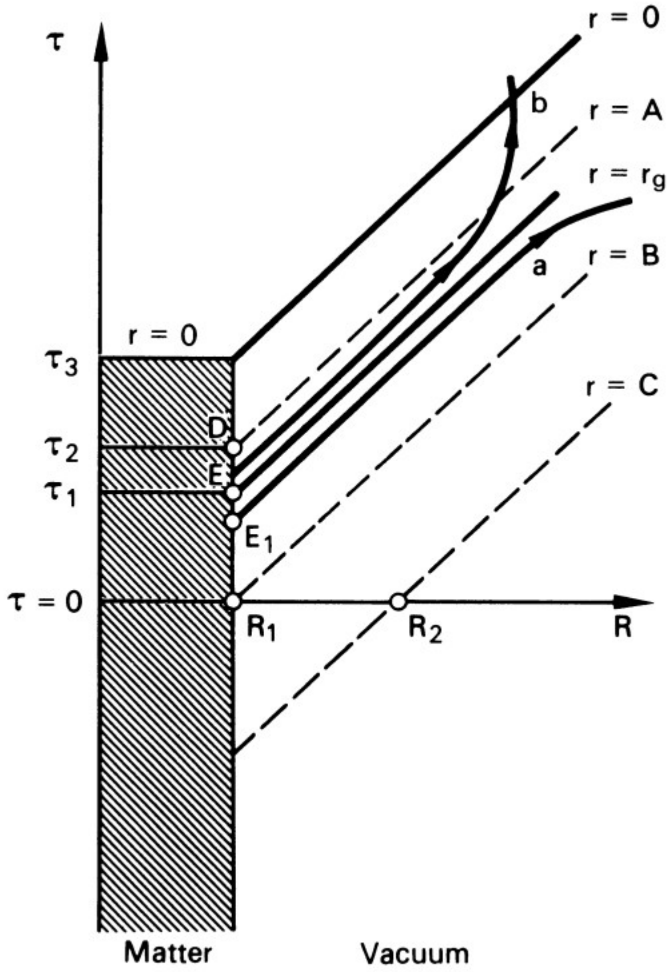

FIG. 25—.Collapse of a spherical dust cloud in a freely falling reference frame (for discussion see appendix to § 4.5). Here *a* and *b* are the world lines of light rays. Ray *a*, emitted from E_1 near time τ_1, propagates near $r = r_g$ for a long time (according to the time of *any* reference frame).

no new disturbances can be received from under the Schwarzschild sphere. Naturally, all these conclusions are valid not only for a collapsing body made of dust but also for matter with nonzero pressure.

Thus, the asymptotic field of a contracting body is stationary, with small deviations from sphericity, when $t \to \infty$.

The rotation of the body brings about an oblateness, i.e., a deviation from sphericity. The perturbations in the external field due to such deviations from sphericity are quantities of second order in the body's angular velocity, as compared with the first-order perturbations of the field due to the rotation itself. The effect of rotation upon the external field was considered in detail in § 4.3.

During the contraction of a rotating ball the external gravitational field does not change with time (up to terms linear in the angular momentum K), and the asymptotic field will be a Schwarzschild field plus a correction caused by the rotation

$$g_{03} = \sin^2 \theta \, (2K/r) . \tag{4.5.1}$$

Such a conclusion is not surprising. During the contraction of the ball, the mass M and the angular momentum K are conserved. Hence, the asymptotic field depends on both of these quantities.

What is the nature of the asymptotic field of a contracting body whose nonsphericity is caused not by rotation but, for example, by a nonsymmetrical distribution of mass? The asymptotic field must be stationary. It was demonstrated in § 4.2 that, if corrections to the Schwarzschild field for quadrupole and higher multipole moments (produced by a change in the field's source) are time-independent, then, however small they might be at finite distances from S_m, they become arbitrarily large near S_m and create a true singularity, $C = \infty$, there. On the other hand, as we mentioned at the beginning of this section, in the comoving reference frame of a contracting body with small initial, nonspherical, density perturbations the moment when the body's surface crosses the Schwarzschild surface is not special; it is not accompanied by a true singularity, either in the metric or in the density. Comparison of these results suggests that the quadrupole and higher multipole moments of the external gravitational field must attenuate in the relativistic stages of contraction of a nonsymmetrical body.

Let us attempt to establish the law which governs such attenuation. Consider the approach to the asymptotic field (in the first approximation, and near the Schwarzschild surface) as a passage through a sequence of static states. (About the validity of this assumption, see below.) We shall call this sequence of states "quasistatic" and we shall denote its quadrupole moment by $q(t)$. Examination of the equations for static, axisymmetric, quadrupole perturbations of the Schwarzschild metric indicates that when $g_{00} \to 0$, the components of the metric perturbations that are different from zero take the following form:

$$\begin{aligned} h_{00} &\sim q(1 - r_g/r) \ln (1 - r_g/r) , \\ h_{11} &\sim q(1 - r_g/r) \ln (1 - r_g/r) , \\ h_{22} &\sim h_{33} \sim q \ln (1 - r_g/r) , \end{aligned} \tag{4.5.2}$$

where q is the quadrupole parameter of the perturbation. In these equations multiplicative factors that do not depend on $(1 - r_g/r)$ are omitted.

When the body contracts with $q \neq 0$, all quantities $h_{\mu\nu}$ must remain finite in the comoving frame. Since h_{22} and h_{33} are not affected by a transformation from a comoving coordinate system to the Schwarzschild system, it is obvious that, as $r \rightarrow r_g$,

$$q \lesssim 1/\ln (1 - r_g/r) \sim 1/t . \tag{4.5.3}$$

The last relation in equation (4.5.3) was obtained from the equation (3.5.1) for the law of free fall in a Schwarzschild field. Near the Schwarzschild surface all processes occur at the rate given by equation (4.5.3) (including, e.g., the propagation of gravitational waves). Thus, the quadrupole moment q decays at least as rapidly as $q \sim t^{-1}$. The same applies to higher multipole moments.

More careful analyses of collapse with small nonspherical perturbations (Price 1970; Israel 1970) reveal that the decay of the perturbations is even more rapid than $q \sim t^{-1}$. The body always remains deformed, as seen by a comoving observer. However, as it approaches its Schwarzschild sphere, the body radiates away all nonspherical deformations of its external gravitational field, except the rotational perturbations discussed above. If the gravitational waves did not backscatter off the Schwarzschild curvature of spacetime, the metric perturbations would die exponentially at late times as

$$h_{ij} \sim \exp \left\{ -\frac{1}{\tau} [t - r - r_g \ln (r/r_g - 1)] \right\} , \quad \tau \sim r_g/c .$$

However, Price (1970) has shown that, because of backscatter, the outgoing gravitational waves leave behind a "tail." The strength of this tail dies out, at fixed radius, as

$$h_{ij} \sim t^{-(2l+2)} \ln t .$$

Here l is the order of the multipole considered ($l = 2$ for quadrupole perturbations, etc.). Interestingly, this decay law for the wave tail is valid for long-wavelength electromagnetic waves, as well as for the gravitational waves which carry off the deformations of the metric.

An important consequence of the above is this: At very late times the asymptotic, external field of a contracting, deformed, slowly rotating body is (to first order) a Schwarzschild field plus stationary "rotational perturbations" in the off-diagonal terms.

An analysis of the motions of test particles and light rays in such a field suggests that the properties of the motion are qualitatively the same as they are in the Schwarzschild field (§§ 3.9 and 3.10). For an external observer, a particle with an impact parameter that is smaller than the critical one is gravitationally captured; upon completing a finite number of spiraling revolutions, it approaches the Schwarzschild surface $g_{00} = 0$ asymptotically as $t \rightarrow \infty$.

The same is true for light rays. No radiation or information can reach an external observer from under the sphere S_m; a gravitational self-closure takes place.

These conclusions are especially important for analyses of the catastrophic contraction of stars, which will be discussed in the next part of this book.

4.6 WHAT HAPPENS TO MATTER AFTER IT FALLS THROUGH THE EVENT HORIZON?

The problem posed in the heading of this section inevitably must be faced. Actually, in the case of strict spherical symmetry, as was demonstrated in § 3.12, the contracting body is necessarily compressed to a point soon after it crosses $r_g = 2Gm/c^2$, so far as the comoving observer is concerned; all of the matter in the sphere is compressed to infinite density. What happens after that? True, the external observer cannot learn anything about it; so far as he is concerned, as $t \rightarrow \infty$ the body's surface approaches r_g, and everything that happens after that is for him in the absolute future (see § 3.12). But what is the final fate of the contracting body, not for an outside observer, but for a comoving observer on the surface of the body?

The relativistic contraction of a spherical body, as noted previously, is unstable. In the course of contraction, perturbations increase without bound as $\rho \rightarrow \infty$ (see Vol. II). Can the evolution of the asymmetries prevent the creation of a singularity in the solution and transform the contraction into expansion after a certain maximum density has been reached? A partial answer to this question has been given by Penrose (1965, 1967) and by Hawking and Penrose (1969). They have shown that if a body contracts to dimensions smaller than r_g, and if other, reasonable conditions are satisfied, then the evolution of a true singularity in the solution is unavoidable. Whether or not *all* of the matter in the body reaches infinite density cannot be established by using the methods of Penrose and Hawking. However, other methods developed by Lifshitz and Khalatnikov (1960*a*, *b*; 1963), Lifshitz, Sudakov, and Khalatnikov (1961), and Belinsky and Khalatnikov (1969) have yielded considerable information about the nature of the singularities for a wide class of solutions to the Einstein field equations. These results and the "singularity theorems" of Penrose, Hawking, and Geroch will be discussed in connection with cosmology in Vol. II of this work.

always finite.

The physical properties of this S_M are the same of those of the Schwarzschild sphere!

Pag. 441 (458) –

We can rewrite the condition for linkage of the protons to the field lines as

$$H > 10^{-12}(r_K/r)^{3/2} \text{ gauss.} \quad (13.4.12)$$

Pag. 456 (473) –

455 (472) –

What could cause the necessary quadrupole moment?

The magnetic field, inclined at an angle relative to the axis of rotation, will produce some deformation.

However, Ostriker and Gunn have shown that the dipole magnetic field needed for the magnetic deceleration is too weak to produce the necessary deformation.

⇒ "One has to assume an internal field of the order of 10^{15} gauss with magnetic

ϕ is measured in units of c^2 (0.1 c^2 is the typical magnitude of the gravitational potential near the surface of a neutron star, cf. the next section); and $u \equiv -dr/dt \approx 1.2 \times 10^{13}\, r^{-1/2}\, (M/M_\odot)^{1/2}$.

In our search for the link between γ and the temperature change during free fall, let us consider first the case in which one can neglect the role of the last term of equation (13.4.9). In this case the falling gas will cool due to radiation reaction if the temperature "at infinity" is small enough (i.e., if the second term on right-hand side of eq. [13.4.9] dominates). In this case, the cooling law will be $T \approx (A \ln (r/r_0) + T_0{}^{1/2})^2$ initially; however, since $T_0 \sim 10000°$ K, recombination will quickly come into play, and the temperature will level off at a constant value, $T =$ const., corresponding to $\gamma = 1$. On the other hand, if the temperature "at infinity" is large, then the role of radiation reaction will diminish continuously during the fall, the first term of equation (13.4.9) will dominate, and the temperature change will approach $T \sim 1/r$, corresponding to $\gamma \rightarrow \frac{5}{3}$. The critical temperature separating these two extreme cases is

$$T_k = 2 \times 10^6 (L/L_0)^2 (0.1/\phi)^2 (M_\odot/M)^2 \beta^2 \text{ °K} . \qquad (13.4.10)$$

The existence of two limiting cases, together with the great difference between the values of γ for those cases, shows the importance of taking into account the last term in equation (13.4.9). The general situation, unfortunately, has not yet been investigated. However, by limiting ourselves to a consideration of Compton scattering between the plasma's electrons and the outward-flying photons, we can write the last term of equation (13.4.9) in the form (Zel'dovich and Shakura 1969)

$$-\frac{dQ_i/dt}{\frac{3}{2}R^* u} = 2 \times 10^6 \left(\frac{L}{L_0}\right)(T - T_p)\left(\frac{1}{r^{3/2}}\right), \qquad (13.4.11)$$

where T_p is the photon temperature. By inserting this term into equation (13.4.9) one readily sees that the temperature is practically constant for $r < 3 \times 10^{12}\, (L/L_\odot)^2$, and is equal to T_p. Other processes will obviously have only weak influence on this conclusion, but they will be important in determining what happens at larger radii.

We should note, however, that there is probably a justification, independent of the above considerations, for idealizing the accreting matter as a fluid. This justification is the existence of a magnetic field, frozen into the plasma. More particularly, the Larmor radius for a proton moving with thermal velocity turns out to be smaller than the characteristic length scale of the infalling matter whenever $H > 1.3\, T^{1/2}\, r^{-1}$ gauss. Taking account of the fact that $T \leq T_\infty(r_c/r)$, and assuming $T_\infty = 10000°$ K, $r_c = 10^{14}$ cm, we can rewrite the condition for linkage of the protons to the field lines as

$$H > 10^{-12}(r_c/r)^{3/2} \text{ gauss} . \qquad (13.4.12)$$

Tucker 1968). Thus, the problem of the energy balance of the Crab Nebula has found a solution.

The next question is how the transfer of energy and angular momentum occurs. The most plausible idea relies on magnetic dipole radiation (Pacini 1968; Gunn and Ostriker 1969). As shown by Gunn and Ostriker (1969) a magnetic field of the order of 3×10^{12} gauss at the surface gives the needed braking torque. For magnetic dipole radiation

$$dE/dt = I\omega\ (d\omega/dt) = -\text{const.}\ (d^2\mathfrak{M}/dt^2)^2 = -\text{const.}\ \mathfrak{M}^2\omega^4 .$$

With a constant magnetic moment $\mathfrak{M}$ this gives

$$d\omega/dt = -a\omega^3 , \quad (2/\omega^2) - (2/\omega_0^2) = at , \quad \omega = (2at + 1/\omega_0^2)^{-1/2} ;$$

and with $\omega_0^2 \gg \omega^2$,

$$\omega = 1/(2at)^{1/2} , \qquad d\omega/dt = -\omega/2t .$$

This law is fairly well confirmed by observations; the initial rotational velocity, which could be different for different pulsars, cancels out. The constant a varies by not more than a factor of about 10 over the life of a pulsar, $dP/dt = 3 \times 10^{-15}/P$, which means $d\omega/dt = 10^{-13}\omega^3$.

For the Crab pulsar, the exact time of birth is known so that the deceleration law can be checked. One finds $d\omega/dt = -\omega/2370$ years $= -\omega/2t$. In actuality, the explosion was in the year 1053 A.D., $t = 916$ years ago. The agreement is not too bad.

There is another source of deceleration—gravitational radiation emitted by the rotating star. Of course, if the star is symmetric around its axis of rotation, it will not radiate. Assume that the star possesses a quadrupole moment which is constant in the corotating frame. Then

$$dE_r/dt = I\omega\dot{\omega} = -\text{const.}\ (d^3Q/dt^3)^2 = -\text{const.}\ Q^2\omega^6 .$$

The corresponding law of deceleration is

$$\omega = \left(at + \frac{1}{\omega_0^4}\right)^{-1/4} \rightarrow bt^{-1/4} ,$$

i.e.,

$$d\omega/dt = -\omega/4t ,$$

which is in worse accord with the observations, but with a discrepancy of the opposite sign.

A combination of gravitational and magnetic dipole radiation can be found which matches exactly the age and current deceleration rate of the Crab Nebula's pulsar. By assuming an initial angular velocity of $\Omega_0 = 10^4$, the authors obtain $(L_0)_{\text{grav}} = 3 \times 10^{48}$ ergs sec^{-1}, $(L_0)_{\text{mag}} = 5 \times 10^{45}$ ergs sec^{-1}; and for the current epoch, $L_{\text{grav}} = 2 \times 10^{38}$ ergs sec^{-1}, $L_{\text{mag}} = 10^{39}$ ergs sec^{-1}.

What could cause the necessary quadrupole moment? The magnetic field, inclined at an angle relative to the axis of rotation, will produce some deformation. However, Ostriker and Gunn have shown that the dipole magnetic field needed for the magnetic deceleration is too weak to produce the necessary deformation. One has to assume an internal field of the order of 10^{15} gauss with magnetic field lines hidden inside the star in order to sustain the necessary asymmetry against the force of gravity.[14]

Although the numbers given are plausible, it is obvious that caution is needed; the results are too new to be definitive.

The gravitational radiation escapes completely from the pulsar and its surroundings. In connection with Weber's experiment the important point is the existence of a rigorous upper limit on the action of a pulsar on a resonant detector of gravitational waves; this limit does not depend on any assumption about the star's asymmetry. In the absence of other mechanisms of deceleration, the total energy emitted in gravitational waves per unit angular frequency is obviously

$$\Delta E_\omega/\Delta\omega = \Delta\left(\tfrac{1}{2}\, I\, \omega_r^2\right)/\Delta\omega = I\, \omega_r \Delta\omega_r/\Delta\omega = \tfrac{1}{4} I\omega\ .$$

Here it is taken into account that the frequency of the emitted waves is twice the angular velocity of rotation ω_r. For the maximum possible $I = 3.5 \times 10^{45}$ g cm^2 of a neutron star, and for the $\omega = 10^4$ of Weber's apparatus, we find

$$\Delta E_\omega/\Delta\omega = \tfrac{1}{4} \times 3.5 \times 10^{45} \times 10^4 = 10^{49} \text{ ergs}\ .$$

The corresponding averaged flux at a distance of 10 kpc. (galactic nucleus) is

$$F_\omega = \frac{\Delta E_\omega}{\Delta\omega 4\pi r^2} = 10^5 \text{ ergs cm}^{-2}\text{ Hz}^{-1}\ .$$

This is definitely below the limit of Weber's sensitivity.

Slowly rotating pulsars, such as those we observe now including the Crab pulsar, lose their energy largely by electromagnetic processes. We shall not attempt to give a detailed picture of these processes, nor shall we present a detailed theory for the directed radiation. As mentioned above, Ostriker and Gunn calculate the energy emitted by a rotating magnetic dipole. Other authors are considering charged particles and plasma which rotate with the magnetic field out to the radius where the linear velocity of rotation attains the speed of light (Gold 1968, 1969; Goldreich 1969). These two different points of view give the same order of magnitude for the rates of loss of energy and angular momentum. How can one understand this coincidence?

Consider the electromagnetic field in vacuum. It is a static dipole field $|H| \sim |M|/r^3$ in the near zone, i.e., at distances less than the reduced wavelength of the radiation emitted, $r < \lambdabar = c/\omega$, where $\lambdabar = \lambda/(2\pi)$. At greater distances it is an outgoing-wave field, with an energy flux of the order of $q = H^2/4\pi c$. The formula for the radiation is obtained by joining the fields at $r = ƛ$: we find $q = (M/ƛ^3)^2(c/4\pi)$:

---

[14] The idea of a strong internal magnetic field, much greater than the external dipole field, is familiar for ordinary stars.

$$Q = 4\pi r^2 q = 4\pi ƛ^2(M/\lambda^3)^2(c/4\pi) \sim M^2\omega^4/c^3 \sim c^{-3}(d^2M/dt^2)^2 .$$

(Note that for a rotating dipole $r = ƛ = c/\omega$ coincides with the condition $v = \omega r = c$; we have calculated the Poynting vector at the radius where $v = c$.) If the field carries charged particles, their density is of the order of the energy density of the field itself. Therefore, the energy flux carried by a plasma injected with the help of the field should be equal to the Poynting flux. This explains the coincidence.

If a rotating body loses energy, it always loses angular momentum as well at a corresponding rate: d(angular momentum)$/dt$ = (angular velocity)^{-1}d(energy)$/dt$. A rigorous Newtonian proof is given by Ostriker and Gunn (1969); and the analogous proof in general relativity is given by Hartle (1970).

By ignoring the superconductivity of the neutron star, one estimates that the time required for the magnetic field to decay is $\sim 10^7$ years. This is just the time of the active life of typical pulsars. Schwartzman (1970*d*) has pointed out that as the magnetic field decreases, particle ejection can be changed into accretion of surrounding matter onto the neutron star. Gas accretion onto a pulsar with a magnetic field is accompanied by Langmuir plasma vibrations, and by a transformation of the energy of such vibrations into electromagnetic radiation. Thus the pulsar radiation, which decays at first, can grow again because of accretion. However, the radiation must finally terminate when the pulsar is $\sim 10^7$ years old.

13.11 THE SUPERFLUIDITY AND SUPERCONDUCTIVITY OF HIGHLY COMPRESSED MATTER, AND THEIR INFLUENCE ON THE BEHAVIOR OF NEUTRON STARS

The interaction of neutrons in the highly compressed matter inside neutron stars is likely to lead to superfluidity. Experimental studies of atomic nuclei reveal that nuclear forces between like particles are attractive: two neutrons in vacuum cannot be bound; but nevertheless, when they are in the fields of other particles, for example in a nucleus, they are paired. The same effect probably occurs in a homogeneous, degenerate nuclear fluid.

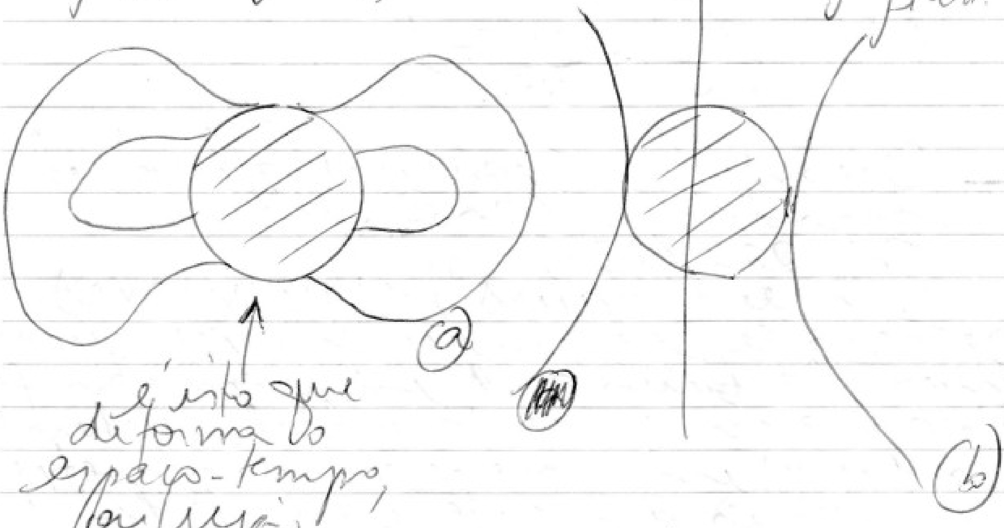
Pairs of neutrons are Bose particles and therefore their behavior must be analogous to that of ^{4}He atoms in liquid helium. But as Kapitsa found experimentally, liquid ^{4}He at temperatures below 2° K is a superfluid. In neutron matter, superfluidity may exist at temperatures below ~ 1 MeV $= 10^{10}$ ° K. The same reasoning leads to the prediction that the protons in nuclear matter (whose number is of the order of a few percent of all baryons) will be paired, and will give rise to the phenomenon of superconductivity. A discussion of these properties and of the order of magnitude of the critical

(% %

field lines hidden inside the star in order to sustain the necessary asymmetry against the force of gravity.[14]

Pág. 466(477) Fig. 72

Topology of the magnetic field of stars (a), and (b) a metagalactic field.



é isto que deforma o espaço-tempo, ou seja, o field é que gera a gravidade. A gravidade é decorrência das forças fundamentais da matéria.

Fundamental, melhor!!!

Pág. 463(480) ⇒ $M = 10^8 M_\odot$, the external regular field will have a strength $H_0 \approx H_i\, n^{-1/2} \approx 10^{-7}$ gauss.

(with $\nabla \times v = 0$; i.e., without vorticity) only on the microscopic scale. It is known that discrete, quantized vortex lines distributed in the liquid make the macroscopic behavior similar to that of a normal, viscous liquid. The same can be said of convection and convective heat transfer in the star. Still, there is a difference: the transfer of velocity from the superfluid neutron liquid to the proton component (which is tied to the magnetic field) is slow. Consequently, the relaxation of the stars fluid motions to an equilibrium, rigid-body rotation after a change in the rotation velocity can take a long time.

This discussion of hydrodynamic effects may sound pessimistic; but in the case of pulsars, even minute changes in period can be measured. There are very interesting hypotheses which explain the detailed variations in the periods of some pulsars by the superfluidity of the nuclear matter and the rigidity of the outer layers of the neutron star. Even if the effects are small, they are of great intrinsic interest, because they provide a means for studying the properties of matter under extreme conditions which are far outside the realm of possible laboratory physics.

Perhaps the details of the period variations (with jumps, etc., as observed in the Vela and Crab pulsars) will give, with the help of a complete theory, additional information on the mass, density, etc., of the pulsar.

13.12 Magnetic and Magnetohydrodynamic Phenomena in Collapsing Bodies

Ginzburg (1964) was the first to point out that the collapse of a star must be accompanied by a great increase of its magnetic field. Since then several contributions have concentrated on this problem (see below). In analyzing the collapse of stars and of very large gas masses, one must take account of the qualitatively different topologies of the external magnetic fields of these objects (Kardashev 1964). According to observational data and contemporary theories of stellar origin, the magnetic field of a normal star (e.g., the Sun) has a quasi-dipole nature. The topology of such a field is shown in Figure 72. Most of the magnetic field lines close not too far from the star. The topology of the external field of a galaxy or of a metagalactic object is different. According to contemporary ideas (Pikel'ner 1965), the field lines are not closed; they extend practically to infinity, thus connecting the body with the surrounding medium and with other objects.

Magnetic processes in collapse, including phenomena in the surrounding envelope, are rather complex; they have probably been investigated even less than the effects of rotation. Thus, we will limit ourselves to a very general analysis of such processes. Let us begin with the collapse of normal stars. It is known from observations that the surface magnetic fields of normal stars can be as large as $\sim 10^4$ gauss. (For comparison, the Sun's magnetic field is ~ 1 gauss.) In all cases, the magnetic energy is considerably smaller than the gravitational energy.

The conductivity of stellar matter is rather high; for stars similar to the Sun, $\sigma_{\odot} = 10^{16}\ \mathrm{sec}^{-1}$. Hence, the field attenuation time is (Pikel'ner 1961)

$$t_{\odot} \approx 4\pi\sigma_{\odot}R^{2}_{\odot}/c^{2} \approx 7 \times 10^{17}\ \mathrm{sec} \approx 2 \times 10^{10}\ \mathrm{years}\,,$$

which is considerably greater than the age of the Sun ($\sim 5 \times 10^{9}$ years). It is clear that the field attenuation time is considerably greater than the characteristic contraction time for any star (Ginzburg 1964). When a normal star is transformed to a neutron star, its conductivity increases enormously.

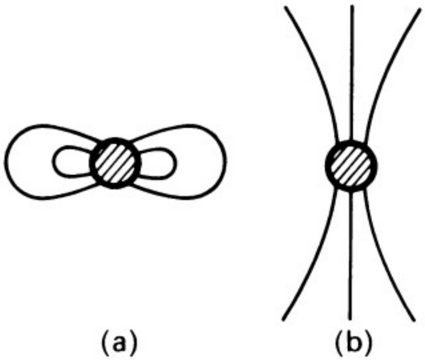


FIG. 72.—Topology of the magnetic field of (a) a star, and (b) a metagalactic object

Thus, we can always regard the field as "frozen into" the stellar matter. Under such conditions, $H \sim R^{-2}$ during contraction, and the magnetic energy increases as $E_{\mathrm{magnetic}} \sim H^{2}R^{3} \sim R^{-1}$; i.e., it increases by the same factor as the gravitational energy. In normal stars, as mentioned above, $E_{\mathrm{magnetic}} \ll E_{\mathrm{grav}}$; thus the magnetic field has no influence whatsoever upon the dynamics of the stellar collapse, for the star as a whole.

How will the magnetic field change during relativistic collapse, when a normal star is transformed to a frozen star? This question has been investigated by Ginzburg (1964) and by Ginzburg and Ozernoy (1964).

As we have emphasized, the field is "frozen" into the stellar matter; hence, in contraction to dimensions $\sim r_g$ it must reach the colossal magnitude of $\sim 10^{10}$–10^{14} gauss as seen by an observer comoving with the matter. To a stationary observer, however, the field will appear to behave very differently as $R \rightarrow r_g$. To find this behavior, Ginzburg and Ozernoy first considered the static problem.

Visualize a sequence of static, gravitating, magnetic spheres with successively smaller dimensions, and with fixed magnetic flux. Examine their external (dipole) magnetic fields. In the classical theory, the dipole moment d of each sphere is proportional to R: $d = d_0(R/R_0)$, where d_0 is the dipole moment for radius R_0; d approaches zero as $R \to 0$. Ginzburg (1964) has demonstrated that in the relativistic theory, in the limit as $R \to r_g$, the dipole moment varies according to the modified law

$$d = \frac{d_0 r_g}{R_0 \times 3 \ln [r_g/(R - r_g)]} .$$

Thus, $d \to 0$ when $R \to r_g$.

Turn now from a sequence of static stars to the variation with time of the magnetic moment of a collapsing star. At the surface, the magnetic field is computed exactly as in the stationary case, so the dipole field in the near zone decreases exactly as before. Knowing the dependence of the star's radius R on time (cf. § 11.6), Ginzburg and Ozernoy find finally that, as $t \to \infty$,

$$d = d_0 r_g^2/(3R_0 ct) .$$

[*Note added by K. S. Thorne:* Actually, this result is not correct because in the late stages of collapse, as R nears r_g, every radius r enters the wave zone within a time $\Delta t \sim r_g/c$ after the star's surface passes $R = r$. Thus, a correct analysis cannot avoid dealing with wave-zone phenomena. An analysis taking them into account (Price 1970, 1971*a*, *b*) reveals the same decay law for the magnetic field at late times,

$$(\text{field strength at fixed } r) \propto t^{-(2l+3)} \ln t = t^{-5} \ln t ,$$

as for nonspherical perturbations in the gravitational field (§ 5.4).]

What is the physical explanation for the attenuation of the magnetic field? The magnetic field is produced by circular electric currents in the star. Since all processes attenuate as seen by the external observer, the rotation speed of the charges, v, approaches 0; since $v \to 0$, the current attenuates, $I \to 0$. This attenuation of the current results in an attenuation of the external magnetic field of a collapsing star, as measured by an observer at fixed Schwarzschild radius r.

The change with time of the magnetic field during contraction produces an electrical eddy field. In the near (non-wave) zone, this eddy field may generate a curent-carrying layer in the plasma that surrounds the star, and/or may generate magnetohydrodynamic waves (Ginzburg and Ozernoy 1964). These processes have never been investigated, so we will limit ourselves to some comments about the distant (wave) zone (Novikov 1964*a*). Let r_g/c and r_g be the characteristic time and scale of the near-zone phenomena, respectively. Then the wave zone begins at a radius $l > r_g$. Let the external magnetic field of the star include a dipole term with a magnetic moment $d = \Phi R$, where $\Phi = \text{const}$. Estimate the total energy radiated by the external magnetic field during its attenuation. It is clear a priori that the energy radiated will be of the order of the total energy of the magnetic field at $R \sim r_g$, because when $R \sim r_g$, the contraction velocity is of the order c, and there exists no dimensionless parameter in which the radiated energy could be expanded. We will make a more precise calculation under the assumption that, in the process of collapse, the matter falls almost freely. Then

$$R_{,tt} = -GM/R^2\,, \quad R_{,t} = (2GM/R)^{1/2}\,. \tag{13.12.1}$$

The total power radiated is

$$I = (2/3c^3)(d_{,tt})^2\,. \tag{13.12.2}$$

Substituting equation (13.12.1) into equation (13.12.2), we get for the instantaneous power when the star is at radius R,

$$I = (\Phi^2 c/6r_g{}^2)(r_g/R)^4\,, \tag{13.12.3}$$

and, for the total energy radiated during the contraction to radius R,

$$E = (\Phi^2/15r_g)(r_g/R)^{2.5}\,. \tag{13.12.4}$$

If $\Phi \approx 3 \times 10^{21}$ (erg cm)$^{1/2}$, as it is for the Sun, and $r_g \approx 3 \times 10^5$ cm, then

$$I \approx 5 \times 10^{41}(r_g/R)^4 \text{ ergs sec}^{-1}\,, \tag{13.12.5}$$

$$E \approx 3 \times 10^{36}(r_g/R)^{2.5} \text{ ergs}\,. \tag{13.12.6}$$

Most of the radiation emerges in a single burst which lasts for a time $\sim r_g/c$.[15] This calculation was performed in the nonrelativistic theory; and the formulae used lose their validity near the Schwarzschild sphere. However, they should yield a correct estimate of the order of magnitude of the power and energy radiated. The total energy radiated in this case is not large. We will see below that the energy radiated is much greater when the contracted body is $\sim 10^5$–$10^8 M_\odot$ rather than $\sim 1\ M_\odot$ as assumed above.

Up to now we have tacitly assumed that the plasma which surrounds the star does not interfere with the outflow of the radiation. The radiation frequencies are low, $\omega \sim c/r_g$, especially for large masses. Even when the plasma has very low density, the natural frequency of plasma vibrations,

$$\omega_0 = (4\pi e^2 n_e/m_e)^{1/2} \approx 2 \times 10^4\, n_e{}^{1/2} \text{ sec}^{-1}\,,$$

is considerably larger than ω. This suggests that radiation might not occur at all. However, if the occurrence of radiation is to be prevented, then, in addition to the condition $\omega > \omega_0$, it is necessary that the maximum possible current which the plasma can support, $I_{\max} = n_e ec$ (where n_e is the electron number density and e is the electron charge), be capable of compensating for the variation of the magnetic field in the near zone. Let us calculate the critical value of the density of the surrounding plasma for which radiation no longer occurs (Novikov 1964*a*). From Maxwell's equations, we obtain

$$|\nabla \times H| = 4\pi\, I_{\max}/c = 4\pi n_e e\,. \tag{13.12.7}$$

---

[15] The decay of the pulse is caused by the relavitistic freezing of all processes when $R \to r_g$; see above.

We restrict ourselves to order-of-magnitude estimates. Consider the characteristic stage of contraction when $(R - r_g) \sim r_g$. Since $|\nabla \times H| \sim H/r_g$ and $H \sim \Phi/r_g$, we obtain from equation (13.12.7)

$$\Phi_{\rm crit} \approx 4\pi\, n_e e r_g^3 \, .$$

Thus, if the inequality

$$n_e < \Phi/(4\pi r_g^3) \, , \tag{13.12.8}$$

is satisfied, electromagnetic waves are generated in the wave zone (beginning at distances $L > r_g$), even when $c/r_g \ll \omega_0$. Substituting $\Phi \approx 3 \times 10^{21}$ and $(r_g)_\odot \approx 3 \times 10^5$ cm into equation (13.12.8), we find

$$n_e < \sim 10^{15}\ \mathrm{cm}^{-3} \, . \tag{13.12.9}$$

For comparison, the electron concentration in the solar corona near the surface of the Sun is $\sim 10^8$ cm^{-3}.

Thus, when condition (13.12.9) is satisfied, radiation is emitted by the star in the form of a single pulse, though it may be absorbed by the plasma in the wave zone far from the star. Let us recall again that the total energy radiated by normal stars is relatively small.

Let us now turn our attention from normal stars to the contraction of very massive gas clouds. The gravitational contraction of huge clouds with magnetic fields was presumably responsible for the formation of various types of galaxies and of radio galaxies. This has been particularly emphasized recently in contributions by Piddington (1964) and Pikel'ner (1965). This raises the question whether, under certain conditions, a contracting gas cloud with a magnetic field can become a supermassive star (quasar).

Here we deal with a different magnetic-field topology than in the case of a normal star (see Fig. 72). The lines of force link the contracting cloud to the surrounding medium. At the onset of contraction, the magnetic energy of the cloud is probably already of the order of its rotational energy, and the contraction is accompanied by a continual loss of angular momentum. Contraction causes "constrictions" in the lines of the magnetic field.[16] The processes which occur during this contraction and constriction are only poorly understood, so we will confine ourselves to very rough estimates. In interstellar clouds there exist magnetic fields with an intensity of $\sim 10^{-5}$ gauss. Consider an initial cloud with $M = 10^8\, M_\odot$. The external regular field will have a strength $H_0 \approx H_1 n^{-1/2} \approx 10^{-7}$ gauss. After equilibrium evolution and collapse down to r_g, the density of the cloud will have changed by approximately twenty-four orders of magnitude (from the initial density of $\sim 10^{-24}$ g cm^{-3} to a final density of ~ 1 g cm^{-3}), and the field will have grown by sixteen orders of magnitude to an intensity $H \approx 10^9$ gauss. The increase of the field energy is accompanied by a growth of the energy of the particles which are frozen onto the field.

Will the magnetic field emit radiation during its contraction? Criterion

---

[16] On this subject, see contributions by Mestel (1959).

(13.12.8), for the emission of radiation in the above case when the initial field at the surface of the cloud is $H_0 \approx 10^{-7}$ gauss, reads

$$n_e < 10^4(10^8 M_\odot/M)^{7/3}\ \mathrm{cm}^{-3}\,. \qquad (13.12.10)$$

Since it is likely that $H_0 \sim M^{1/2}$, the exponent on the expression in the parentheses might be 3 rather than $\frac{7}{3}$. Thus, the plasma density required to prevent the emission of radiation ranges from $\sim 10^4\ \mathrm{cm}^{-3}$ for $M \approx 10^8\ M_\odot$ to 10^{11}–$10^{13}\ \mathrm{cm}^{-3}$ for $M \approx 10^5\ M_\odot$.

If the plasma density satisfies criterion (13.12.8), then radiation is emitted. Let us estimate the total power and energy radiated for $M \approx 10^8\ M_\odot$, using formulae (13.12.5) and (13.12.6):

$$I = 10^{54}(r_g/R)^4\ \mathrm{ergs\ sec^{-1}}\,, \qquad E = 5 \times 10^{56}(r_g/R)^{2.5}\ \mathrm{ergs}\,.$$

If H_0 scales with mass as $H_0 \sim M^{-1/2}$, then I and E scale as $I \sim M^{-5/3}$, $E \sim M^{-2/3}$. If H_0 is independent of mass, then $I \sim M^{-2/3}$, $E \sim M^{1/3}$. Thus, the electromagnetic radiation from the external magnetic field is quite impressive for the collapse of superlarge masses, in contrast to the collapse of normal stars; possibly such radiation plays a significant role in the energy balance of quasars during their collapse stage.

13.13 THE STATISTICS OF STARS AT THE ENDPOINT OF STELLAR EVOLUTION

Do astronomical observations yield any indications about the final fates of massive stars, and about the conditions for the creation of neutron stars and frozen stars?

If the collapse of a star produces an explosion which destroys the entire star or almost the entire star, then the explosion, of course, must be visible from a tremendous distance. It is natural to identify such catastrophes with supernova outbursts, which are observed by astronomers. In such an outburst, an energy of the order of 10^{52} ergs or even more is released.

Unfortunately, it is entirely unclear at present just what portion of the mass of the star is emitted in a supernova outburst of Type I or Type II. For details see the review by the Burbidges (1958), and the monograph by Shklovsky (1966).

Assume that every star with a mass that is greater than $\sim 1.5\ M_\odot$ terminates its evolution by a supernova outburst; then the number of supernovae in a time interval Δt must equal the number of massive stars which terminate their evolution during that time interval. Let us estimate this number (Hoyle and Fowler 1963; Zwicky 1958; Schwarzschild 1958; Novikov and Ozernoy 1964; Hoyle, Fowler, Burbidge, and Burbidge 1964) and compare it with the observational data.

Assume that each massive star in the process of its evolution does not lose a substantial amount of mass, or at least that the mass losses are not so great

Topological Quantum Field Theory as Topological Quantum Gravity

Kishore Marathe

Abstract. We discuss a special case of the gauge theory to string theory correspondence in the Euclidean version of the theories, where exact results are available. We show how the Witten-Reshetikhin-Turaev invariant in $SU(n)$ Chern-Simons theory on S^3 is related via conifold transition to the all-genus generating function of the topological string amplitudes on a Calabi-Yau manifold. This result can be thought of as an interpretation of TQFT (Topological Quantum Field Theory) as TQG (Topological Quantum Gravity).

Mathematics Subject Classification (2000). Primary 81T45; Secondary 58D29.

Keywords. Chern-Simons theory, string amplitudes, conifold transition, Witten-Reshetikhin-Turaev invariants, knot invariants, topological field theory, topological quantum gravity.

1. Introduction

This talk[1] and in fact, our conference premise ignores the strong admonition by Galileo against[2] "disputar lungamente delle massime questioni senza conseguir verità nissuna". However, I do follow his most important advice: "To read the book of Universe which is wide open in front of our eyes, you must know the language in which it is written. This is the language of Geometry." I will discuss the geometric setting which has had great success in the study of fundamental particles and forces. I will also follow Gallileo's preference and discuss "a small truth" which shows a beautiful and quite unexpected relationship between topological quantum field theory and string theory amplitudes, both calculated in the Euclidean version of the theories. The result is thus primarily of interest in geometric topology. Quantum group computations initiated by Reshetikhin and Turaev and Kohno's special functions corresponding to representations of mapping class groups in the space of conformal blocks also lead to the same result.

---

[1] Given at the workshop on Mathematical and Physical Aspects of Quantum Gravity

[2] lengthy discussions about the greatest questions that fail to lead to any truth whatever.

Topological quantum field theory was ushered in by Witten in his 1989 paper [4] "QFT and the Jones' polynomial". WRT (Witten–Reshetikhin–Turaev) invariants arose as a byproduct of the quantization of Chern-Simons theory used to characterize the Jones' polynomial. At this time, it is the only known geometric characterization of the Jones' polynomial, although the Feynman integrals used by Witten do not yet have a mathematically acceptable definition. Space-time manifolds in such theories are compact Riemannian manifolds. They are referred to as Euclidean theories in the physics literature. Their role in physically interesting theories is not clear at this time and they should be regarded as toy models.

The unification of electric and magnetic fields by Maxwell is one of the most important chapters in mathematical physics. It is the only field theory which has had great predictive success in classical physics and an extension to the quantum domain. Predictions of Quantum Electrodynamics are in agreement with experimental observations to a very high degree of accuracy. Yang-Mills theory predicted massless particles and was unused for over two decades until the mechanism of symmetry breaking led to the electro-weak theory and the standard model. String theory and certain other supersymmetric theories seem to be the most promising candidates to lead to the so called grand unification of all four fundamental forces. Unifying different string theories into a single theory (such as M-theory) would seem to be the natural first step. Here even the physical foundations are not yet clear. From a mathematical point of view we would be lucky if in a few years we know what are the right questions to ask.

This year we are celebrating a number of special years. The Gauss' year and the 100th anniversary of Einstein's "Annus Mirabilis" (the miraculous year) are the most important among these. Indeed, Gauss' "Disquisitiones generale circa superficies curvas" was the basis and inspiration for Riemann's work which ushered in a new era in geometry. It is an extension of this geometry that is the cornerstone of relativity theory. More recently, we have witnessed the marriage between Gauge Theory and the Geometry of Fiber Bundles from the sometime warring tribes of Physics and Mathematics. Marriage brokers were none other than Chern and Simons. The 1975 paper by Wu and Yang [5] can be regarded as the announcement of this union. It has led to many wonderful offspring. The theories of Donaldson, Chern-Simons, Floer-Fukaya, Seiberg-Witten, and TQFT are just some of the more famous members of their extended family. Quantum Groups, CFT, Supersymmetry, String Theory, Gromov-Witten theory and Gravity also have close ties with this family. In this talk we will discuss one particular relationship between gauge theory and string theory, that has recently come to light. The qualitative aspects of Chern-Simons theory as string theory were investigated by Witten [17] almost ten years ago. Before recounting the main idea of this work we review the Feynman path integral method of quantization which is particularly suited for studying topological quantum field theories. For general background on gauge theory and geometric topology see, for example, [12, 13, 14].

In section 2 we introduce the Feynman path integral approach to QFT. The Euclidean version of this theory is applied in section 3 to the Chern-Simons Lagrangian to obtain the skein relations for the Jones-Witten polynomial of a link in S^3. A by product of this is the family of WRT invariants of 3-manifolds. They are discussed in section 4. Sections 5 to 7 are devoted to studying the relation between WRT invariants of S^3 with gauge group $SU(n)$ and the open and closed string amplitudes in generalized Calabi-Yau manifolds. This result is a special case of the general program introduced by Witten in [17]. A realization of this program even within the Euclidean field theory promises to be a rich and rewarding area of research. We have given some indication of this at the end of section 7. Various formulations of Einstein's equations for gravitational field are discussed in section 8. They also make a surprising appearance in Perelman's proof of Thurston's Geometrization conjecture. No physical application of Euclidean gravitational instantons is known at this time. So their appearance in supersymmetric string theory does not give the usual field equations of gravitation. However, topological amplitudes calculated in this theory can be thought of as Euclidean TQG. We give some further arguments in the concluding section 9 in support of supersymmetric string theory as a candidate for the unification of all four fundamental forces.

2. Quantum Observables

A **quantum field theory** may be considered as an assignment of the **quantum expectation** $< \Phi >_\mu$ to each gauge invariant function $\Phi : \mathcal{A}(M) \to \mathbb{C}$, where $\mathcal{A}(M)$ is the space of gauge potentials for a given gauge group G and the base manifold (space-time) M. Φ is called a **quantum observable** or simply an **observable** in quantum field theory. Note that the invariance of Φ under the group of gauge transformations $\mathcal{G}$ implies that Φ descends to a function on the moduli space $\mathcal{B} = \mathcal{A}/\mathcal{G}$ of gauge equivalence classes of gauge potentials. In the Feynman path integral approach to quantization the quantum or vacuum expectation $< \Phi >_\mu$ of an observable is given by the following expression.

$$< \Phi >_\mu = \frac{\int_{\mathcal{B}(M)} e^{-S_\mu(\omega)} \Phi(\omega) \mathcal{D}\mathcal{B}}{\int_{\mathcal{B}(M)} e^{-S_\mu(\omega)} \mathcal{D}\mathcal{B}}, \tag{1}$$

where $e^{-S_\mu}\mathcal{D}\mathcal{B}$ is a suitably defined measure on $\mathcal{B}(M)$. It is customary to express the quantum expectation $< \Phi >_\mu$ in terms of the **partition function** Z_μ defined by

$$Z_\mu(\Phi) := \int_{\mathcal{B}(M)} e^{-S_\mu(\omega)} \Phi(\omega) \mathcal{D}\mathcal{B}. \tag{2}$$

Thus we can write

$$< \Phi >_\mu = \frac{Z_\mu(\Phi)}{Z_\mu(1)}. \tag{3}$$

In the above equations we have written the quantum expectation as $< \Phi >_\mu$ to indicate explicitly that, in fact, we have a one-parameter family of quantum where $F_\Upsilon = \frac{\partial F}{\partial \Upsilon}$. Thus F_Υ, which depends on the higher derivative couplings $F^{(g)}$, $g \geq 1$, encodes the corrections to the area law.

If the prepotential is sufficiently simple, one can find explicit solutions of the attractor equations [15, 35, 47].[17] In particular, we can now compare $\mathcal{S}_{\text{macro}}$ to the $\mathcal{S}_{\text{micro}}$ computed from state counting (10) [15]:

$$\begin{aligned}
&\mathcal{S}_{\text{macro}}(q,p) \\
&= \frac{A}{4} + \text{Correction term} \\
&= 2\pi \frac{\frac{1}{6}|q_0|(C_{ABC}p^Ap^Bp^C + \frac{1}{2}c_{2A}p^A)}{\sqrt{\frac{1}{6}|q_0|(C_{ABC}p^Ap^Bp^C + c_{2A}p^A)}} + 2\pi \frac{\frac{1}{12}|q_0|c_{2A}p^A}{\frac{1}{6}|q_0|(C_{ABC}p^Ap^Bp^C + c_{2A}p^A)} \\
&= 2\pi \sqrt{\tfrac{1}{6}|q_0|(C_{ABC}p^Ap^Bp^C + c_{2A}p^A)} \\
&= \mathcal{S}_{\text{micro}} \ . \qquad (22)
\end{aligned}$$

In the second line we can see explicitly how the higher derivative terms modify the area. But, when sticking to the naive area law, one finds that $\frac{A}{4}$ differs from $\mathcal{S}_{\text{micro}}$ already in the first subleading term in an expansion in large charges. In contrast, when taking into account the modification of the area law, $\mathcal{S}_{\text{macro}}$ and $\mathcal{S}_{\text{micro}}$ agree completely. In other words 'string theory state counting knows about the modification of the area law.' This provides strong evidence that string theory captures the microscopic degrees of freedom of black holes, at least of supersymmetric ones.

At this point one might wonder about the role of other types of higher derivatives terms. So far, we have only included a very particular class, namely those which can be described using the Weyl multiplet. The full string effective action also contains other higher derivative terms, including terms which are higher powers in the curvature. Naively, one would expect that these also contribute to the black hole entropy. However, as we will see in the next sections, one can obtain an even more impressive agreement between microscopic and macroscopic entropy by just using the terms encoded in the Weyl multiplet. One reason might be the close relationship between the terms described by the Weyl multiplet and the topological string, which we are going to review in the next section. There are two other observation which indicate that the Weyl multiplet encodes all contributions relevant for the entropy.[18] The first observation is that when one just adds a Gauss-Bonnet term to the Einstein Hilbert action, one obtains the same entropy formula (10) as when using the full Weyl multiplet [38, 37]. The second is that (10) can also be derived using gravitational anomalies [41, 40]. Both suggest that the black hole entropy is a robust object, in the sense that it does not seem to depend sensitively on details of the Lagrangian.

---

[17] One can also construct the solution away from the horizon, at least iteratively [13, 64].

[18] For toroidal compactifications of type-II string theory there are no R^2-corrections, but the entropy of string states is non-vanishing. This case seems to require the presence of higher derivative terms which are not captured by the Weyl multiplet. See [4] for further discussion.

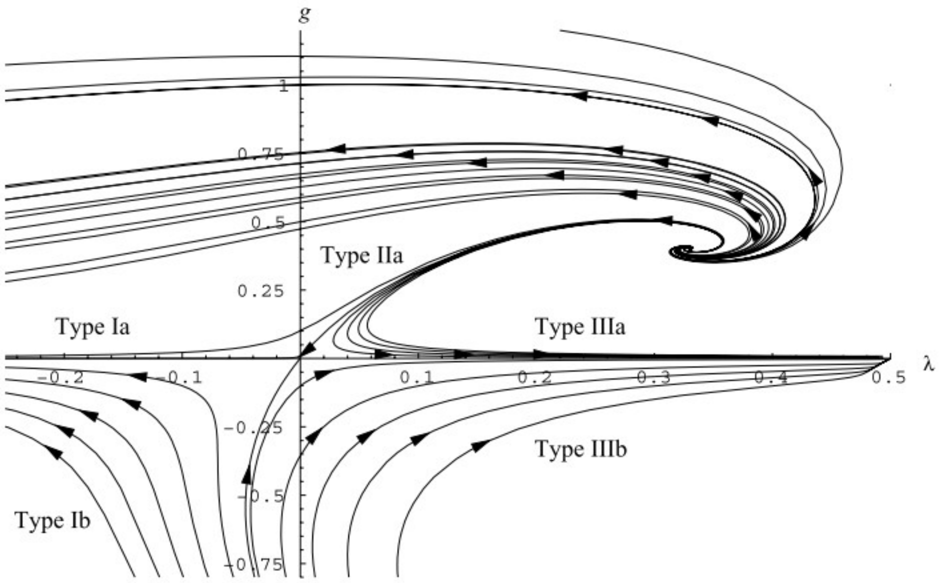

Figure 1. Part of theory space of the Einstein-Hilbert truncation with its RG flow. The arrows point in the direction of decreasing values of k. The flow is dominated by a non-Gaussian fixed point in the first quadrant and a trivial one at the origin. (From [9].)

exact RG equations no practical tool was known which would have allowed a nonperturbative calculation of the $\boldsymbol{\beta}$-functions in the physically interesting case of $d = 4$ spacetime dimensions. However, as we saw above, the effective average action in the Einstein-Hilbert approximation does indeed predict the existence of a NGFP in a nonperturbative setting. It was first analyzed in [13, 8, 9], and also first investigations of its possible role in black hole physics [25] and cosmology [26, 27] were performed already.

The detailed analyses of refs. [8, 9] demonstrated that the NGFP found has all the properties necessary for asymptotic safety. In particular one has a pair of complex conjugate critical exponents $\theta' \pm \mathrm{i}\,\theta''$ with $\theta' > 0$, implying that the NGFP, for $k \to \infty$, attracts all trajectories in the half-plane $g > 0$. (The lower half-plane $g < 0$ is unphysical probably since it corresponds to a negative Newton constant.) Because of the nonvanishing imaginary part $\theta'' \neq 0$, all trajectories spiral around the NGFP before hitting it.

The question of crucial importance is whether the fixed point predicted by the Einstein-Hilbert truncation actually approximates a fixed point in the exact theory, or whether it is an artifact of the truncation. In refs. [8, 10, 9] evidence was found which, in our opinion, strongly supports the hypothesis that there does indeed exist a non-Gaussian fixed point in the exact 4-dimensional theory, with exactly

Coulomb force between two charges is

5. $\frac{1}{4\pi} \frac{q_1 q_2}{r_{12}^2}$ (8.14) ↙

In the Gaussian system we should replace 1/(4κ) by 1/(16πκ) and the factor of 4π disappears from the Coulomb's force.

Pág. 243(264) Euler characteristic of the Euclidean ERN solution using the Gauss-Bonnet theorem adapted to manifolds with boundaries. The

B$
-256- - -* ! - B$ 7 !A 3 ! " H ' 1"
(' '$ 7! * !" .

Since

$$\left({}^\star d\,{}^\star\omega\right)_{\rho_1\cdots\rho_{k-1}} = (-1)^{k(d-k+1)-1}\,\text{sign}\, g\,\nabla_\mu \omega^\mu_{\rho_1\cdots\rho_{k-1}}, \tag{1.133}$$

we find that the relation between δ and the divergence is

$$(\delta\omega)_{\rho_1\cdots\rho_{k-1}} = (-1)^d \nabla_\mu \omega^\mu{}_{\rho_1\cdots\rho_{k-1}}. \tag{1.134}$$

Only k-forms can be integrated on k-dimensional manifolds. If ω is a $(d-1)$-form defined on a d-dimensional manifold M with boundary $\partial\mathrm{M}$, then *Stokes' theorem* states that

$$\int_{\mathrm{M}} d\omega = \int_{\partial\mathrm{M}} \omega. \tag{1.135}$$

It is convenient to define *volume forms* for a manifold and its lower-dimensional submanifolds. Their contraction with other tensors results in differential forms that can be integrated. Thus, we define in a d-dimensional manifold, for $(d-n)$-dimensional submanifolds M^{d-n}, $0 \leq n \leq d$, the volume forms

$$d^{d-n}\Sigma_{\mu_1\cdots\mu_n} \equiv dx^{\nu_1}\cdots dx^{\nu_{d-n}}\frac{1}{(d-n)!\sqrt{|g|}}\epsilon_{\nu_1\cdots\nu_{d-n}\mu_1\cdots\mu_n}. \tag{1.136}$$

Observe that the standard invariant-volume form for the total manifold M^d is just $d^d\Sigma$ up to a sign (we now use the signature $(+-\cdots-)$):

$$d^d\Sigma = (-1)^{d-1}dx^1 \wedge \cdots \wedge\ dx^d\sqrt{|g|} \equiv (-1)^{d-1}d^dx\sqrt{|g|}. \tag{1.137}$$

Now, if we have a rank-n completely antisymmetric contravariant tensor $T^{\mu_1\cdots\mu_n}$ and contract it with the volume element $d^{d-n}\Sigma_{\mu_1\cdots\mu_n}$, we have constructed a $(d-n)$-form that can be integrated over a $(d-n)$-dimensional submanifold. Up to numerical factors, that form is the Hodge dual of the n-form that one gets by lowering the indices of $T_{\mu_1\cdots\mu_n}$:

$$\frac{1}{n!}d^{d-n}\Sigma_{\mu_1\cdots\mu_n}T^{\mu_1\cdots\mu_n} = {}^\star T. \tag{1.138}$$

We can also take the divergence of the tensor and contract it with the volume element $d^{d-n-1}\Sigma_{\mu_1\cdots\mu_{n-1}}$. The result is

$$\frac{(-1)^{d-n}}{(n-1)!}d^{d-n+1}\Sigma_{\mu_1\cdots\mu_{n-1}}\nabla_\rho T^{\rho\mu_1\cdots\mu_{n-1}} = d\,{}^\star T. \tag{1.139}$$

Stokes' theorem for the exterior derivative of form ${}^\star T$ integrated over a $(d-n+1)$-dimensional submanifold M^{d-n+1} with $(d-n)$-dimensional boundary $\partial\mathrm{M}^{d-n+1}$ is now

$$\int_{\mathrm{M}^{d-n+1}} d^{d-n+1}\Sigma_{\mu_1\cdots\mu_{n-1}}\nabla_\rho T^{\rho\mu_1\cdots\mu_{n-1}} = \frac{(-1)^{d-n}}{n}\int_{\partial\mathrm{M}^{d-n+1}} d^{d-n}\Sigma_{\mu_1\cdots\mu_n}T^{\mu_1\cdots\mu_n}. \tag{1.140}$$

The $n=1$ case is the *Gauss–Ostrogradski theorem*,

$$\int_{\mathrm{M}^d} d^dx\sqrt{|g|}\,\nabla_\mu v^\mu = (-1)^{d-1}\int_{\partial\mathrm{M}} d^{d-1}\Sigma_\mu v^\mu. \tag{1.141}$$

The Vielbein and spin-connection 1-forms and the torsion 2-form are

$$e^a = e_\mu{}^a dx^\mu, \qquad \omega^{ab} = \omega_\mu{}^{ab} dx^\mu, \qquad T^a = \tfrac{1}{2} T_{\mu\nu}{}^a dx^\mu \wedge dx^\nu, \tag{1.142}$$

These 1-forms are related by the *structure equation*

$$de^a + \omega_b{}^a \wedge e^b + T^a = 0, \tag{1.143}$$

which (in the absence of torsion) gives a convenient way of finding ω. The curvature 2-form and the Ricci-tensor 1-form are given by

$$\begin{aligned} R^{ab} &= \tfrac{1}{2} R^{ab}{}_{\mu\nu} dx^\mu \wedge dx^\nu = d\omega^{ab} + \omega_c{}^a \wedge \omega^{cb}, \\ R^a &= R_\mu{}^a dx^\mu = R_{\mu\lambda}{}^{ab} e^\lambda{}_b dx^\mu. \end{aligned} \tag{1.144}$$

1.8 Extrinsic geometry

Let us consider a hypersurface Σ embedded in a d-dimensional spacetime with metric $g_{\mu\nu}$ and with normal unit vector n^μ:

$$n^\mu n_\mu = \varepsilon, \qquad \begin{cases} \varepsilon = +1, & \Sigma \text{ spacelike}, \\ \varepsilon = -1, & \Sigma \text{ timelike}. \end{cases} \tag{1.145}$$

The metric induced on Σ by $g_{\mu\nu}$ is defined by

$$h_{\mu\nu} = g_{\mu\nu} - \varepsilon n_\mu n_\nu. \tag{1.146}$$

$h_{\mu\nu}$ has $(d-1)$-dimensional character but it is written in d-dimensional form and it is evidently singular and cannot be inverted. Its indices are raised and lowered with g. Observe that $h_{\mu\nu} n^\nu = 0$ and thus h can be used to project tensors onto the hypersurface Σ.

A way to measure how Σ is curved inside the spacetime would be to measure the variation of the normal unit vector along it. Mathematically this would be expressed by

$$\mathcal{K}_{\mu\nu} \equiv h_\mu{}^\alpha h_\nu{}^\beta \nabla_{(\alpha} n_{\beta)}, \tag{1.147}$$

where $\mathcal{K}_{\mu\nu}$ is the *extrinsic curvature* or *second fundamental form*.

We can consider a field of unit vectors n^μ defined in the whole spacetime determining a family of hypersurfaces. Then we can calculate the Lie derivative of the induced metrics in the direction of the normal unit vectors. We find that this is twice the extrinsic curvature,

$$\mathcal{K}_{\mu\nu} = \tfrac{1}{2} \mathcal{L}_n h_{\mu\nu}. \tag{1.148}$$

The trace of the extrinsic curvature is denoted by $\mathcal{K}$, and given by

$$\mathcal{K} = h^{\mu\nu} \mathcal{K}_{\mu\nu} = h^{\mu\nu} \nabla_\mu n_\nu. \tag{1.149}$$

From this point of view, if BHs can be understood as particle-like objects, looking for BHs with a well-defined scalar charge is utterly hopeless. One should look instead for "black strings" and instantons and in due time we will do so and find them.[4]

There is another point of view concerning scalar fields: in some cases they should be interpreted not as matter fields but as "local coupling constants" (as in the case of the string-theory dilaton) or, more generally, as *moduli fields*, which we will define in Chapter 11, in which case they should be treated as backgrounds and there would be no room for the notion of scalar charge.

In conclusion, if we want to find new BH solutions, we need to couple the Einstein–Hilbert action to matter fields that have associated conserved charges. The charges must be those of point-particles or we will naturally obtain solutions describing extended objects instead of black holes. Thus, we have to consider vector fields and the simplest one is an Abelian vector field A_μ. We are going to study in some detail the resulting system because later we will find generalizations of all the concepts and formulae developed here.

8.2 The Einstein–Maxwell system

The action for gravity coupled to an Abelian vector field A_μ is the so-called Einstein–Maxwell action[5] obtained by adding the Einstein–Hilbert and the Maxwell action with $\eta_{\mu\nu}$, ∂_μ, and d^4x replaced by $g_{\mu\nu}$, ∇_μ, and d^4x:

$$\boxed{S_{\rm EM}[g_{\mu\nu}, A_\mu] = S_{\rm EH}[g] + \frac{1}{c}\int d^4x\sqrt{|g|}\,\left[-\tfrac{1}{4}F^2\right].} \tag{8.15}$$

$F_{\mu\nu}$ is the field strength of the electromagnetic vector field A_μ and is again given by

$$F_{\mu\nu} = 2\partial_{[\mu}A_{\nu]}, \qquad F^2 = F_{\mu\nu}F^{\mu\nu}, \tag{8.16}$$

since, in the absence of torsion, $\nabla_{[\mu}A_{\nu]} = \partial_{[\mu}A_{\nu]}$. The components of A_μ and $F_{\mu\nu}$ in a given coordinate system are customarily split in this way,

$$(A_\mu) = (\phi, -\vec{A}), \qquad (F_{\mu\nu}) = \begin{pmatrix} 0 & E_1 & E_2 & E_3 \\ -E_1 & 0 & -B_3 & B_2 \\ -E_2 & B_3 & 0 & -B_1 \\ -E_3 & -B_2 & B_1 & 0 \end{pmatrix}, \tag{8.17}$$

---

[4] This argument really applies to pseudoscalar fields.

[5] In this section we work in the Heaviside system of units, so the Coulomb force between two charges is

$$\frac{1}{4\pi}\frac{q_1 q_2}{r_{12}^2}. \tag{8.14}$$

In the Gaussian system we should replace $1/(4c)$ by $1/(16\pi c)$ and the factor of 4π disappears from the Coulomb force. The dimensions of the vector field A_μ are $M^{1/2}L^{1/2}T^{-1}$ (that is, L^{-1} in natural units $\hbar = c = 1$) and the electric charge's units are $M^{1/2}L^{3/2}T^{-1}$, so it is dimensionless in natural units. At the end we will introduce another system of units, which will be the one we more often will work with, taking $c = 1$ and replacing the factor of $1/(4c)$ in front of F^2 by $1/\left(64G_{\rm N}^{(4)}\right)$.

where $\vec{E} = (E_1, E_2, E_3)$ and $\vec{B} = (B_1, B_2, B_3)$ are the electric and magnetic 3-vector fields in that coordinate system, and, thus, with $\vec{\nabla} = (\partial_{\underline{1}}, \partial_{\underline{2}}, \partial_{\underline{3}})$

$$\begin{cases} E_i = F_{\underline{0i}}, \\ B_i = -\frac{1}{2}\epsilon_{ijk} F_{\underline{kl}}, \end{cases} \qquad \Leftrightarrow \qquad \begin{cases} \vec{E} = -\vec{\nabla}\phi - \dfrac{1}{c}\dfrac{\partial}{\partial t}\vec{A}, \\ \vec{B} = \vec{\nabla} \times \vec{A}. \end{cases} \tag{8.18}$$

The field strength (and the action) is invariant under the Abelian gauge transformations

$$A'_\mu = A_\mu + \partial_\mu \Lambda \tag{8.19}$$

with smooth, gauge parameter Λ. Depending on which gauge group we consider ($\mathbb{R}$ or U(1)), Λ must be a single-valued or multivalued function.[6] In differential-forms language

$$A = A_\mu dx^\mu, \qquad A' = A + d\Lambda, \qquad F = \tfrac{1}{2} F_{\mu\nu} dx^\mu \wedge dx^\nu = dA, \tag{8.20}$$

and the gauge invariance of F is a consequence of $d^2 = 0$. Using these differential forms, the Maxwell action can be rewritten as follows:

$$S_{\mathrm{M}}[A] = \frac{1}{8c} \int F \wedge {}^\star F. \tag{8.21}$$

Observe that there is no matter charged with respect to A_μ in this system. This is analogous to the presence of no matter fields in the Einstein–Hilbert action. However, the Einstein–Hilbert action contains the self-coupling of gravity and therefore the presence of a coupling constant in it makes sense, whereas in the Maxwell theory there are no *direct* interactions between photons and, in principle, there is neither an electromagnetic coupling constant nor a unit of electric charge. We will see that things are a bit more complicated in the presence of gravity, through which photons do interact.

The equations of motion of $g_{\mu\nu}$ and A_μ are

$$G_{\mu\nu} - \frac{8\pi G_{\mathrm{N}}^{(4)}}{c^4} T_{\mu\nu} = 0, \tag{8.22}$$

$$\nabla_\mu F^{\mu\nu} = 0 \quad \text{(Maxwell's equation)}, \tag{8.23}$$

where

$$T_{\mu\nu} = \frac{-2c}{\sqrt{|g|}} \frac{\delta S_{\mathrm{M}}[A]}{\delta g^{\mu\nu}} = F_{\mu\rho} F_\nu{}^\rho - \tfrac{1}{4} g_{\mu\nu} F^2 \tag{8.24}$$

is the energy–momentum tensor of the vector field, which is traceless[7] in $d = 4$. The tracelessness of the electromagnetic energy–momentum tensor implies that $R = 0$ and the

---

[6] If the gauge group is $\mathbb{R}$, the elements of the group will be $e^{\Lambda/L}$, whereas, if it is U(1), they will be $e^{i\Lambda/L}$, where L is a constant introduced to make the exponent dimensionless because Λ is dimensionful. In the second case Λ will have to be identified with $\Lambda + 2\pi L$. When there is a unit of charge, L is related to it.

[7] This property is associated with the invariance of the Maxwell Lagrangian in curved spacetime under Weyl rescalings of the metric,

$$g'_{\mu\nu} = \Omega^2(x) g_{\mu\nu}. \tag{8.25}$$

In fact, if $\Omega = e^\sigma$, then for infinitesimal transformations $\delta_\sigma g_{\mu\nu} = 2\sigma(x) g_{\mu\nu}$ we have

$$\delta_\sigma S_{\mathrm{M}} = \frac{\delta S_{\mathrm{M}}}{\delta g_{\mu\nu}} \delta_\sigma g_{\mu\nu} \sim \sigma T^{\mu\nu} g_{\mu\nu} = 0. \tag{8.26}$$

Einstein equation takes the simpler form

$$R_{\mu\nu} = \frac{8\pi G_{\rm N}^{(4)}}{c^4} T_{\mu\nu}. \tag{8.27}$$

On taking the divergence of the Einstein equation and using the contracted Bianchi identity for the Einstein tensor $\nabla_\mu G^{\mu\nu} = 0$, we find

$$F_{\nu\rho}\nabla_\mu F^{\mu\rho} - \tfrac{3}{2} F^{\mu\rho}\nabla_{[\mu}F_{\rho\nu]} = 0. \tag{8.28}$$

Since the Levi-Cività connection is symmetric,

$$\nabla_{[\mu}F_{\rho\nu]} = \partial_{[\mu}F_{\rho\nu]} = 0 \qquad \text{(the Bianchi identity)} \tag{8.29}$$

identically, using the definition of $F_{\mu\nu}$, and then we see that the Einstein equation implies generically the Maxwell equation. Using Eq. (1.62), the Maxwell equation can also be written in a simpler, equivalent, form:

$$\partial_\mu\left(\sqrt{|g|}F^{\mu\nu}\right) = 0. \tag{8.30}$$

The equations are written in terms of the field strength F and usually they are solved in terms of it. However, we are ultimately interested in the vector field A itself and we have to make sure that the F we obtain is such that it is related to some vector field by Eq. (8.16) or Eq. (8.20). It turns out that, locally, A exists if the electromagnetic Bianchi identity Eq. (8.29) is satisfied.[8]

The Bianchi identity can also be written in this form (by contracting Eq. (8.29) with $\epsilon^{\mu\nu\rho\sigma}$, introducing it into the partial derivative (because it is constant), and using the

---

[8] In fact, if we are given F and the Bianchi identity is satisfied, we can always find the corresponding vector potential by using, e.g., the formula

$$\boxed{A_\mu(x) = -\int_0^1 d\lambda\lambda x^\nu F_{\mu\nu}(\lambda x).} \tag{8.31}$$

To check this formula it is necessary to use the Bianchi identity: taking the curl of the l.h.s.,

$$\partial_{[\rho}A_{\mu]}(x) = -\int_0^1 d\lambda\lambda\partial_{[\rho}[x^\nu F_{\mu]\nu}(\lambda x)], \tag{8.32}$$

and operating,

$$\partial_{[\rho}\big(F_{\mu]\nu}(\lambda x)\big) = \lambda\partial_{[\rho}F_{\mu]\nu}(\lambda x) - \tfrac{1}{2}\lambda\big(\partial_\nu F_{\rho\mu}\big)(\lambda x), \tag{8.33}$$

where the Bianchi identity Eq. (8.29) has been used in the last identity, one obtains

$$\begin{aligned}\partial_{[\rho}A_{\mu]}(x) &= \tfrac{1}{2}\int_0^1 d\lambda\left\{\lambda^2 x^\nu\partial_\nu F_{\rho\mu}(\lambda x) - \lambda F_{\mu\rho}(\lambda x)\right\} = \tfrac{1}{2}\int_0^1 d\lambda\frac{d}{d\lambda}\left[\lambda^2 F_{\rho\mu}(\lambda x)\right]\\ &= \frac{1}{2}F_{\rho\mu}(x).\end{aligned} \tag{8.34}$$

*D)! " 3

definition of the Hodge dual and Eq. (8.30) for the divergence):

$$\nabla_\mu {}^\star F^{\mu\sigma} = 0. \tag{8.35}$$

In the language of differential forms, the Maxwell equation and Bianchi identity are

$$d^\star F = 0, \tag{8.36}$$

$$dF = 0, \tag{8.37}$$

and the Bianchi identity is just a consequence of the definition Eq. (8.20) and $d^2 = 0$.

Then, if we work with the field strength, we find that there are two pairs of equations, (8.23) and (8.35) and (8.36) and (8.23), which are (as pairs) invariant if one replaces F by ${}^\star F$ (by virtue of ${}^{\star\star}F = -F$). This is an *electric–magnetic-duality* transformation. The name is due to the fact that this transformation interchanges the electric and magnetic fields in any given coordinate system according to

$$\vec{E}\,' = \vec{B}, \qquad \vec{B}\,' = -\vec{E}. \tag{8.38}$$

Actually, this pair of homogeneous equations (the Maxwell equation and the Bianchi identity) would be invariant under the (invertible) substitution for F of any linear combination of F and ${}^\star F$. We would have a symmetry of all the equations of motion if the Einstein equation were also invariant under this replacement. We will later see in Section 8.7 that this is the case and that the Einstein–Maxwell theory is invariant under electric–magnetic duality.

The four Maxwell equations in Minkowski spacetime can be deduced from the Maxwell equation and the Bianchi identity (two of them imply the existence of the potential A_μ and are equivalent to the latter). We have

$$\begin{aligned} \partial_\mu F^{\mu\nu} = 0 \quad &\Leftrightarrow \quad \begin{cases} \vec{\nabla}\cdot\vec{E} = 0, \\ \vec{\nabla}\times\vec{B} - \dfrac{1}{c}\dfrac{\partial}{\partial t}\vec{E} = 0, \end{cases} \\ \partial_\mu {}^\star F^{\mu\nu} = 0 \quad &\Leftrightarrow \quad \begin{cases} \vec{\nabla}\cdot\vec{B} = 0, \\ \vec{\nabla}\times\vec{E} + \dfrac{1}{c}\dfrac{\partial}{\partial t}\vec{B} = 0. \end{cases} \end{aligned} \tag{8.39}$$

8.2.1 Electric charge

The electric charge can be defined in terms of a source coupled to the electromagnetic field (this is analogous to the energy–momentum-pseudotensor approach for the gravitational field) or in terms of the Noether current associated with the gauge invariance (the approach that leads to Komar's formula and its generalizations for the gravitational field). The two definitions are equivalent and are very closely related to each other because the gauge invariance of the free theory imposes strong constraints on the possible couplings.

(% B

Euler characteristic χ is a topological invariant whose (de quem) value is an integer and the Gauss-Bonnet theorem states that the integral of the 4-form (naquele)

-256- - -* ! - B$ 7 !A 3 ! " H
' 1"
(%$$ % B " ! 7! ! " !

The next values of interest from the string-theory-supergravity point of view are $a = 1$;

$$\boxed{\begin{aligned} ds^2 &= H^{-1} W dt^2 - H\left[W^{-1} dr^2 + r^2 d\Omega^2_{(2)}\right], \\ e^{-2\varphi} &= e^{-2\varphi_0} H, \qquad \omega = h\left[1 - (\alpha/\sqrt{2})^2\right], \end{aligned}} \tag{12.23}$$

and $a = 1/\sqrt{3}$;

$$\boxed{\begin{aligned} ds^2 &= H^{-\frac{3}{2}} W dt^2 - H^{\frac{3}{2}}\left[W^{-1} dr^2 + r^2 d\Omega^2_{(2)}\right], \\ e^{-2\varphi} &= e^{-2\varphi_0} H^{\frac{\sqrt{3}}{2}}, \qquad \omega = h\left[1 - \alpha^2/3\right]. \end{aligned}} \tag{12.24}$$

$d = 4$ stringy solutions with these metrics will appear in the compactification of solutions that describe the intersection of two and three extended objects, respectively, instead of just one as in the previous case. We are going to see how this comes about in Section 20.1.

Finally, we have $a = 0$, the RN BH:

$$\boxed{\begin{aligned} ds^2 &= H^{-2} W dt^2 - H^{2}\left[W^{-1} dr^2 + r^2 d\Omega^2_{(2)}\right], \\ e^{-2\varphi} &= e^{-2\varphi_0}, \qquad \omega = h\left[1 - (\alpha/2)^2\right]. \end{aligned}} \tag{12.25}$$

This case will be seen to arise from the intersection of four extended objects in higher dimensions.

In four dimensions, we can define the mass M, electric charge q, and "scalar charge" Σ more precisely by the asymptotic expansions

$$g_{tt} \sim 1 - \frac{2G_{\rm N}^{(4)} M}{r}, \qquad A_t \sim \frac{4G_{\rm N}^{(4)} e^{2a\varphi_0} q}{r}, \qquad \varphi \sim \varphi_0 + \frac{G_{\rm N}^{(4)} \Sigma}{r}. \tag{12.26}$$

The dilaton-dependent factor $e^{2a\varphi_0}$ in the definition of the electric charge is related to the integral definition

$$q = \frac{1}{16\pi G_{\rm N}^{(4)}} \int_{S^2_\infty} e^{-2a\varphi \star} F, \tag{12.27}$$

which is in turn related to the modification of the Gauss law introduced by the dilaton.

For $a \neq 1$ the integration constants in the solutions are given by

$$\begin{aligned} h &= \frac{1+a^2}{1-a^2} G_{\rm N}^{(4)} \left(M \pm \sqrt{M^2 - 4(1-a^2) e^{2a\varphi_0} q^2}\right), \\ \alpha &= \frac{1-a^2}{1+a^2} \frac{4e^{a\varphi_0} q}{M \pm \sqrt{M^2 - 4(1-a^2) e^{2a\varphi_0} q^2}}, \\ \omega &= \frac{2a^2}{1-a^2} G_{\rm N}^{(4)} M \pm \frac{2}{1-a^2} G_{\rm N}^{(4)} \sqrt{M^2 - 4(1-a^2) e^{2a\varphi_0} q^2}, \end{aligned} \tag{12.28}$$

and Σ is related to the conserved charges by

$$\Sigma = \frac{4a^2 e^{2a\varphi_0} q^2}{M \pm \sqrt{M^2 - 4(1-a^2) e^{2a\varphi_0} q^2}}. \tag{12.29}$$

For $a = 1$

$$h = \frac{4G_N^{(4)} e^{2\varphi_0} q^2}{M}, \qquad \alpha = -\frac{M}{e^{\varphi_0} q}, \qquad \omega = -2G_N^{(4)} \frac{M^2 - 2e^{2\varphi_0} q^2}{M}, \tag{12.30}$$

and Σ is related to the conserved charges by

$$\Sigma = -\frac{2G_N^{(4)} e^{2\varphi_0} q^2}{M}. \tag{12.31}$$

The extremality condition always takes the form

$$\left(\frac{\omega}{2G_N^{(4)}}\right)^2 = M^2 + \frac{1}{a^2}\Sigma^2 - 4e^{2\varphi_0} q^2 = 0. \tag{12.32}$$

Thermodynamics of four-dimensional dilaton BHs. The coupling to scalar fields requires a modification of the first law of BH thermodynamics, which has to include a new term [259, 260, 446] in order to take into account possible variations of the energy due to variations of the scalar fields. This term is proportional to the "scalar charges" and to the variations of the values of the scalar fields at infinity (*moduli*) that characterize the vacuum of the theory,

$$\Sigma_a d\varphi^a. \tag{12.33}$$

Apart from this new term, the temperature and the entropy of dilaton BHs are related to the area and surface gravity of the event horizon by the standard formulae. When $\omega \leq 0$ (as we will assume) the event horizon is placed at $r = -\omega$. Its area is given by

$$A = 4\pi H^{\frac{2}{1+a^2}} r^2 \Big|_{r=-\omega}, \tag{12.34}$$

and so the entropy is given by

$$S = \pi (h + |\omega|)^{\frac{2}{1+a^2}} |\omega|^{\frac{2a^2}{1+a^2}}. \tag{12.35}$$

The temperature is given by

$$T = \frac{1}{4\pi} (h + |\omega|)^{-\frac{2}{1+a^2}} |\omega|^{\frac{1-a^2}{1+a^2}}. \tag{12.36}$$

These expressions can be compared with those in [539], where the thermodynamics of four-dimensional dilaton BHs was studied, with $|\omega| = r_+ - r_-$ and $h + |\omega| = r_+$.

The behavior of T and S in the extreme limit depends on the value of the parameter a:

$$\lim_{\omega \to 0} \begin{cases} T \to 0, & S \to \pi h^{\frac{2}{1+a^2}}, \quad 0 \leq a < 1, \\ T \to h, & S \to 0, \quad a = 1, \\ T \to \infty, & S \to 0, \quad a > 1, \end{cases} \tag{12.37}$$

Below $a = 1$ the behavior is similar to that of the RN BH, which also means that near the extreme limit the specific heat is positive. Above $a = 1$ the behavior is similar to that of the Schwarzschild BH in the zero-mass limit and the specific heat is negative.

Electric–magnetic duality in the four-dimensional a-model. In four dimensions the a-model has electric–magnetic duality: the equations of motion are invariant under the discrete transformation

$$F' = \tilde{F} \equiv e^{-2a\varphi}\,{}^{\star}F, \qquad \varphi' = \tilde{\varphi} \equiv -\varphi. \tag{12.38}$$

Tilded fields are, by definition, the S-dual fields. This symmetry allows us to transform the above electrically charged solutions into magnetic solutions that have the same (Einstein-frame) metric. All the properties that depend on the Einstein metric (for instance, thermodynamical properties) are not affected by this transformation. However, in some cases we are interested in properties that depend on the metric given in a different frame (such as the string frame, that we will study, or the KK frame that we studied in Chapter 11) that is related to Einstein's by a conformal rescaling by a function of the dilaton. Since the dilaton changes in this electric–magnetic transformation, so does the (KK or stringy) metric. A good example is provided by the electric–magnetic-duality rotation of the electrically charged KK BH studied on page 328.

For special values of the parameter a there are also dyonic dilaton BH solutions, carrying both electric and magnetic charges.[4] This trivially happens for $a = 0$, the Einstein–Maxwell plus uncoupled scalar case, because in this case (as we have already seen) the electric–magnetic-duality symmetry is a continuous symmetry and one can continuously rotate the purely electric solution into the purely magnetic one. In the case $a = 1$ there is no obvious reason for this to happen. However, the $a = 1$ model is a truncation of the $N = 4, d = 4$ SUEGRA action that we are going to see next, which does have a continuous electric–magnetic-duality symmetry.

The dyonic solutions take the form[5] [432, 447, 612]

$$\boxed{\begin{aligned}
ds^2 &= (H_1 H_2)^{-1} W dt^2 - H_1 H_2 \big[W^{-1} dr^2 + r^2 d\Omega^2_{(2)}\big],\\
A_t &= \frac{-4G_{\rm N}^{(4)} e^{\varphi_0} q}{r_- - G_{\rm N}^{(4)}\Sigma}(H_1^{-1} - 1), \qquad \tilde{A}_t = \frac{1}{4\pi}\frac{e^{-\varphi_0} p}{r_- + G_{\rm N}^{(4)}\Sigma}(H_2^{-1} - 1),\\
e^{-2\varphi} &= e^{-2\varphi_0} H_1/H_2,\\
H_1 &= 1 + \frac{r_- - G_{\rm N}^{(4)}\Sigma}{r}, \qquad H_2 = 1 + \frac{r_- + G_{\rm N}^{(4)}\Sigma}{r},\\
W &= 1 - \frac{2r_0}{r}, \qquad r_\pm = M \pm r_0,\\
r_0^2 &= M^2 + \Sigma^2 - 4\left[e^{2\varphi_0} q^2 + e^{-2\varphi_0}\left(\frac{p}{16\pi G_{\rm N}^{(4)}}\right)^2\right],\\
\Sigma &= \frac{2}{M}\left[e^{2\varphi_0} q^2 - e^{-2\varphi_0}\left(\frac{p}{16\pi G_{\rm N}^{(4)}}\right)^2\right].
\end{aligned}} \tag{12.39}$$

---

[4] There is no theorem ensuring this, but all attempts to build dyonic solutions for other values of a have been unsuccessful.

[5] Solutions with additional scalar hair are also possible, but we will not deal with them any further.

Here we have used the S-dual potential $\tilde{A}_\mu$ which is the potential related to the S-dual field strength,

$$\tilde{F}_{\mu\nu} = 2\partial_{[\mu}\tilde{A}_{\nu]}, \tag{12.40}$$

whose existence is ensured by the equation of motion of A_μ, which is just the Bianchi identity for $\tilde{F}_{\mu\nu}$. Knowledge of the electric components F_{tr} and $\tilde{F}_{tr}$ and of the metric and dilaton is enough to find all the components $F_{\mu\nu}$, but this form of presenting the result is more elegant and convenient since it exhibits the symmetries of the theory acting on the solution. In particular, we see that S duality interchanges A_μ and $\tilde{A}_\mu$ and q and $p/(16\pi G_N{}^{(4)})$, and takes φ_0 to $-\varphi_0$, which also takes Σ to $-\Sigma$.

The purely electric dilaton BH solutions with $a = 1$ are recovered when $H_2 = 1$ and the purely magnetic ones when $H_1 = 1$. When $H_1 = H_2 = H$ the scalar becomes trivial and we recover the RN solutions. Thus, these solutions are the most general from the point of view of electric–magnetic duality.

As usual, when $W = 1$, H_1 and H_2 can be arbitrary harmonic functions in three-dimensional Euclidean space. They may but need not have coincident poles and, thus, the solutions describe electric and magnetic monopoles and dyons in static equilibrium.

Solutions of the four-dimensional ($a = 1$)-model with primary scalar hair and electric charge have been presented in [19] and probably can be generalized to all values of a and to higher dimensions. We will not pursue this issue any further.

12.2 Dilaton/axion black holes

The a-model is a good starting point from which to study BH solutions of supergravity/superstring theories, but it is clearly too simple. It is natural to introduce successive generalizations to this model that make it closer to the real thing. In higher dimensions we can introduce differential-form potentials of higher rank, but these are associated with extended objects. In four dimensions we can introduce, as a first step, additional vector fields, all of them coupled in the same way to the scalar field. Then, we can introduce new scalars or different couplings of the scalar(s) to the vector fields. We would have an action of the form

$$S = \frac{1}{16\pi G_{\rm N}^{(4)}} \int d^4x \sqrt{|g|} \left[R + \tfrac{1}{2} g_{ij} \partial_\mu \varphi^i \partial^\mu \varphi^j - \tfrac{1}{4} M_{ij} F^i{}_{\mu\nu} F^{j\,\mu\nu}\right], \tag{12.41}$$

where $g^{ij}(\varphi)$ and $M_{ij}(\varphi)$ are some square matrices depending on the scalars. g^{ij} can be interpreted as the inverse metric of some space of which the scalars φ_i are the coordinates. The scalar kinetic term is a *σ-model*.

A good example of an action of this kind is provided by the four-dimensional KK action that one obtains from $\hat{d} = 4 + N$ dimensions by compactification on T^N, Eq. (11.195). The scalars parametrize an $\mathbb{R}^+ \times \mathrm{SL}(N, \mathbb{R})/\mathrm{SO}(2)$ coset space.

There is another kind of couplings of scalars to vectors that we can introduce in four dimensions: couplings of the form

$$-\tfrac{1}{4} N_{ij}(\varphi) F^i{}_{\mu\nu}{}^\star F^{j\,\mu\nu}. \tag{12.42}$$

($ $! ,! 7! ! => % ! " .

The conservation law for the current $d^{\star} j = 0$ suggests the following definition for the charge q_p associated with $A_{(p+1)}$:

$$q_p \equiv \int_{\mathrm{B}^{(d-p-1)}} {}^{\star} j, \tag{18.38}$$

where, by definition, $\mathrm{B}^{(d-p-1)}$ is a *capping surface* whose boundary is (topologically) $\partial \mathrm{B}^{(d-p-1)} = \mathrm{S}^{(d-p-2)}$. More precisely, this is the charge contained in the capping surface. The total charge would be calculated by integrating over a capping surface whose boundary is the $(d-p-2)$-sphere at infinity $\mathrm{S}^{(d-p-2)}_{\infty}$. As usual this definition is invariant under smooth deformations of the capping surface in source-free ($j = 0$) regions.

Using the generalization of the Gauss law Eq. (18.37) and Stokes' theorem, we obtain the usual definition

$$\boxed{q_p = (-1)^{d+p} \int_{\mathrm{S}^{(d-p-2)}} {}^{\star} F_{(p+2)},} \tag{18.39}$$

which is also invariant under smooth deformations of the $(d-p-2)$-dimensional surface in source-free regions.

Given a p-brane sweeping out a $(p+1)$-dimensional worldvolume $\mathrm{W}^{(p+1)}$, we can immediately construct a conserved current for it that generalizes Eq. (8.49) for the current of a point-like charged object:

$$\begin{aligned} j^{\mu_1 \cdots \mu_{p+1}}(x) &= q_p \int_{\mathrm{W}^{(p+1)}} dX^{\mu_1} \wedge \cdots \wedge dX^{\mu_{p+1}} \frac{\delta^{(d)}(x - X(\xi))}{\sqrt{|g(X)|}} \\ &= q_p \int_{\mathrm{W}^{(p+1)}} d^{p+1}\xi \frac{\partial (X^{\mu_1} \cdots X^{\mu_{p+1}})}{\partial (\xi^{\mu_1} \cdots \xi^{\mu_{p+1}})} \frac{\delta^{(d)}(x - X(\xi))}{\sqrt{|g(X)|}}. \end{aligned} \tag{18.40}$$

The charge associated with this current is q_p, except when the p-brane worldvolume has boundaries, since, in that case, we can continuously deform the surface of integration and contract it to a point without meeting the p-brane source, obtaining zero charge. This is easy to visualize for a string of finite length in a four-dimensional target space: the string charge with respect to a 2-form potential is calculated through a closed line integral around the string that can be slid off the string and contracted to a point as shown in Figure 18.1. In a sense this explains why the KR 2-form does not appear in the open-string spectrum. It is clear now that $q_p \neq 0$ only when the p-brane has compact topology or extends to infinity. A brane with boundaries can also carry charge if the boundaries are attached to another object just as open strings are attached to D-branes. This case, which is more complicated (and interesting), will be studied in Section 19.6 since it depends strongly on the theory we are considering.

On substituting the above p-brane current into the interaction term Eq. (18.34), we obtain the standard form of the WZ term for p-branes which appears in the p-brane worldvolume action,

$$(-1)^{(p+1)} q_p \int_{\mathrm{W}^{(p+1)}} A_{(p+1)}. \tag{18.41}$$

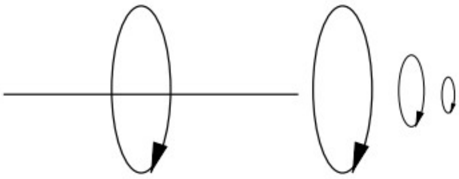

Fig. 18.1. Open strings cannot carry charge.

Electric–magnetic duality for extended objects. The electric–magnetic dual of a charged p-brane is, by definition, an object that couples to the electric-magnetic dual of the $(p+1)$-form potential $A_{(p+1)}$. We have seen several examples, for instance, in Section 16.5.5, in which we used Poincaré duality to replace the KR 2-form completely by its dual in various dimensions and also in Sections 16.1.3 and 17.1.1 in which we defined the on-shell duals of the RR potentials that appear in the $N = 2A, B, d = 10$ supergravity actions, not being able to replace the original potentials completely by their duals.

In all (massless) cases, the dual is a $(\tilde{p}+1)$-form $\tilde{A}_{(\tilde{p}+1)}$ with $\tilde{p} = d - p - 4$, whose field strength is, by definition, the Hodge dual of $\tilde{F}_{\tilde{p}+2} = {}^\star F_{(p+2)}$. The electric-magnetic dual of a p-brane is therefore a $\tilde{p}$-brane with $\tilde{p} \neq p$ in general, which is electrically charged with respect to $\tilde{A}_{(\tilde{p}+1)}$. Only in even dimensions do objects with $p = (d-4)/2$ have duals of the same dimension, and then we can have p-brane dyons.

A new feature with respect to point-particles is that there can be *self-dual p-branes*, charged with respect to a self-dual potential: point-particles couple only to vectors, which are dual to vectors in $d = 4$, but, in $d = 4$, self- or anti-self-duality is consistent only with a Euclidean signature. However, self-dual 2-forms in $d = 6$ and 4-forms in $d = 10$ can be consistently defined. They occur in $N = (1, 0), d = 6$ SUGRA (Section 13.4.1) and in $N = 2B, d = 10$ SUEGRA (Chapter 17), and are associated with chiral theories.

Dirac charge quantization. The charge of a p-brane moving in the background $A_{(p+1)}$ field sourced by a dual $\tilde{p}$-brane is quantized as in the case of point-particles [718, 881, 882].[5]

Let us consider the quantum propagation of a charged p-brane moving along a closed path[6] so its worldvolume is topologically a $(p+1)$-sphere $\mathrm{S}^{(p+1)}$. The interesting term in the path integral is the WZ term which, using Stokes' theorem, can be written in the form

$$(-1)^{(p+1)} q_p \int_{\mathrm{B}^{(p+2)}} dA_{(p+1)} = (-1)^{(p+1)} q_p \int_{\mathrm{B}^{(p+2)}} F_{(p+2)}, \tag{18.42}$$

where $\mathrm{B}^{(p+2)}$ is one of the many possible $(p+2)$-dimensional capping surfaces with $\partial \mathrm{B}^{(p+2)} = \mathrm{S}^{(p+1)}$. To avoid having any ambiguities in the path integral, the difference between choosing two different capping surfaces $\mathrm{B}_1^{(p+2)}$ and $\mathrm{B}_2^{(p+2)}$ must be an integer multiple of 2π:

---

[5] The derivation of the Dirac quantization condition we are about to explain is different from those used in Section 8.7.2 for point-particles, which can also be generalized to charged p-branes.

[6] This will be the analog of a point-particle moving along a closed path encircling a Dirac string.

$$(-1)^{(p+1)} q \int_{\mathrm{B}_1^{(p+2)}} F_{(p+2)} - (-1)^{(p+1)} q \int_{\mathrm{B}_2^{(p+2)}} F_{(p+2)} = 2\pi n. \tag{18.43}$$

Now, the first capping surface plus the second (with reversed orientation) form (topologically) a $(p+2)$-sphere $\mathrm{S}^{(p+2)}$, and we arrive at the condition

$$q_p \int_{\mathrm{S}^{(p+2)}} F_{(p+2)} = (-1)^{(p+1)} 2\pi n. \tag{18.44}$$

Defining now the "magnetic" charge, or, better, the electric charge of the dual $\tilde{p}$-brane, by

$$\boxed{p_p = q_{\tilde{p}} = (-1)^{d+\tilde{p}} \int_{\mathrm{S}^{p+2}} F_{(p+2)},} \tag{18.45}$$

the above result takes the form of the generalization of the Dirac quantization condition we were after:

$$\boxed{q_p q_{\tilde{p}} = 2\pi n, \qquad n \in \mathbb{Z}.} \tag{18.46}$$

The charge quantization condition for p-brane dyons was found in [305].

Observe that, in the string σ-model action Eq. (15.31), the constant that plays the role of the charge with respect to the KR 2-form is the string tension T. This identity, which has the form of a BPS bound, indicates that the object described by the action is a BPS object. All the extended objects we are going to deal with have the same property.

Observe also that, even though we have defined a scalar charge q_p because this is a useful quantity, this number does not give all the information. Actually, the charge should be the tensor

$$\boxed{Z^{\mu_1\cdots\mu_p} \sim \int_{\Sigma} d^{d-1}\Sigma_{\mu} j^{\mu\mu_1\cdots\mu_p}} \tag{18.47}$$

(where Σ is a spacelike hypersurface) and includes information about spatial orientation, etc. This explains why objects with the same tensions and q_ps can be in equilibrium if they are parallel (so their $Z^{\mu_1\cdots\mu_p}$s are identical) but not when one of them is tilted. These tensorial charges appear naturally in supersymmetry algebras, as we are going to see in Section 19.5.

18.1.3 The coupling of p-branes to scalar fields

A spacetime scalar $K(X)$ can be introduced in only one place in the NG action if we want to preserve reparametrization invariance and the gauge invariance of the WZ term,

$$S_{\mathrm{NG}}^{(p)}[X^{\mu}(\xi)] = -T_{(p)} \int d^{p+1}\xi (K/K_0) \sqrt{|g_{ij}|}. \tag{18.48}$$

5.4 A spacetime approach to Quantum Gravity theory

5.4.1 Motivation

The histories approach to General Relativity suggests a new, spacetime-focussed, approach to Quantum Gravity, characterized by two features that are not implemented in the existing Quantum Gravity schemes.

First, the Lorentzian metric is quantized, analogous to the 'external' quantum field in the history approach to scalar quantum field theory [22; 14]. This contrasts with conventional canonical Quantum Gravity where only a spatial three-metric is quantised. Second, the history scheme incorporates general covariance via a manifest representation of the spacetime diffeomorphism group.

The canonical quantisation scheme was originally developed with the hope of providing a background independent formulation of Quantum Gravity. The general procedure involves (i) a $3+1$ splitting of spacetime; (ii) the construction of a suitable Hilbert space to accommodate the basic kinematical quantities of the theory; and (iii) the definition of self-adjoint operators that represent the Hamiltonian constraints. The imposition of the constraints on the state vectors then projects out the physical degrees of freedom.

The canonical treatment of Quantum Gravity introduces a spacelike foliation that enters the quantum description. However, the physical predictions should be independent of the choice of this foliation. This is part of the famous 'problem of time', as are attempts to understand the spacetime diffeomorphism group in this context. These issues are significantly addressed by the histories formulation with its genuine spacetime description of physical quantities.

The definition of the history group provides the HPO formalism with a quantisation scheme that follows the general lore of canonical quantisation, providing however a fully covariant description – see for example the quantum treatment of minisuperspace models in [3].

The obvious technical problem in a histories-based quantisation is the rigorous implementation of the dynamics by a history analogue of the Hamiltonian constraint operator. As in standard canonical theory, the classical expression is non-quadratic – indeed non-polynomial – in the field variables, and so the construction of an operator for the Hamiltonian constraint seems a hopeless task using conventional methods. For this reason, we intend to exploit the basic ideas of loop quantum gravity, which has been a promising approach for the construction this operator.

5.4.2 Towards a histories analogue of loop quantum gravity

Loop quantum gravity is a successful canonical theory in many respects. The basic algebra is defined with reference to objects that have support on loops in the three-dimensional surface Σ.

The first step in the application of the histories formalism to loop quantum gravity is to develop the histories analogue of the connection formalism of General Relativity. The original formulation of the programme involved the consideration of self-dual $SL(2, \mathbf{C})$ connections on spacetime, together with a field of tetrads for a Lorentzian metric [26; 4]. However, the mainline approach in loop quantum gravity finds it more convenient to employ in quantisation a real $SU(2)$ connection, proposed by Barbero [5]. The Barbero connection may be obtained as a variable in a state space, extending that of canonical General Relativity; or it may be obtained from a Lagrangian action (the Holst Lagrangian by [11]). However, the latter procedure involves gauge fixing, and it is not clear whether the connection may be defined in its absence – see [19; 20] for related discussions.

The histories description for classical gravity in term of the Holst Lagrangian has been developed in [25]. The basic variables at the covariant level is an $SL(2, \mathbf{C})$ connection and a field of tetrads on spacetime M, together with their conjugate variables. The corresponding history space carries a symplectic action of the group $Diff(M)$ of spacetime diffeomorphisms. The introduction of an equivariant foliation functional allows the translation of the spacetime description into that of an one-parameter family of canonical structures. The results of the metric-based theory can be fully reproduced in this construction: the set of constraints corresponding to the Holst Lagrangian is invariant under the action of the spacetime $Diff(M)$ group. Hence the generators of the spacetime diffeomorphisms group can also be projected onto the reduced state space.

The next step would involve choosing the basic variables for quantisation. Following the spirit of loop quantum gravity, we may try to identify a loop algebra, and then construct a histories Hilbert space by studying its representation theory. The obvious place to start would be the loop algebra corresponding to the spacetime $SL(2, \mathbf{C})$ connection of the covariant description. This, however, would involve a representation theory for loop variables with a non-compact gauge group, which to the best of our knowledge has not yet been fully developed. Moreover, we would have to identify a new role for the tetrad fields, because at this level they commute with the connection variables.

It may be more profitable to work with ‘internal’ fields, namely the ones that correspond to one-parameter families of the standard canonical variables. This would allow the consideration of connections with compact gauge group. However, a complication arises, because of the gauge-dependence of the definition of the Barbero connection. A gauge-fixing condition, at this level, breaks the background independence of the theory. In [25] we show that a connection sharing all properties of the Barbero connection can be defined in a gauge invariant way, albeit in a larger space than the one usually employed.

A history quantisation may be therefore envisioned that will employ variables defined with support on a two-dimensional cylinder – giving a history analogue of the T_0 variables – and a three-dimensional space $S \times R$ (where S is a spatial two-surface), as a history analogue of the T_1 variables. The price of gauge-invariance is that additional canonical variables have to be quantised: they correspond to a unit timelike vector field that determines the possible ways that the group $SU(2)$ can be embedded into $SL(2, C)$ – see [14] for the quantisation of a related structure in the context of quantum field theories.

The above is a potential point of divergence between histories quantisation and the canonical loop approach, which is necessary in light of the strong restrictions placed by our requirement of full spacetime general covariance. At present the research is focussed on finding a proper algebra for quantisation. An interesting possibility is that the histories formalism may provide spacetime geometric operators: for example, an operator for spacetime volume; or 'length' operators that distinguish between spacelike and timelike curves.

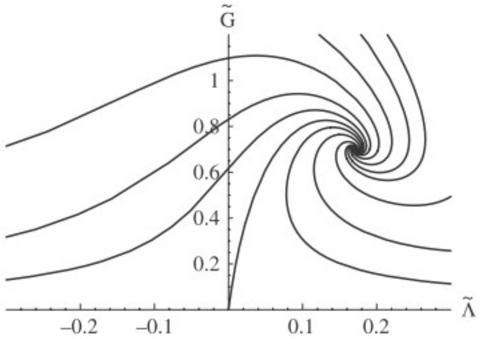

Fig. 8.2. The flow in the Einstein–Hilbert truncation, see eqs. (8.23) and (8.24). The nontrivial FP at $\tilde{\Lambda} = 0.171$, $\tilde{G} = 0.701$ is UV-attractive with eigenvalues $-1.69 \pm 2.49i$. The Gaussian FP is attractive along the $\tilde{\Lambda}$-axis with eigenvalue -2 and repulsive in the direction (0.04, 1.00) with eigenvalue 2.

Lauscher & Reuter [22] and Reuter & Saueressig [37] have studied the gauge- and cutoff-dependence of the FP in the Einstein–Hilbert truncation. The dimensionless quantity $\Lambda' = \Lambda G$ (the cosmological constant in Planck units) and the critical exponents have a reassuringly weak dependence on these parameters. This has been taken as a sign that the FP is not an artifact of the truncation. Lauscher & Reuter [23] have also studied the ERGE including a term R^2 in the truncation. They find that in the subspace of $\tilde{\mathcal{Q}}$ spanned by $\tilde{\Lambda}$, $\tilde{G}$, $1/\xi$, the non-Gaussian FP is very close to the one of the Einstein–Hilbert truncation, and is UV-attractive in all three directions. More recently, the FP has been shown to exist if the Lagrangian density is a polynomial in R of order up to six (Codello, Percacci and Rahmede, in preparation). In this truncation the UV critical surface is three dimensional.

There have been also other generalizations. Niedermaier [28] considered the RG flow for dimensionally reduced $d = 4$ gravity, under the hypothesis of the existence of two Killing vectors. This subsector of the theory is parametrized by infinitely many couplings, and has been proved to be asymptotically safe.

Matter couplings have been considered by Percacci & Perini [31; 32]. Consider the general action

$$\Gamma_k(g_{\mu\nu}, \phi) = \int d^4x \sqrt{g} \left(-\frac{1}{2} g^{\mu\nu} \partial_\mu \phi \partial_\nu \phi - V(\phi^2) + F(\phi^2) R \right), \qquad (8.25)$$

where V and F are arbitrary functions of ϕ^2, analytic at $\phi^2 = 0$. This action has a so-called Gaussian-Matter FP, meaning that only the coefficients of the ϕ-independent terms in (8.25) (namely $g^{(0)}$ and $g^{(1)}$) are nonzero. The critical surface has dimension four and there are no marginal operators. In the presence of other, minimally coupled matter fields, the dimension of the critical surface can be

We consider spacetime manifolds M which are diffeomorphic to $\mathbb{R} \times \Sigma$ where Σ is a 3D manifold of arbitray topology. Consider any principal $SU(2)$ bundle[7] $\mathcal{P}$ over Σ and denote by A the pull back by local sections of a connection on P. Likewise, consider an associated, under the adjoint representation of $SU(2)$, vector bundle whose local sections are $su(2)$ valued vector densities E. We now consider a new phase space with the following symplectic structure

$$\{E^a_j(x), A^k_b(y)\} = \kappa \iota \delta^a_b \delta^k_j \delta(x, y) \tag{13.11}$$

where $\kappa = 8\pi G_N,\ G_N$ is Newton's constant and $\iota > 0$ is any positive real number [19; 20]. All other brackets vanish.

We now want to establish the connection with the ADM formulation. Consider a Dreibein whose local sections are $su(2)$ valued one forms e. Then $q_{ab} = \delta_{ij} e^i_a e^j_b$ and $E^a_j = |\det(e)| e^a_j$ where $e^a_j e^j_b = \delta^a_b,\ e^a_j e^k_a = \delta^k_j$ and q is the pull back of the spacetime metric to Σ. Next, denote the pull back by local sections of the spin connection[8] associated with e by Γ. Then $A^j_a = \Gamma^j_a + \iota K_{ab} e^b_j$ where K_{ab} is the pull back to Σ of the extrinsic curvature of the foliation $M \cong \mathbb{R} \times \Sigma$.

The non-trivial result is now the following. We may use the relations just displayed to invert $q_{ab} = H_{ab}(A, E),\quad P^{ab} = \Pi^{ab}(A, E)$ where H, Π are functions which can be easily derived by the reader from the definition $P^{ab} = \sqrt{\det(q)}[q^{ac}q^{bd} - q^{ab}q^{cd}]K_{cd}$ of the momentum conjugate[9] to q. Define the Gauss constraint

$$C_j := \partial_a E^a_j + \epsilon_{jkl} A^k_a E^a_l. \tag{13.12}$$

Then one can show that the Poisson brackets of H, Π, using the symplectic structure (13.11) are precisely the Poisson brackets of q, P up to terms which vanish when $C_j = 0$. In other words, the phase space spanned by A, E with symplectic structure (13.11) and constraint (13.12) imposed is precisely the ADM phase space of geometrodynamics. Notice that H, Π are Dirac observables with respect to the Gauss constraint.

We can now define the algebra $\mathfrak{P}$ of elementary observables based on A, E. The analogy with an $SU(2)$ gauge theory familiar from the electroweak theory naturally suggests the use of techniques which are standard in (lattice) gauge theory. To that end, let s, S be a one- and two-dimensional submanifold of Σ respectively, which

---

use real valued ι and multiply the Hamiltonian constraint by a sufficiently high power of $\sqrt{|\det(E)|}$ in order to make it polynomial. The work of [25; 26; 27; 28; 29; 30; 31; 32] showed that the representation for $\mathfrak{A}$ supports the Hamiltonian constraint only if one uses the non-polynomial form. The reason for this is again background independence.

[7] One can show that principal $SU(2)$ bundles over 3D Σ are necessarily trivial but we will not need this in what follows.

[8] It is defined by the covariant constance of e, i.e. $D_a e^j_b = 0$.

[9] I.e. $\{P^{ab}(x), q_{cd}(y)\} = 16\pi G_N \delta^a_{(c} \delta^b_{d)} \delta(x, y)$.

will play the role of labelling smearing functions. Furthermore, let k be an $su(2)$ valued, smooth function on Σ. We define holonomy and flux functions

$$A(s) := \mathcal{P}\exp(\int_p A), \quad E_k(S) := \int_S \mathrm{Tr}(k \ *E) \tag{13.13}$$

where $*E$ is the metric independent, pseudo-two form dual to E. Now consider an arbitrary, finite collection of paths s. Their union forms a finite[10] graph γ and we may compose the paths s from the edges of the resulting graph. We now call a function cylindrical over a graph provided it is a complex valued function of the $A(s)$ where s runs through the edges of the graph. The cylindrical functions form an Abelean *-algebra which we denote by Cyl. Next, denote by $Y_{k,S}$ the Hamiltonian vector field of $E_k(S)$. Then $\mathfrak{P}$ is defined as the Lie algebra of cylindrical functions f and vector fields v equipped with the following Lie bracket $[(f, v), (f', v')] = (v[f'] - v'[f], [v, v'])$. The most important building block in that algebra is

$$Y_{k,S}[A(s)] = \{E_{k,S}, A(s)\} = \iota\kappa A(s_1)k(s \cap S)A(s_2) \tag{13.14}$$

where $s = s_1 \circ s_2$ and we have assumed that $s \cap S$ is precisely one point, the general case being similar.

13.3.1.1 The quantum algebra $\mathfrak{A}$ and its representations

The corresponding $\mathfrak{A}$ is defined by formally following the procedure of section 13.2. We now consider its representation theory. Since we are dealing with a field theory the representation theory of $\mathfrak{A}$ will be very rich so we have to downsize it by imposing additional physical requirements. The natural requirement is that the representation derives from a state invariant under the automorphisms of the bundle P. Locally these automorphisms can be identified with the semidirect product $\mathfrak{G} := \mathcal{G} \rtimes \mathrm{Diff}(\Sigma)$ of local $SU(2)$ gauge transformations and spatial diffeomorphisms. The requirement of $\mathfrak{G}$-invariance is natural because both groups are generated canonically, that is by the exponential of the respective Hamiltonian vector fields, from the Gauss constraint and spatial diffeomorphism constraint respectively. For instance we have with $C(\Lambda) = \int_\Sigma \ d^3x \ \Lambda^j C_j$ and $C(\vec{N}) = \int_\Sigma \ d^3x \ N^a C_a$ that

$$\begin{aligned} \alpha_{g_\Lambda}(A(s)) \ &:= \ \exp(X_{C(\Lambda)}) \cdot A(s) = g_\Lambda(b(s)A(s)g_\Lambda(f(s)) \\ \alpha_{\varphi_{\vec{N}}}(A(s)) \ &:= \ \exp(X_{C(\vec{N})}) \cdot A(s) = A(\varphi_{\vec{N}}(s)), \end{aligned} \tag{13.15}$$

where $g_\Lambda = \exp(\Lambda)$ and $\varphi_{\vec{N}}$ is the diffeomorphism defined by the integral curves of the vector field $\vec{N}$. Here, $b(s)$, $f(s)$ respectively denote beginning and final point of the path s and X_F denotes the Hamiltonian vector field of F.

---

[10] Technically paths and surfaces must be semi-analytic and compactly supported in order for that to be true [1; 2; 21] but we will not go into these details here.

where $M = \Sigma \times \mathbb{R}$ (for Σ an arbitrary Riemann surface), ω is an $SU(2)$-connection and the triad e is an $su(2)$-valued 1-form. The gauge symmetries of the action are the local $SU(2)$ gauge transformations

$$\delta e = [e, \alpha]\,, \qquad \delta\omega = d_{\omega}\alpha, \tag{15.3}$$

where α is a $su(2)$-valued 0-form, and the "topological" gauge transformation

$$\delta e = d_{\omega}\eta, \qquad \delta\omega = 0, \tag{15.4}$$

where d_{ω} denotes the covariant exterior derivative and η is a $\mathtt{su(2)}$-valued 0-form. The first invariance is manifest from the form of the action, while the second is a consequence of the Bianchi identity, $d_{\omega}F(\omega) = 0$. The gauge symmetries are so large that all the solutions to the equations of motion are locally pure gauge. The theory has only global or topological degrees of freedom.

Upon the standard $2+1$ decomposition, the phase space in these variables is parametrized by the pull back to Σ of ω and e. In local coordinates one can express them in terms of the two-dimensional connection A_a^i and the triad field $E_j^b = \epsilon^{bc} e_c^k \delta_{jk}$ where $a = 1, 2$ are space coordinate indices and $i, j = 1, 2, 3$ are $su(2)$ indices. The Poisson bracket is given by

$$\{A_a^i(x), E_j^b(y)\} = \delta_a^{\ b}\ \delta^i_{\ j}\ \delta^{(2)}(x, y). \tag{15.5}$$

Local symmetries of the theory are generated by the first class constraints

$$D_b E_j^b = 0, \quad F_{ab}^i(A) = 0, \tag{15.6}$$

which are referred to as the Gauss law and the curvature constraint respectively. This simple theory has been quantized in various ways in the literature [5], here we will use it to introduce the spin foam representation.

15.3.2 Spin foams from the Hamiltonian formulation

The physical Hilbert space, $\mathscr{H}_{\text{phys}}$, is defined by those "states in $\mathscr{H}_{\text{kin}}$" that are annihilated by the constraints. As discussed in the chapter by Thiemann (see also [2; 4]), spin network states solve the Gauss constraint – $\widehat{D_a E_i^a}|s\rangle = 0$ – as they are manifestly $SU(2)$ gauge invariant. To complete the quantization one needs to characterize the space of solutions of the quantum curvature constraints $\widehat{F}_{ab}^i$, and to provide it with the physical inner product. As discussed in Section 15.2 we can achieve this if we can make sense of the following formal expression for the generalized projection operator P:

$$P = \int D[N] \exp(i \int_{\Sigma} \mathrm{Tr}[N\widehat{F}(A)]) = \prod_{x\subset\Sigma} \delta[\widehat{F(A)}], \tag{15.7}$$

The transformation has to be such that it implements the evolution equations as operatorial relations acting on the space of wavefunctions in the Heisenberg representation, where

$$U(q|q') = \langle n+1, q'|n, q\rangle, \tag{20.11}$$

and where $|n+1, q'\rangle$ and $|n, q\rangle$ are the eigenvectors of the configuration operators $\hat{q}$ in the Heisenberg representation at levels $n+1$ and n respectively. The evolution equations take the form,

$$\begin{aligned} \langle n+1, q|\hat{q}_{n+1} - f(\hat{q}_n, \hat{p}_n)|n, q'\rangle &= 0, & (20.12)\\ \langle n+1, q|\hat{p}_{n+1} - g(\hat{q}_n, \hat{p}_n)|n, q'\rangle &= 0, & (20.13) \end{aligned}$$

with f, g the quantum evolution equations, which are chosen to be self-adjoint in order for the transformation to be unitary. Explicit examples of this construction for cosmological models can be seen in [17]. If at the end of this process one has constructed a transformation that is truly unitary the quantization is complete in the discrete space and one has a well defined framework to rigorously compute the conditional probabilities that arise when one uses a relational time to describe the physical system. This is a major advantage over attempts to construct the relational picture with systems where one has constraints. There are some caveats to this construction that are worth pointing out. As we mentioned, our construction generically yields discrete theories that are constraint-free. To be more precise, the theories do not have the constraints associated with space-time diffeomorphisms. If the theory under consideration has other symmetries (for instance the Gauss law of Yang–Mills theory or gravity written in the new variable formulation), such symmetries may be preserved upon discretization (we worked this out explicitly for Yang–Mills and BF theory in [4]). The resulting discrete theory therefore will have some constraints. If this is the case, the above construction starts by considering as wavefunctions states that are gauge invariant and endowed with a Hilbert space structure given by a gauge invariant inner product. The resulting theory has true (free) Lagrange multipliers associated with the remaining constraints. The unitary transformation will depend on such parameters. An alternative is to work in a representation where the constraints are solved automatically (like the loop representation for the Gauss law). There one has no constraints left and the inner product is the kinematical one in the loop representation and the unitary transformation does not depend on free parameters. Other issues that may arise have to do with the fact that in many situations canonical transformation do not correspond quantum mechanically to unitary transformations. This problem has been discussed, for instance, by Anderson [1]. He noted that the only canonical transformations that can be implemented as unitary transformations are those that correspond to an isomorphism of a phase space into itself. This is important for the discrete theories in the following way. If one has a continuum constrained theory, its physical phase space is on the constraint surface. The discrete theories have a phase space that includes the constraint surface of the continuum theory. However, the discrete phase space variables cover only a subspace of the kinematical phase space of the continuum theory. There are inaccessible sectors that correspond to complex values of the Lagrange multipliers in the discrete theory. Therefore, in order that the canonical transformation of the discrete theory be an isomorphism, one may have to choose a physical Hilbert space for the discrete theory that is a subspace of the kinematical space instead of just taking it to be coincident. This has to be done carefully, since restricting the Hilbert space may imply that some physical quantities fail to be well defined in the physical Hilbert space. We have explored some of these issues in some quantum mechanical models that have a relational description. We have shown that one can successfully recover the traditional quantum mechanical results in a suitable continuum limit by carefully imposing a restriction on the kinematical Hilbert space, and that one can define variables that approximate any dynamical variable of the continuum theory in the continuum limit in the restricted Hilbert space (see [6]).

20.5 The quantum continuum limit

As we argued in the discussion of the model analyzed by Rovelli, a good measure of how close one is to the continuum theory in a given solution of the discrete theory is to evaluate the constraint of the continuum theory. Such constraint is only exactly satisfied in the continuum limit. An alternative way of presenting this is to consider the construction of a "Hamiltonian" such that exponentiated would yield the unitary evolution between n and $n+1$, $\hat{U} = \exp(i\hat{H})$ where $\hbar = 1$ and $\hat{H}$ has units of action. Such a Hamiltonian can only be constructed locally since in some points of the evolution the logarithm of the unitary transformation is not well defined. Such a Hamiltonian can be written as a formal expansion in terms of the constraint of the continuum theory (a way of seeing this is to notice that in the continuum limit this Hamiltonian has to vanish since it incorporates the timestep). If one chooses an initial state such that $\langle\hat{H}\rangle \ll 1$ the evolution will preserve this ($\hat{H}$ is an exact constant of the motion). This will continue until one reaches a point where $\hat{H}$ is not well defined. The evolution will continue, but it will not necessarily remain close to the continuum limit. In certain cosmological examples this point coincides with the point where the continuum theory has the singularity, for example [17]. Therefore a first condition on the quantum states in the continuum limit $\langle\hat{H}\rangle \ll 1$. A second condition is that the expectation values of the physical variables should not take values in the points where $\hat{H}$ is not well defined. A third condition is not to

The discussion can be made more precise when addressed in the Hamiltonian formalism. GR is an example of a constrained theory: there is a set of first class constraints that encode the diffeomorphism symmetry.[1] Observable quantities are functions on phase space that commute with the constraints. It is pretty hard to construct a general complete set of observables. However, taking advantage of the fact that physics should be relational allowed us to construct a large set of such observables [13].

To simplify the analysis let us consider the relativistic free particle: in this case, we have time reparametrization invariance, encoded in the mass shell constraint $H = p^2 - m^2 = 0$. It is easy to construct the algebra of observables: it is given by the Poincaré algebra $\{J_{\mu\nu},\ p_\mu\}$. This set of observables does not include the important notion of position. To define this concept, we need to introduce the following Rovelli terminology of a *partial observable*[2] $b(\tau)$ as a clock. A natural observable[3] is then the value of another partial observable $a(\tau)$ when $b(\tau)$ is T. If separately a and b are not observable, since not commuting with the mass shell constraint, the quantity

$$a(b^{-1}(T)) = \int d\tau a(\tau)\dot{b}(\tau)\delta\left(b(\tau) - T\right) \tag{26.1}$$

is clearly time reparametrization invariant, and therefore observable. For example, if we take b to be x_0, and a to be x_i, we obtain the trajectories of the relativistic particle in terms of the time x_0:

$$x_\mu(T) = x_\mu + \frac{p_\mu}{p_0}(x_0 - T).$$

Notice that of course this observable can be constructed from the Poincaré algebra [14].

In the language of constrained mechanics, $b(\tau) = T$ is a gauge fixing, or a second class constraint. From the physics point of view, the degree of freedom b is the reference frame. Obviously there is the issue of the invertibility of b. In general the choice of clock might not lead to a function which is invertible everywhere. This means that the clock ceased to be a good clock. This issue has to be studied in a case per case analysis.

Introducing second class constraints means that we can reduce the phase space to obtain the physical phase space. The reduced symplectic form is called the Dirac bracket, and is not in general identical to the canonical Poisson bracket. This leads to complications when one wants to quantize such system.

---

[1] There might be more constraints according to the choice of variables. For example, if using the pair (tetrad, connection), there is also the Gauss law.

[2] Let be f a function on phase space, not commuting with the first class constraint H, then we define $f(\tau) = e^{\tau\{H,.\}}f$.

[3] That is the outcome of a measurement or, according to Rovelli, a complete observable [12].

The general theory of quantization of a constrained system has been set up by Dirac [15]. Let us deal only with a set of first class constraints $\{C_i\}$. We first quantize the algebra of partial observables $\mathcal{A}_k$ and then construct the kinematical Hilbert space $\mathcal{H}_k$ carrying the representation of $\mathcal{A}_k$. We quantize then the constraints C_i:

$$\mathcal{A}_k \to \hat{\mathcal{A}}_k,\ C_i \to \hat{C}_i.$$

In general it might be difficult to construct $\mathcal{H}_k$ but also to quantize the constraints C_i, since they might be non-polynomial functions of partial observables. This is precisely what happened in the first try to quantize GR [16].

The great accomplishment of LQG was to describe GR in terms of variables that allowed one to construct the Hilbert space and quantize the constraints.

From the kinematical Hilbert space, we construct physical Hilbert $\mathcal{H}_{\text{phys}}$ space, which is in the kernel of the constraints $\hat{C}_i$. For this, it is useful to introduce the projector[4]

$$P : \mathcal{H}_k \to \mathcal{H}_{\text{phys}} \equiv \{P|\psi\rangle_k\} \text{ with } P \sim \int d\lambda e^{i\lambda\hat{C}} \sim \delta(\hat{C}).$$

The physical quantum observables are also obtained upon projection

$$\hat{A} \in \hat{\mathcal{A}}_k \to P\hat{A}P \in \hat{\mathcal{A}}_{\text{phys}}.$$

In order to have some physical quantities, we can construct the relational observables analog to (26.1):

$$P\delta(\hat{B}-b)\hat{A}\delta(\hat{B}-b)P, \text{ with } \hat{A}, \hat{B} \in \hat{\mathcal{A}}_k,$$

where $\delta(\hat{B}-b)$ denotes the projection of $\hat{B}$ on the eigenspace with eigenvalue b. The degrees of freedom $\hat{B}$ can be identified as a quantum reference frame (QRF): the physics of QG should be understood in terms of QRF. This new type of physics is extremely rich and interesting to explore. Since in the context of QG it is a bit hard to explore this, we can look for some toy models to mimic this structure.

In fact interestingly the notion of QRF has already been introduced in quantum information theory (QIT), in concrete models that can also be experimentally tested! Let us choose, for example,[5] a quantum universe made of N qubits $\vec{\sigma}^i$,[6] which is globally invariant under $SO(3)$ rotations [17].

---

[4] It will be a projector if the constraints have zero in their discrete spectrum. If this is not the case, it is not a projector; we need to use distributions. This a mathematical subtlety important in QG, but not relevant to the current discussion.

[5] There are many other little toy models where one can play around to mimic gravitational effects. For example, one can look at *analog gravity* models [20], or constrained harmonic oscillators [21]. Of course all these models are finite dimensional, which (over?)simplifies drastically the analysis.

[6] I use the notational shortcut $\vec{\sigma}^i \equiv \mathbf{1} \otimes \ldots \otimes \vec{\sigma} \otimes \mathbf{1} \otimes \ldots$, the Pauli matrices being at the ith position.

the Ashtekar formulation, which are the $SU(2)_L$ connection A^i_a and its conjugate momenta $\tilde{E}^a_i \approx e \wedge e$ this becomes

$$F^i_{ab} + \frac{\Lambda}{3}\epsilon_{abc}\tilde{E}^c_i = 0. \tag{28.13}$$

One can solve this with a Hamilton–Jacobi function on configuration space [51; 47], which is a function $S(A^i)$ such that $\tilde{E}^a_i = \frac{\delta S(A^i)}{\delta A^i_a}$. This leads to the equation

$$F^i_{ab} + \frac{\Lambda}{3}\epsilon_{abc}\frac{\delta S(A^i)}{\delta A^i_a} = 0. \tag{28.14}$$

There is also the Gauss's law constraint which requires that

$$\mathcal{D}_a\tilde{E}^a_i = \mathcal{D}_a\frac{\delta S(A^i)}{\delta A^i_a} = 0. \tag{28.15}$$

These have a unique solution

$$S(A^i) = -\frac{k}{4\pi}\int Y_{\mathrm{CS}}(A^i) \tag{28.16}$$

where $Y(A^i)$ is the Chern–Simons invariant. Thus we can consider the Chern–Simons invariant to be a time functional on the Euclidean configuration space.

If we choose $\Sigma = S^3$ we find that there is a periodicity due to the property that under large gauge transformations with winding number n

$$\int Y_{\mathrm{CS}}(A^i) \rightarrow \int Y_{\mathrm{CS}}(A^i) + 8\pi^2 n \tag{28.17}$$

This means that the Euclidean configuration space is a cylinder which further implies that *all correlation functions, for any fields in the theory* are periodic in an imaginary time variable given by the Chern–Simons functional $S(A^i)$. But by the KMS theorem, this means that the theory is at a finite temperature. If one works out the periodicity one finds precisely the temperature (28.12).

This applies to the full Quantum Gravity theory because it means that any quantum state on the full configuration space of the theory will be periodic in imaginary time. Thus, with very little effort we greatly extend the significance of the de Sitter temperature. This is an example of the power of seeing General Relativity in terms of connection variables and it is also an example of the importance of topological field theory to the physics of Quantum Gravity.

28.4 The problem of the emergence of classical spacetime

We have just seen that LQG gets several things about gravitational physics right, including the entropy of horizons and the temperature of de Sitter spacetime. There

2.2 The Lovelock and Horndeski Uniqueness Theorems

2.2.1 Lovelock Theory

Our purpose in this lecture is to present Lovelock theory in relation to Horndeski theory. To this end it is mostly sufficient to truncate Lovelock theory to what is usually called Einstein-Gauss-Bonnet (EGB) theory in the literature. Unlike the name suggests, this is the five or six dimensional version of Lovelock theory originally discussed by Lanczos [3]. Let us start with the uniqueness theorem defining Lovelock theory and stick to six dimensions in order to fix notation. The five dimensional theory is identical. Consider $\mathscr{L} = \mathscr{L}(\mathscr{M}, g, \nabla, \nabla^2)$ where $(\mathscr{M}, g)$ is a six dimensional locally differentiable Lorentzian manifold without boundary[3] and ∇ is the Levi-Civita metric connexion over $\mathscr{M}$. The field equations obtained upon metric variation of the action,

$$S^{(6)} = \frac{{M_{(6)}}^4}{2} \int \sqrt{-g^{(6)}} \left[R - 2\Lambda + \alpha \hat{G} \right], \tag{2.2}$$

are unique and admit the following properties:

- they depend on a symmetric two-tensor $\mathscr{E}_{AB}$
- the equations of motion are second-order PDE's with respect to the metric field variables
- satisfying Bianchi identities.

Here, $M_{(6)}$ is the fundamental mass scale in six-dimensional spacetime, $\hat{G}$ is the Gauss-Bonnet density reading,

$$\hat{G} = R_{ABCD} R^{ADCB} - 4 R_{AB} R^{AB} + R^2 , \tag{2.3}$$

and Λ is the cosmological constant. The field equations in vacuum are

$$\mathscr{E}_{AB} = G_{AB} + \Lambda g_{AB} + \alpha H_{AB} = 0 , \tag{2.4}$$

where G_{AB} stands for the standard Einstein tensor. Uppercase Latin indices will refer to six-dimensional coordinates whereas Greek indices will always refer to four dimensional space-time. We have also introduced the Lanczos or second order Lovelock tensor,

$$H_{AB} = \frac{g_{AB}}{2} \hat{G} - 2 R R_{AB} + 4 R_{AC} R^C{}_B + 4 R_{CD} R^C{}_A{}^D{}_B - 2 R_{ACDE} R_B{}^{CDE} . \tag{2.5}$$

---

[3] The result depicted here is easily extended to manifolds with boundaries [12].

Naturally, the Lanczos tensor is also divergence free, $\nabla^A H_{AB} = 0$. It is important to note that, just like GR in four dimensions, i.e. under the same set of hypotheses, EGB theory is the unique and most general metric theory with second order PDE's in five or six space-time dimensions. This is a non-trivial statement since the terms appearing in the action already contain second order derivatives. In a moment we will see that in higher than six dimensions this property is generalized by adding the relevant higher order Lovelock terms. Furthermore in four dimensions the tensor (2.5) is identically zero. Therefore we can note as a prelude that Lovelock theory is the unique massless metric theory in arbitrary dimensions identical to GR with a cosmological constant in four dimensional spacetime.

Before moving on it is useful to discuss some tensorial properties. The Lanczos tensor (2.5) can be elegantly written (in arbitrary dimension) using the following rank four tensor that will be useful to us later on,

$$\begin{aligned} P_{ABCD} = R_{ABCD} + R_{BC}\, g_{AD} - R_{BD}\, g_{AC} - R_{AC}\, g_{BD} + R_{AD}\, g_{BC} \\ +\frac{1}{2} R\, g_{AC}\, g_{BD} - \frac{1}{2} R\, g_{BC}\, g_{AD}, \end{aligned} \tag{2.6}$$

as

$$H_{AB} = -2 P_{ACDE} R_B{}^{CDE} + \frac{g_{AB}}{2}\hat{G}\,. \tag{2.7}$$

The 4 index tensor P_{ABCD} has several interesting tensorial properties. For a start it is divergence free (in all indices) since Bianchi identities of the curvature tensor are simply written as $\nabla^D P_{ABCD} = 0$. It has the same index symmetries as the Riemann curvature tensor. Its bi-tensor obtained by tracing two of its non-consecutive indices yields

$$P^B{}_{ACB} = (D-3) G_{AC}, \tag{2.8}$$

the Einstein tensor. In fact divergence freedom of the Einstein tensor can be seen to originate from this relation. In a nutshell, one can say that P_{ABCD} is the curvature tensor whose bi-tensor is the Einstein tensor, just as the Ricci tensor is the bi-tensor of the Riemann tensor. A last interesting property is that a metric is an Einstein space, $R_{AB} = \frac{g_{AB}}{D} R$, if and only if $P_{ABCD} = R_{ABCD}$.

In four dimensions, the $P_{\mu\nu\rho\sigma}$ tensor is even more very special. Indeed it has all the above properties but, additionally it can be pictured in a very similar way to the Faraday tensor in electromagnetism,

$$\star\, F_{\mu\nu} = \tfrac{1}{2}\epsilon_{\mu\nu\kappa\rho}\, F^{\kappa\rho} \tag{2.9}$$

In analogy here, $P_{\mu\nu\rho\sigma}$ is a 4 tensor, and coincides with the double dual (i.e. for each pair of indices) of the Riemann tensor defined as,

$$P^{\mu\nu}{}_{\rho\sigma} = ({}^\star R^\star)^{\mu\nu}{}_{\rho\sigma} \doteq -\frac{1}{2}\epsilon^{\rho\sigma\lambda\kappa}\, R_{\lambda\kappa}{}^{\xi\tau}\, \frac{1}{2}\epsilon_{\xi\tau\mu\nu}, \tag{2.10}$$

where $\epsilon_{\mu\nu\rho\sigma}$ is the rank 4 Levi-Civita tensor. Finally since in four dimensions we have that $H_{\mu\nu} = 0$ we obtain the Lovelock identity,

$$P_{\alpha\nu\rho\sigma} R_{\beta}{}^{\nu\rho\sigma} = \frac{g_{\alpha\beta}}{4}\hat{G} \tag{2.11}$$

which will be useful to us later on (see [19] for extensions).

In order to define the generic Lovelock densities one can use the elegant language of differential forms [12]. Alternatively we take the route taken by Lovelock using the generalized Kronecker delta symbols; the same route taken later on by Horndeski,

$$\delta^{A_1\dots A_h}_{B_1\dots B_h} = \begin{vmatrix} \delta^{A_1}_{B_1} & \dots & \delta^{A_1}_{B_h} \\ \vdots & & \vdots \\ \delta^{A_h}_{B_1} & \dots & \delta^{A_h}_{B_h} \end{vmatrix} \tag{2.12}$$

$$= h!\delta^{A_1}_{[B_1} \dots \delta^{A_h}_{B_h]} \tag{2.13}$$

which is antisymmetric in any pair of upper or lower indices. In fact we have $\delta^{A_1\dots A_h}_{B_1\dots B_h} = \epsilon_{B_1\dots B_h}\epsilon^{A_1\dots A_h}$ with respect to the Levi-Civita symbols. Once this has been digested the Lovelock densities are the complete contraction of the above with the Riemann curvature tensor,

$$L_{(h/2)} = \frac{1}{2^h}\delta^{A_1 A_2 \dots A_h}_{B_1 B_2 \dots B_h}\; R_{A_1 A_2}{}^{B_1 B_2} \;\dots\; R_{A_{(h-1)} A_h}{}^{B_{(h-1)} B_h} \tag{2.14}$$

As such we can check that $L_{(1)}$ is the Einstein-Hilbert term whereas $L_{(2)}$ is the Gauss-Bonnet combination. This immediately means that for $h > D$ all Lovelock densities vanish. Therefore the Lovelock Langrangian is given by,

$$L = \sum_{h=0}^{k} c_h L_h \tag{2.15}$$

where $k = [(D-1)/2]$. The case $h = D$ is quite special because then the Lovelock density is a topological one. Indeed we can query what is special about Lovelock densities. The answer lies in differential geometry (see for example [20]). One can trace the origin of such terms in the early works of Gauss who measuring geodesic distances noted that scalar (Gauss) curvature of two dimensional surfaces depended only on the first fundamental form, in other words the intrinsic metric of the surface and its derivatives. This was the basis of what he called the Egregium theorem; scalar curvature (unlike other extrinsic curvature components) does not depend on the variation of the normal vector field on the surface i.e. on how the surface is embedded in three dimensional space. Then later on Euler in his work on surface triangulations noted that two dimensional surfaces can be topologically classified by their "Euler" number, χ: $\chi[\mathscr{M}] = 2 - 2h$ where h is the number of topological handles. So one can take an arbitrary surface with no boundary and continuously deform it to a sphere, a torus a double torus and so on.[4] This completely classifies topologically two dimensional surfaces. In other words all topological properties of two dimensional surfaces can be understood or characterized by their Euler number. Gauss and Bonnet essentially related this topological number to a differentiable geometric quantity, the scalar curvature, resulting in the celebrated relation,

$$\chi[\mathscr{M}_2] = \frac{1}{4\pi} \int_{\mathscr{M}} R. \tag{2.16}$$

The Gauss-Bonnet theorem on surfaces has nothing to do with the Gauss-Bonnet term given above (2.3). For our purposes the above Gauss-Bonnet relation means that the Einstein-Hilbert term is in two dimensions is a topological invariant i.e. the Einstein tensor in two dimensional space-time is identically zero. This analogy goes through for all Lovelock terms as a corollary to the works of Chern [21] who generalized the theorem of Gauss and Bonnet to higher dimensions finding the relevant higher order curvature scalars. For example we have,

$$\chi[\mathscr{M}_4] = \frac{1}{32\pi^2} \int_{\mathscr{M}} \hat{G} \tag{2.17}$$

and thus the Lanczos or Gauss-Bonnet density is a topological invariant in four dimensions whose integral is the generalised Euler or Chern topological number. Beware this does not mean that the Gauss-Bonnet scalar is zero or constant in four dimensions. It means that the Lanczos density is identically zero $H_{\mu\nu} = 0$ as we admitted earlier.

Dimensionally extending the Chern scalar densities we obtain the Lovelock densities (2.14) i.e. just those densities whose variation leads to second order field equations. Any higher order derivatives present in the variation of Lovelock densities conveniently end up as total divergent terms and thus do not contribute to the field equations. In a similar way for example, in seven or eight dimensions, the six-dimensional Euler density will be promoted to a Lovelock density of third power in the curvature tensor and so forth. This explains the nice and unique properties of the Lovelock densities and Lovelock theory in general. For more details the reader can consult [12].

2.2.2 *Horndeski Theory*

So much for the moment concerning higher dimensional metric theories. In four space-time dimensions we know that the unique classical metric theory is GR with

---

[4] When a surface has a boundary an analogous result holds.

(%/ $$ 9 7!) ! ! ! 1!

discussion on stability of EGB vacua see [37]). The lower branch is ghost free [38] and is the branch that we will consider from now on omitting the '+' branch. The horizon sections, parametrized by the four dimensional metric $h^{(4)}_{\mu\nu}$ are constrained by the field equations to be Einstein spaces,

$$R^{(4)}_{\mu\nu} = \frac{R^{(4)}}{D-2} h^{(4)}_{\mu\nu} \tag{2.38}$$

But as we can see from the lapse function which has to be a function of the radial variable r, a new geometric condition now appears whereupon the horizon quantity ${R^{(4)}}^2 - 6\hat{G}^{(4)}$ has to be constant. Combining the two conditions gives,

$$C^{\alpha\beta\gamma\mu} C_{\alpha\beta\gamma\nu} = \Theta \delta^{\mu}_{\nu} \tag{2.39}$$

where Θ is a given constant and $C_{\alpha\beta\gamma\nu}$ is the four dimensional Weyl tensor associated to $h^{(4)}_{\mu\nu}$. This is a supplementary condition for EGB theories, the Dotti-Gleiser condition, (2.39) imposed in addition to the usual Einstein space condition (2.38) for higher dimensional general relativity. Clearly then, for EGB theory, the lapse function for the black hole carries a supplementary information particular to the type of horizon section for the black hole solution. For example, the Euclidean Schwarszchild metric is not a legitimate internal metric anymore since it does not verify (2.39). Both of the conditions (2.38) and (2.39) present a geometric similarity in that we ask for (part of) *the curvature tensor to be analogous to the spacetime metric*. The main difference being that the curvature tensor in (2.39) is the Weyl tensor and, given its symmetries, it is actually its square which has to be analogous to the spacetime metric. Clearly horizons with $\Theta \neq 0$ will not be homogeneous spaces and not even asymptotically so. Another interesting point is that the Gauss-Bonnet scalar, whose spacetime integral is the Euler characteristic of the horizon, has to be constant for these solutions to be valid. The Gauss-Bonnet scalar of the internal space then reads $\hat{G}^{(4)} = 4\Theta + 24\kappa^2$ and the potential [33, 34],

$$V(r) = \kappa + \frac{r^2}{12\alpha}\left(1 - \sqrt{1 + \frac{12}{5}\alpha\Lambda - 24\frac{\alpha^2\Theta}{r^4} + 24\frac{\alpha M}{r^5}}\right) \tag{2.40}$$

since $R^{(4)} = 12\kappa$. For $\Theta = 0$, we obtain the black holes first discussed by Boulware and Deser (see [39]). In this case since the Weyl curvature is zero the horizon sections are geometries of constant curvature. Taking $\Lambda = 0$ we note that these black holes are asymptotically flat and are an extension of the higher dimensional version of the Schwarzschild solution. In fact taking the limit of α small and large r one obtains precisely the latter GR solution. Recently these black holes have been reported to have a spin 2 instability for small enough mass parameter [40]. This result has been extended to Lovelock black holes [41]. It is not yet understood what is the physical nature of this "short distance scale instability" and if it is somehow related to thermodynamic instability and quantum Hawking radiation.

Putting this aside we now want to examine cases of Einstein metrics whose squared Weyl curvature is not zero but constant. This is a special case of Einstein metric and the Dotti-Gleiser condition is much like a supplementary requirement. What is already clear is that any such solution will not be asymptotically "usual" as the fall off the relevant term is 5 rather than six dimensional. Indeed notice that the Θ-term in (2.40) has a fall off rate of a five-dimensional Boulware-Deser black hole [39] and is therefore dominant over the "usual" mass term contribution, [42]. We now investigate a simple example which will have interesting four dimensional consequences.

Consider a four-dimensional space which is a product of two 2-spheres,

$$ds^2 = \rho_1^2 \left(d\theta_1^2 + \sin^2\theta_1 d\phi_1^2\right) + \rho_2^2 \left(d\theta_2^2 + \sin^2\theta_2 d\phi_2^2\right) , \tag{2.41}$$

where the (dimensionless) radii ρ_1 and ρ_2 of the spheres are constant. The entire six-dimensional metric reads,

$$ds_{(4)}^2 = -V(r)\, dt^2 + \frac{dr^2}{V(r)} + r^2\rho_1^2 \left(d\theta_1^2 + \sin^2\theta_1 d\phi_1^2\right) + r^2\rho_2^2 \left(d\theta_2^2 + \sin^2\theta_2 d\phi_2^2\right) , \tag{2.42}$$

with lapse function

$$V(r) = \frac{R^{(4)}}{12} + \frac{r^2}{12\alpha}\left(1 - \sqrt{1 - 24k^2\alpha - 24\Theta\frac{\alpha^2}{r^4} + 24\alpha\frac{M}{r^5}}\right) . \tag{2.43}$$

In order for (2.42) to be a solution to the equations of motion the spheres have to be of equal radius, $\rho_1 = \rho_2$. This ensures that (2.42) is an Einstein space. The second condition is then immediately verified for a product of 2-spheres. We have $\kappa = \frac{1}{3\rho_1^2} > 0$ and $\Theta = \frac{4}{3\rho_1^4}$. Note that even when the 2-sphere curvature is normalized to $\rho_1 = 1$ then $\kappa \neq 1$. A linear redefinition of the r coordinate then shows that the area of the four dimensional space is reduced compared to the homogeneous 4-sphere. In other words space-time is asymptotically altered by an overall solid angle deficit. This results in a genuine curvature singularity at $r = 0$. Of course when we have $M \neq 0$ there is central curvature singularity at $r = 0$ anyway. But, for (2.42) the $r = 0$ singularity is present *even for zero mass whenever* $\Theta \neq 0$! This is not an artefact of EGB theory. In fact it is easy to see, taking the combined limit of $\alpha \to 0$ and large r, that the resulting GR black hole with $V(r) = \frac{R^{(4)}}{12} + r^2k^2 - \frac{M}{r^3}$ has exactly the same problem at the origin independently of the value of M. For $M = 0$ the GR solution has a naked singularity at the origin. Note again that the lapse function for higher dimensional GR is the same with the higher dimensional Schwarzschild black hole modulo the horizon curvature term. The zero mass solution is singular at the origin wether we are in GR or Lovelock theory. But for Lovelock theory an interesting effect occurs due to the presence of the Θ term in the lapse function.

To see this consider for the moment $M = 0$ in the lapse function (2.42). Then the Θ term in (2.42) is identical to the mass term in the Boulware Deser black hole in five dimensions. Therefore, as we know from the Boulware-Deser solution [39] this extra Θ term generically generates an event horizon cloaking the central $r = 0$ singularity as long as $\alpha \neq 0$! In fact the length scale of this event horizon is given by the coupling constant $\alpha \sim length^2$ which we know from string theory effective actions [43] is related to the fundamental string tension α'. One then can interpret this horizon as a higher order 'quantum' cloak of an otherwise naked singularity present in GR. Details for the horizon structure can be found in [34]. We will come back to this solution in order to construct a Galileon black hole.

Let us, before moving on, make some final remarks regarding these solutions. First we should note that most probably these multiple sphere solutions can be unstable to linear perturbations. It has been shown in GR [31] that there is a "balloon instability" whereupon one of the spheres wants to deflate with respect to the other. This geometric effect may remain true in the above EGB version [33] although the perturbation equations for EGB in lesser symmetry change completely compared to GR. It is also probable that this instability may be stabilized by the inclusion of a magnetic field in the relevant solution [44]. Secondly we should note that the above construction involving multiples of equal radius spheres, can be undertaken in arbitrary even dimensional spacetime as long as we truncate Lovelock theory to EGB. If one considers higher order Lovelock terms it is not known under what geometric conditions the horizon sections will be admissible. One may expect a higher order condition of the type (2.39) in third and higher curvature order... We expect the horizon sections to be more and more constrained as higher order Lovelock terms come into play. At the same time since horizon sections will be of higher dimension this will allow for a richer geometry. This is also an open question. Finally, putting it all together we have arrived to the following result concerning EGB theory: *given the anzatz (2.30), the only asymptotically flat solution of six dimensional EGB theory with zero cosmological constant, is the Boulware Deser solution [39]*. This is because whenever $\Theta \neq 0$ the solution is not asymptotically flat for six dimensional space-time. Therefore we can deduce that EGB theory is very similar in this aspect to four dimensional GR lifting the degeneracy present in higher dimensional GR due to the additional elegant geometric condition (2.39).

2.4 From Lovelock to Horndeski Theory: Kaluza-Klein Reduction

In order to apply higher dimensional Lovelock theory to cosmology or gravity in four dimensional space-time one needs some means of approach to four dimensional gravity. There are at least two routes, braneworlds and Kaluza Klein reduction. In the recent past Lovelock theory had an important implication in the braneworld paradigm [45]. Braneworlds consist of higher dimensional spacetimes endowed with a distributional brane where standard matter is localized. The idea "inspired" in rather loose terms from string theory, is that gravity perceives all the space-time dimensions while matter is localized on a four dimensional braneworld. Since the set-up involves junction or matching conditions an essential feature is the number of extra dimensions, namely codimension, yielding for example a wall or string type of defect. There is a long literature of articles on the subject treating codimension one [12] and codimension two braneworlds (see [46] and references within) involving respectively five and six dimensional EGB theory. In particular Lovelock theory permits, due to the generalized junction conditions [47], well defined codimension two braneworld cosmology [48]. This leads to important consequences since in GR one cannot consider distributional sources for cosmological symmetry and codimension 2. Again, the richer structure of Lovelock theory permits solutions with distributional sources not available in higher dimensional GR. For more details on these aspects see [12] and [46] and references within. Here, we will focus on the more classical Kaluza-Klein compactification since it will give us a direct connection to higher order scalar tensor terms, found in Galileon/Horndeski theory. It will also provide a way to obtain exact black hole solutions [49].

It has been known since a long time [50] that a consistent Kaluza Klein reduction of Lovelock theory gives a scalar-tensor theory with higher order derivatives, but crucially, with second order equations of motion. In this sense many of the Galileon terms discussed later on were known from previous work on Kaluza Klein compactifications and braneworlds [51]. This is the direction we will take here. The most generic of Kaluza-Klein reduction to four dimensions has recently been given in the nice paper of [52]. There it has been shown that only up to the third order Lovelock terms contribute to the Kaluza-Klein compactification in four dimensions. Here we will concentrate on EGB theory i.e. up to second order Lovelock theory. We will consider the simplest consistent toroidal compactification giving rise to one extra scalar degree of freedom.

Start by taking D-dimensional Einstein Gauss-Bonnet theory which is the five or six-dimensional Lovelock theory truncated to arbitrary dimension. The arbitrary dimension D will be important when we end up promoting dimension from a positive integer to a real parameter once we have undertaken a consistent Kaluza-Klein reduction. We have the EGB action with a cosmological constant,

$$S = \frac{1}{16\pi G_N} \int d^D x \sqrt{-g} \left[-2\Lambda + R + \hat{G} \right] \tag{2.44}$$

Consider now the simplest but consistent diagonal reduction along some arbitrary n-dimensional internal curved space $\tilde{\mathbf{K}}$. We aim to reduce this theory down to four space-time dimensions with $D = 4 + n$:

$$ds^2_{(4+n)} = d\bar{s}^2_{(4)} + e^{\phi} d\tilde{K}^2_{(n)} \,. \tag{2.45}$$

This particular frame is chosen in such a way as so there is no conformal factor of ϕ in front of the four-dimensional metric. As such the asymptotic character (i.e. radial fall off) of a Lovelock D dimensional solution will be similar to the four dimensional one. All terms with a tilde refer to the curved n-dimensional internal space, while terms with a bar refer to the (4)-dimensional space-time. One can show for the given metric Anzatz that the KK reduction for n arbitrary is consistent, i.e. that the reduced equations of motion are derived from the reduced action [53]. This reduction is therefore generalised in the manner defined in [54, 55]. The important result of this is that the integer n corresponding to the compact Kaluza-Klein space can be analytically continued to a real parameter of the reduced action. Naturally n corresponds to a dimension only for n integer. The solutions from the four dimensional point of view are still solutions of the resulting effective action for arbitrary n. The four dimensional effective action reads after integrating out the internal space,

$$\begin{aligned}\bar{S}_{(4)} = \int d^4x\, \sqrt{-\bar{g}}\, e^{\frac{n}{2}\phi} \Big\{ & \bar{R} - 2\Lambda + \alpha\bar{G} + \frac{n}{4}(n-1)\partial\phi^2 - \alpha n(n-1)\bar{G}^{\mu\nu}\partial_\mu\phi\partial_\nu\phi \\ & -\frac{\alpha}{4}n(n-1)(n-2)\partial\phi^2\nabla^2\phi + \frac{\alpha}{16}n(n-1)^2(n-2)\left(\partial\phi^2\right)^2 \\ & + e^{-\phi}\tilde{R}\left[1 + \alpha\bar{R} + \alpha 4(n-2)(n-3)\partial\phi^2\right] + \alpha\tilde{G}e^{-2\phi}\Big\}\ , \end{aligned} \tag{2.46}$$

For $\alpha = 0$ this effective action is just the usual toroidal KK effective action. The higher order Gauss-Bonnet term gives rise to several higher order scalar-tensor Galileon (or equivalently Horndeski) terms, [14, 15, 56, 57] with very particular potentials. The Galileon field ϕ can then simply be understood to be the scalar field parametrising the volume of the internal space.

Indeed, apart from the usual lower order terms appearing in standard Kaluza Klein compactification of Einstein dilaton theories, we see the emergence of several higher order terms. For a start we have the four dimensional Gauss Bonnet term $\bar{G}$ which will contribute to the scalar field variation although it is a topological term for four dimensional GR. Secondly we have $\bar{G}^{\mu\nu}\partial_\mu\phi\partial_\nu\phi$ involving the coupling of the Einstein tensor with the kinetic term. Here, rather than metric-scalar interaction, as for the standard kinetic term of ϕ we have a curvature-scalar interaction which we will see has very interesting consequences in the forthcoming section. This term has equations of motion of second order essentially due to the divergence free property of the Einstein tensor $G_{\mu\nu}$. For example if one considers $\bar{R}^{\mu\nu}\partial_\mu\phi\partial_\nu\phi$ this is not true. It has also shift symmetry in the scalar field typical of certain Galileon terms. Furthermore we have, what is often called the DGP term, $\partial\phi^2\nabla^2\phi$ appearing in the decoupling limit of the DGP model [25] and then the standard Galileon term $\left(\partial\phi^2\right)^2$ which are also shift symmetric in ϕ. The last line in the effective action takes part only for a curved internal space in the face of Ricci and Gauss Bonnet curvature. Reducing from the EGB action yields terms up to quartic order in derivatives (either of the metric or the scalar, or a mixed combination of the two). Reducing higher order Lovelock densities yields terms with a higher number of derivatives. A typical example is the higher order permissible curvature-scalar interaction,

$$P^{\mu\nu\alpha\beta}\nabla_\mu\phi\nabla_\alpha\phi\nabla_\nu\nabla_\beta\phi \tag{2.47}$$

which involves six derivatives and one can show [9] originates from the Kaluza-Klein reduction of the third order Lovelock density [52]. Again the reader will recollect the divergence freedom of the double dual tensor giving second order field equations. Taking for example $R^{\mu\nu\alpha\beta}\nabla_\mu\phi\nabla_\alpha\phi\nabla_\nu\nabla_\beta\phi$ would fail this Galileon property.

Although this effective action is very complex, and its field equations even more so, it is "simple" to generate solutions for the above (2.46) in four dimensions [53]. One starts from a convenient Lovelock solution in D dimensions. Since we want the four dimensional solution to have, at least locally, spherical horizon sections we have to consider a solution where the $(D-2)$ dimensional horizon sections are $(D-2)/2$-products of two spheres. This is precisely the extension of the six dimensional solution we discussed in the previous section (2.42) generalized to arbitrary dimensions [53]. The solution reads,

$$d\bar{s}^2_{(4)} = -V(R)dt^2 + \frac{dR^2}{V(R)} + \frac{R^2}{n+1} d\bar{K}^2_{(2)}\,, \tag{2.48}$$

$$V(R) = \kappa + \frac{R^2}{\tilde{\alpha}_r}\left[1 \mp \sqrt{1 - \frac{2\tilde{\alpha}_r}{l^2} - \frac{2\tilde{\alpha}_r^2\kappa^2}{(n-1)R^4} + \frac{4\tilde{\alpha}_r m}{R^{3+n}}}\right], \tag{2.49}$$

$$\tilde{\alpha}_r = 2\alpha n(n+1), \qquad \frac{1}{\ell^2} = \frac{-2\Lambda}{(n+2)(n+3)} \tag{2.50}$$

$$e^\phi = \frac{R^2}{n+1}\,, \tag{2.51}$$

Here, n is the dimension of the internal space minus one 2-sphere in other words, $n = D-4$. This is the higher dimensional interpretation of n but once the solution is written out we simply take n an arbitrary real number and (2.48) is still an exact solution and n parametrizes the theory. In our notation here $\kappa = 0, 1, -1$ is the normalised horizon curvature and we have redefined for this section the constants $\tilde{\alpha}_r$ and ℓ. Taking carefully the $\tilde{\alpha}_r \to 0$ limit, gives a standard Einstein dilaton solution with a Liouville potential [49]. Set $\Lambda = 0$, $\kappa = 1$ and let us start by making some qualitative remarks describing properties of the solution without entering into technical details. Note that, taking carefully the $n = 0$ limit switches off the scalar field and the higher-derivative corrections, and we obtain pure GR in (2.46) and a Schwarzschild black hole (2.48). This is particularly interesting since the scalar-tensor solution given above for arbitrary n is a continuous deformation of the Schwarzschild solution. When n is in the neighborhood of zero we are closest to the GR black hole. As we hinted in the previous section the topology of the solution is not that of GR. Indeed the warp factor of the 2-sphere, in (2.48), is recovered only at $n = 0$, i.e. the GR limit. Otherwise the area of the reduced spherical horizon is given by $\frac{4\pi R^2}{n+1}$ rather than the 2-sphere area, $4\pi R^2$. This is again a solid deficit angle (and not a conical deficit angle) the same one we encountered for the Lovelock solution in the previous section. As stressed in the previous sections this will give, at $R = 0$, a true curvature singularity even if $m = 0$. For large R, we have a spacetime metric very similar to that of a gravitational monopole [58]. Expanding 2.49 for small $\tilde{\alpha}_r$ and large R gives,

$$V(R) = 1 + \frac{\tilde{\alpha}_r}{(n-1)R^2} - \frac{2m}{R^{n+1}} + \dots \tag{2.52}$$

This solution is reminiscent of a RN black hole solution where the role of the electric charge is undertaken by the leading horizon curvature correction in $\tilde{\alpha}_r$. This is the particular Θ term we discussed in the previous section. This term dominates the mass term close to the horizon and for $n < 1$. Note that it can be of negative sign depending on the value of n and $\tilde{\alpha}_r$. The further we are from $n = 0$, the GR limit, the further we deviate from a standard four-dimensional radial fall-off. The first important question we want to deal with is the central curvature singularity at $R = 0$, which is due to the solid deficit angle and is present even if $m = 0$. Also note that whenever the square root in the lapse function (2.49) is zero we also have a branch singularity which is also a dangerous curvature singularity. Setting $m = 0$, we find that for $-1 < n < 1$ and $\tilde{\alpha}_r > 0$ the singularity at $R = 0$ is covered by an event horizon created by the higher-order curvature correction. In its absence ($\tilde{\alpha}_r = 0$), this solution would have been singular...The UV (small R) behaviour of the solution is therefore regularised by the presence of the higher-order terms. If $n > 1$ or $n < -1$, then $\tilde{\alpha}_r < 0$ is needed in order to preserve the event horizon. The remaining cases are singular.

Now let us switch on the mass, $m \neq 0$. Whenever $\tilde{\alpha}_r > 0$, we have a single event horizon. When $-1 < n < 1$, there is no branch singularity however small m is. On the contrary, when $n > 1$, the mass is bounded from below in order to avoid a branch singularity:

$$m > \left(\frac{2}{n+3}\right)^{\frac{n+3}{4}} \frac{\tilde{\alpha}_r^{\frac{n+1}{2}}}{n-1}\,. \tag{2.53}$$

When $n < -1$, the solution is also a black hole but the mass term is not falling off at infinity. The region of most immediate interest is whenever n is small but not zero.

The black hole properties are rather different for $\tilde{\alpha}_r < 0$. When $-1 < n < 1$, there is an inner and an outer event horizon as long as the following condition is fulfilled:

$$\left(\frac{1}{2}\right)^{\frac{n+1}{2}} < \frac{m(1-n)}{|\tilde{\alpha}_r|^{\frac{n+1}{2}}} < \left(\frac{2}{n+3}\right)^{\frac{n+3}{4}}\,. \tag{2.54}$$

When $n > 1$, a single event horizon exists, covering a single branch singularity with $R_s < R_h$.

Overall we can say that the KK solution given here has an interesting horizon structure and presents again a quantum cloaking of an otherwise Einstein-Dilaton singular solution. It is however not of ordinary asymptotics bifurcating in this way the no hair paradigm for Galileons [59]. In the last section we will see a way to construct asymptotically ordinary solutions with fake black hole hair.

2.5 Self-tuning and the Fab 4

As we saw in the previous sections Horndeski or Galileon theory encompasses all the possible (single) scalar tensor terms one can consider in order for the equations of motion to be of second order. This is an essential requirement for a well-defined classical modification of gravity [5]. In this section we will question which of the terms in scalar-tensor theory have "self-tuning" properties. Self-tuning is a rather simple and quite old idea with application to the cosmological constant problem. The basic principle consists of finding solutions for flat (or possibly maximally symmetric vacua) of some gravity action endowed with a bulk cosmological constant, independently of the value of the cosmological constant in the action. In order for self-tuning (and not fine tuning) to be effective the cosmological constant should not be fixed with respect to any of the coupling constants in the gravitational action. The idea then is that the cosmological constant is absorbed by a dynamical solution involving the non-trivial scalar field without affecting the gravitational background. This can only be a "partial" solution to the cosmological constant problem since radiative corrections will destabilize this vacuum solution beyond a certain energy scale, the cutoff of the effective gravity theory. It is however an interesting first step especially since no theories were known, before [9], to have such a property without some hidden effective fine tuning of the action coupling constants as for example in codimension one braneworld models (see for example [60]). We should note that recently there has been considerable progress on protecting the cosmological constant from standard model radiative corrections [61] and we refer the interested reader to this article for the model in question which interestingly is a rather minimal extension of GR. Rather, for our purposes, having at hand the general scalar tensor theory we will formulate the following question: is there a subset of Horndeski theory with self-tuning properties? The answer is affirmative as shown in [9], yielding a rather simple and neat geometrical theory which was dubbed by the authors as Fab 4 theory. We start by presenting the theory and then give a specific self tuning solution which elegantly and non-technically gives the general idea. We close the section by showing a simple method to obtain regular black hole solutions in fab 4 and Horndeski theory, independently of self-tuning.

The Fab 4 potentials make up the most general scalar-tensor theory capable of self-tuning. They are given by the following geometric terms,

$$\mathscr{L}_{john} = \sqrt{-g}V_{john}(\phi)G^{\mu\nu}\nabla_\mu\phi\nabla_\nu\phi \tag{2.55}$$

$$\mathscr{L}_{paul} = \sqrt{-g}V_{paul}(\phi)P^{\mu\nu\alpha\beta}\nabla_\mu\phi\nabla_\alpha\phi\nabla_\nu\nabla_\beta\phi \tag{2.56}$$

This procedure gives us an easy way to determine the metric on a sphere. Simply take the metric (2) $ds^2 = dr^2 + r^2 d\theta^2 + r^2 \sin^2\theta d\varphi^2$ and set $r = a$. Then $dr = 0$, so that ds^2 collapses to $a^2(d\theta^2 + \sin^2\theta d\varphi^2)$. From 3-dimensional flat space we have "lost" the coordinate r and gone to a 2-dimensional curved space with coordinates $x^\mu = (x^1, x^2) = (\theta, \varphi)$. Without loss of generality, we can take a as the unit of distance and set $a = 1$. So, on the unit 2-dimensional sphere S^2

$$ds^2 = d\theta^2 + \sin^2\theta d\varphi^2 \tag{3}$$

with a metric given by $g_{11} = g_{\theta\theta} = 1$, $g_{22} = g_{\varphi\varphi} = \sin^2\theta$, and $g_{12} = g_{\theta\varphi} = g_{21} = g_{\varphi\theta} = 0$.

The take-home message here is that curved space is just a skip and a hop away from the familiar change of coordinates. This is fortunate for students of physics: when you learned to change coordinates, you were actually also learning about curved spaces. We are now going to develop a general formalism for changing coordinates. Even though you already know how to change coordinates, it pays to learn this formalism, because we can also use it to study curved space and curved spacetime (which, as you have surely heard, plays a central role in Einstein gravity).

Change of coordinates, curved space, and curved spacetime: basically the same deal, as you will see.

How do we know whether a space is curved or not?

This raises an exceedingly interesting and crucial question: given a space with the metric $g_{\mu\nu}(x)$, how do we know whether it is curved or flat?

A complicated looking metric does not necessarily mean that the space is curved, since somebody could have simply chosen an especially gunky coordinate system. It could be flat space in disguise. To forcefully bring home this point, I invite you to consider $ds^2 = (1 + u^2)du^2 + (1 + 4v^2)dv^2 + 2(2v - u)dudv$ and $ds^2 = (1 + u^2)du^2 + (1 + 2v^2)dv^2 + 2(2v - u)dudv$. One describes flat space, the other a space that at some points is violently curved. Which is which?

Puzzled, you reply: "How could I possibly tell?"

That's in fact the correct answer at this stage of this discussion. The two metrics I just gave you look almost identical except for one single 2 → 4. In one of the most famous episodes in mathematics, Carl Friedrich Gauss (1777–1855) solved this problem for 2-dimensional spaces. His work was then generalized by his student Bernhard Riemann (1826–1866). Later, in chapter VI.1, given any metric in any number of dimensions, you will be able to calculate, and even better, to train the computer to calculate, something called the Riemann curvature tensor, which will tell you once and for all if the space is flat or curved. No more thinking involved! Gauss and Riemann did it for you.

But for now, let me ask you to think about two simple examples in good old 2-dimensional space, for which our intuition is allegedly pretty good. We know that $ds^2 = dr^2 + r^2 d\theta^2$ describes flat space. Consider

$$ds^2 = d\rho^2 + \sin^2\rho \, d\theta^2 \tag{4}$$

Is the space being described flat or curved? Or consider the space described by

$$ds^2 = \cos^2 \rho \, d\rho^2 + \sin^2 \rho \, d\theta^2 \tag{5}$$

Is it flat or curved? You should think about this before reading on. The answers are given in appendix 1.

Remember the civilization of mites in the prologue? You are in the same position as the mite professors of geometry: they can measure the distance between infinitesimally separated points, and from that they have to figure out whether their world is curved. We will face the same problem as the mites when we get to cosmology in parts V and VI.

The logic of differential geometry

Differential geometry, as developed by Gauss and Riemann, tells us that given the metric, we can calculate the curvature. The logic goes as follows. The metric tells you the distance between two nearby points. Integrating, you can obtain the distance along any curve joining two points, not necessarily nearby. Find the curve with the shortest distance. By definition, this curve is the "straight line" between these two points. Once you know how to find the "straight line" between any two points, you can test all of Euclid's theorems to see whether our space is flat. For example, as described in the prologue, the mite geometers could now draw a small circle around any point, measure its circumference, and see if it is equal to 2π times the radius. (See appendix 1.) Thus, the metric can tell us about curvature.

Take an everyday example: given an airline table of distances, you can deduce that the world is curved without ever going outside. If I tell you the three distances between Paris, Berlin, and Barcelona, you can draw a triangle on a flat piece of paper with the three cities at the vertices. But now if I also give you the distances between Rome and each of these three cities, you would find that you can't extend the triangle to a planar quadrangle (figure 1). So the distances between four points suffice to prove that the world is not flat. But the metric tells you the distances between an infinite number of points.

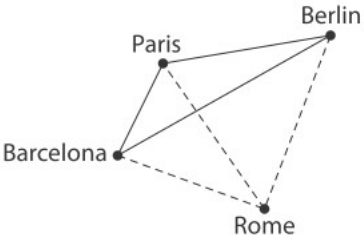

Figure 1 The distances between four cities suffice to prove that the world is not flat.

One can trace the origin of such terms in the early works of GAUSS who measuring geodesic distances noted that scalar (Gauss) curvature of two dimensional surfaces depended only on the first fundamental form, in other words the intrinsic metric of the surface and its derivatives.

This was the basis of what he called the Egregium theorem; scalar curvature (unlike (diferente) other extrinsic curvature (components) does not depend on the variation of the normal vector field on the surface i.e. on how the surface is embedded in three dimensional space.

Then later, for Euler in his work on surface triangulations noted that two dimensional surfaces can be topologically classified by their "Euler" number,

Curved Spaces: Gauss and Riemann

Fear of curves

Surely you have heard that Einstein gravity involves curved spacetime. In my experience, the very mention of the Riemann curvature tensor, which we will come to in due time, inspires fear and trembling in many beginning students of general relativity. “I was doing well in the course,” students would moan, “until we started doing Riemannian geometry!” I actually have a great deal of sympathy for these students: very little in their background prepares them for the Riemann curvature tensor. Unless they have taken an exceptionally good mechanics course, with studies of particle motion on curved surfaces, they typically have no prior exposure to the massive amount of rather technical material needed to calculate the Riemann curvature tensor. Dear reader, take heart: even Einstein had to struggle to master differential geometry.

Given this frightening reputation of Riemannian geometry, we will take baby steps toward curvature. My pedagogical strategy is to first deal with surfaces that you can practically imagine holding in your hands.

Introducing Professor Flat

As I was encouraging a fearful student, Professor Flat came ambling along. A mild mannered man with a somewhat disheveled look, he inquired gently, “Why all the trembling?” We told him, and he nodded. Then he asked the fearful student, “Do you know why it took humans so long to realize that the world was round?”

FS: “Because the world is locally flat, and humans can’t walk very fast.”

PF: “Exactly! In everyday life, we have no need to know that the world is actually round, as long as the distance scale of interest is small compared to the earth’s radius. If you focus on a small enough region on any surface—or any space in any dimension for that matter—it's going to look flat, and you could simply study the small deviation from flat space. Nothing terribly frightening at all!"

Tangent plane

So indeed, let's follow Professor Flat's advice. To get some feel for curvature, let us keep things simple and be content to take some nice curved space, roundish like the sphere. Imagine approaching it with a flat plane until it touches the surface at some point P. The plane is then known as the tangent plane. To focus our minds, consider a sphere of radius L. Since all points on it are equivalent, we might as well have the plane touch the south pole and be perpendicular to the z-axis joining the north and south poles. The southern hemisphere is defined by $z = -\sqrt{L^2 - x^2 - y^2} + L$, where we added the constant L to the usual definition of z so that for convenience, $z = 0$ at the point P we are interested in (the south pole in this case). Near the south pole, $z \simeq \frac{1}{2L}(x^2 + y^2)$: the sphere is locally a parabolic bowl and is well approximated by the tangent plane. It is in this sense that Professor Flat says that the surface is locally flat.

So, consider the tangent plane touching the roundish surface we are studying at some point P. See figure 1. Let z denote the coordinate perpendicular to the plane, and (x, y) the coordinates in the plane, with the point P coordinatized by $(x, y) = (0, 0)$. Locally, we have a quadratic expansion in the small quantities x and y: $z = \frac{1}{2}ax^2 + cxy + \frac{1}{2}by^2$. Here a, b, c have dimension of inverse length, and thus the local region is defined by x, y small compared to a^{-1}, b^{-1}, c^{-1}. (For the sphere, $c = 0$ and $a = b = 1/L$.) Applying Pythagoras, we obtain the distance squared between two nearby points with coordinates (x, y) and $(x + dx, y + dy)$:

$$\begin{aligned} ds^2 &= dx^2 + dy^2 + dz^2 = dx^2 + dy^2 + [(ax + cy)dx + (by + cx)dy]^2 \\ &\equiv g_{xx}dx^2 + g_{yy}dy^2 + 2g_{xy}dxdy \end{aligned} \tag{1}$$

with the metric

$$g_{xx} = 1 + (ax + cy)^2,\ g_{yy} = 1 + (by + cx)^2,\ g_{xy} = (ax + cy)(by + cx) \tag{2}$$

Note that even for the sphere, the metric regarded as a 2-by-2 matrix contains an off-diagonal term in this locally flat coordinate system. Of course, for $x, y \to 0$, the off-diagonal term vanishes and the metric approaches the identity matrix.

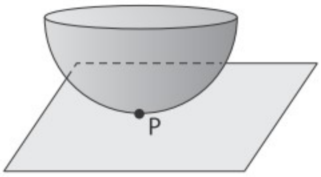

Figure 1 The tangent plane to a curved surface.

We could also write $z \simeq \frac{1}{2}\vec{x}^T M\vec{x}$, with $M = \begin{pmatrix} a & c \\ c & b \end{pmatrix}$ and $\vec{x} = (x, y)$ a column vector which we are writing as a row vector for typographical reasons mentioned in chapter I.3. But we can always rotate the coordinates $\vec{x} = (x, y)$ to some other coordinates $\vec{x}' = (u, v)$ given by $\vec{x}' = \mathcal{R}\vec{x}$. We want the curvature to be an invariant geometric concept not dependent on our coordinate choices. In the new coordinates, M is replaced by $M' = R^{-1}MR$. We know that M possesses two invariant quantities, namely its two eigenvalues μ and ν. But this dovetails perfectly with our discussion in the prologue.

Remember the ant going for her honey? We learned from that story that at a given point, a curved space has an intrinsic and an extrinsic curvature. It all makes sense, then: these two curvatures correspond to the two invariant quantities contained in M. As you will see, we could exploit similar reasoning, asking how things transform under a change of coordinates, to determine the curvature of Riemannian spaces of any dimension.

Let us diagonalize M, so that in the new coordinate basis* $z = \frac{1}{2}\mu u^2 + \frac{1}{2}\nu v^2$. Thus, we have the intuitive result that any surface is locally the sum of two parabolas, $z = \frac{1}{2}\mu u^2 + \frac{1}{2}\nu v^2$, with μ^{-1} and ν^{-1} the radius of curvature of the parabola in the u and in the v direction, respectively. (Expand a circle of radius L around some point, in the same way that we expanded a sphere earlier, $y = -\sqrt{L^2 - x^2} + L \simeq \frac{1}{2L}x^2$, and we see that it is locally a parabola with radius of curvature equal to L.)

Intrinsic versus extrinsic

For a 2-by-2 matrix, its determinant and trace, or equivalently, its two eigenvalues, constitute its two basis-independent attributes. Our insistence that the measure of surface curvature does not depend on whether we use the x, y or the u, v coordinates means that we can have two measures of surface curvature:

$$\text{Intrinsic curvature} = \det M = \mu\nu = ab - c^2 \tag{3}$$

$$\text{Extrinsic curvature} = \left(\tfrac{1}{2}\text{tr}M\right)^2 = \tfrac{1}{4}(\mu + \nu)^2 = \tfrac{1}{4}(a + b)^2 \tag{4}$$

(Note that I have defined the extrinsic curvature to have the same dimension as the extrinsic curvature. The normalization factor $\frac{1}{4}$ is such that the intrinsic and extrinsic curvatures of the sphere, for which $a = b$, $c = 0$, are equal.)

How do I know which is which, intrinsic versus extrinsic curvature? We appeal to the cylinder in the prologue as an example, knowing that it is intrinsically flat. Indeed, for a cylinder† of radius L, $z = -\sqrt{L^2 - x^2} + L$ independent of y and hence $b = c = 0$. We have intrinsic curvature $= 0$ and extrinsic curvature $= a^2 = 1/L^2$, as we would expect. In

---

[*] Note that while M is diagonal, the metric is not.

[†] The cylinder example also underlines the fact that we are always talking about local curvature, as explained in the preceding chapter. Globally, the mites could of course go all the way round and come back to the same place.

Einstein gravity, we are normally only interested in the intrinsic curvature of spacetime, since we can't get out* of spacetime and look at its extrinsic curvature.

Negative curvature

A sphere of radius L has intrinsic and extrinsic curvatures both equal to $1/L^2$. Since every point on the sphere is the same as the south pole, the sphere has constant intrinsic and extrinsic curvatures.

A beginning student named Confusio[1] looked, well, confused. He said: "You mean the curvature at the bottom of a bowl and at the top of a dome are not opposite in sign? Everybody knows that the bowl is curved upward, the dome downward."

Confusio's everyday intuition caused him to think that he was somehow inside the bowl and outside the dome. In fact, the sphere is an infinitely thin surface. There is no conceptual distinction between being on the "inside" and the "outside" of the surface. Of course, we could also turn the bowl upside down. Let's calculate the curvature at "the top of the dome," as Confusio calls it, otherwise known as the north pole. Near the north pole, $z = \sqrt{L^2 - x^2 - y^2} - L \simeq -\frac{1}{2L}(x^2 + y^2)$, so that $a = b = -\frac{1}{L}$, $c = 0$. Thus, the intrinsic curvature is $ab - c^2 = \frac{1}{L^2}$, as expected. Compared to the neighborhood around the south pole, z flips sign, but dz^2 does not, so that the metric, and hence the curvature, have the same value at the north pole and at the south pole, as they should.

Thus, in contrast to everyday perception, a negative curvature surface[2] is one in which the two parabolas bend in opposite directions, $\mu = -\nu$, such as the proverbial saddle. A more contemporary example is the kind of potato chips that come in a cylindrical container. I am surmising that the typical reader of this text is more likely to eat potato chips than to gallop across the steppes with the Golden Horde. An example is a surface that goes like $z = xy$ for $x \simeq 0$, $y \simeq 0$. Then $a = b = 0$, $c = 1$, and $\mu = 1$, $\nu = -1$, and it has negative curvature $R = -1$ at the origin.

Professor Flat: "Confusio, you still look confused. Think of a donut or a bagel, otherwise known as the torus. Do you see that along its hole, the curvature is negative? Along the outer edge, in contrast, the curvature is positive."

Incidentally, it then follows that somewhere on the torus the curvature (we are always talking about intrinsic curvature) vanishes. Do you see where? You could always use the tangent space method here to calculate the curvature and thus check your intuition.

Embedding of curved spaces in higher dimensional flat spaces

In general, we could embed[3] a D-dimensional space in N-dimensional Euclidean space E^N. Write $X^A(x^1, \cdots, x^D)$ for $A = 1, \cdots, N$. For everyday surfaces, $D = 2$ and $N = 3$, but the formalism to be given presently works for arbitrary values of $N > D$. (For the iconic sphere, $(x^1, x^2) = (\theta, \varphi)$ and $(X^1, X^2, X^3) = (X, Y, Z) = (\sin\theta\cos\varphi, \sin\theta\sin\varphi, \cos\theta)$.) We see that x represents coordinates on the surface: as x^μ varies, the points $X^A(x)$ sweep out a D-dimensional space in E^N. In this age of spectacular computer graphics, you can easily generate all kinds of interesting surfaces by playing around with three functions $X^A(x)$ of two variables.

---

* Except in some speculative and unproven theories!

Consider two neighboring points: P described by x^μ and Q described by $x^\mu + dx^\mu$. If the Euclidean coordinates of P are given by X^A, then the Euclidean coordinates of Q are given by $X^A + dX^A = X^A + \frac{\partial X^A}{\partial x^\mu} dx^\mu$. Pythagoras gives us the distance squared between P and Q

$$ds^2 \equiv \sum_A (dX^A)^2 = \sum_A \frac{\partial X^A}{\partial x^\mu} dx^\mu \frac{\partial X^A}{\partial x^\nu} dx^\nu \equiv g_{\mu\nu} dx^\mu dx^\nu \tag{5}$$

with the metric

$$g_{\mu\nu} = \sum_A \frac{\partial X^A}{\partial x^\mu} \frac{\partial X^A}{\partial x^\nu} \tag{6}$$

Here I choose to display the summation over A explicitly. The attentive reader wlll realize that (1) and (2) are examples of these two equations. The metric $g_{\mu\nu}$ is said to be induced by the ambient Euclidean metric.

Another common embedding method is to restrict X^A to satisfy certain conditions. Again, we have the familiar example of the unit sphere defined by $X^2 + Y^2 + Z^2 = 1$. Indeed, writing (X, Y, Z) in terms of (θ, φ) amounts to solving this equation. Instead, we could choose to eliminate* Z. In the notation used above, $(x^1, x^2) = (X, Y)$. Then, $ds^2 = dX^2 + dY^2 + dZ^2 = dX^2 + dY^2 + \frac{(XdX + YdY)^2}{1 - X^2 - Y^2}$. We can clearly exploit the rotational invariance in the $(X$-$Y)$ plane and write[4] $X = r\cos\varphi$, $Y = r\sin\varphi$, $X^2 + Y^2 = r^2$, and $XdX + YdY = rdr$, thus obtaining

$$ds^2 = dr^2 + r^2 d\varphi^2 + \frac{r^2 dr^2}{1 - r^2} = \frac{dr^2}{1 - r^2} + r^2 d\varphi^2 \tag{7}$$

Since the metric in (7) and the usual $ds^2 = d\theta^2 + \sin^2\theta d\varphi^2$ both describe the sphere, they must be related by a coordinate transformation. Do you see how? Another question for you: Why does (7) become singular as $r \to 1$? See appendix 1. Further examples of embedding are given in appendix 2.

Locally flat

The fearful student looks much more relaxed. He asks, "All this is clear enough for actual 2-dimensional surfaces I can visualize, but is it obvious that we can always choose our neighborhood to be locally flat for any space of any dimension D?"

---

* The two solutions of the quadratic equation for Z define two coordinate patches covering the northern and southern hemispheres (minus the equator, strictly speaking), as mentioned in the preceding chapter.

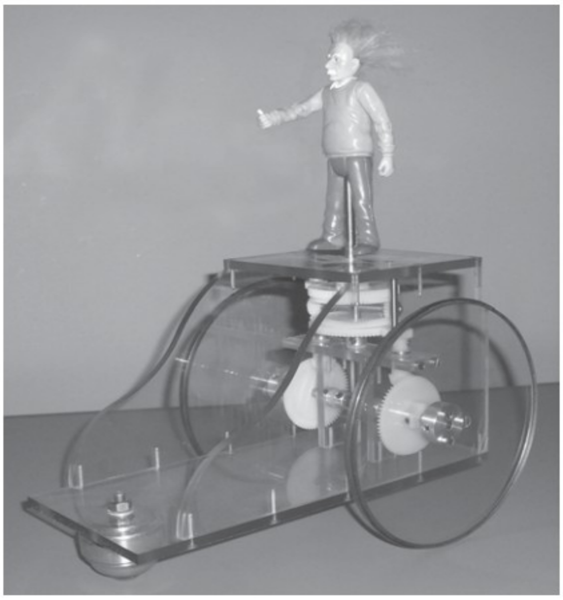

Figure 5 A modern version of the south-pointing carriage described in ancient Chinese chronicles.

Gauss's strategy

To determine the curvature of the surface at a given point P, Gauss's strategy was to study curves on the surface passing through P and calculate their curvatures. This sounds puzzling at first. How did Gauss expect to determine[6] the curvature of a surface by studying the curvature of curves lying on the surface?

To motivate his reasoning, consider the curvature at the saddle point P with coordinates $(x = 0,\ y = 0)$ on the surface $z = \frac{1}{2}px^2 - \frac{1}{2}qy^2$, taking $p > 0,\ q > 0$ for definiteness (a special case of the surface considered in chapter I.5). Imagine yourself walking along the ridge defined by $y = 0$: on both sides of you, the land falls away (see figure 6). When you reach the lowest point $x = 0$ on the ridge, the land in front of you and behind you rises up. Consider the family of curves going through P. For a curve pointing in the y direction, the curvature is positive, while for a curve pointing in the x direction, the curvature is negative. Evidently, for a curve pointing in some other direction, the curvature is intermediate between two extremal values. Gauss proposed to find these two extremal values.

So for a given point P on a curved space, let's look at some curve going through that point and study its tangent vector $\vec{t} = t^\mu \vec{e}_\mu$ with $t^\mu = \frac{dX^\mu}{dl}$. Then

$$\frac{d\vec{t}}{dl} = \frac{dt^\mu}{dl}\vec{e}_\mu + t^\mu \frac{d\vec{e}_\mu}{dl} \tag{13}$$

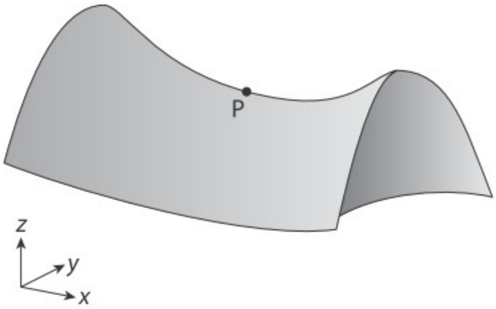

Figure 6 Determining the curvature of a surface with a saddle point P.

Write the right hand side as some linear combination of $\vec{e}_1$, $\vec{e}_2$, and $\vec{n}$, so that

$$\frac{d\vec{t}}{dl} = \kappa_g \vec{e} + \kappa_n \vec{n} \tag{14}$$

with $\vec{e}$ some unit vector given by some linear combination of $\vec{e}_1$ and $\vec{e}_2$. Note in passing that since $\vec{t} \cdot \vec{t} = 1$, we have $\vec{t} \cdot \frac{d\vec{t}}{dl} = 0$ and so $\vec{t} \cdot \vec{e} = 0$. The three unit vectors $\vec{n}$, $\vec{t}$, and $\vec{e}$ form an orthonormal triad. Note also that $\vec{e}_\mu$ and $\vec{n}$ pertain to the surface, while $\vec{t}$ and $\vec{e}$ pertain to the curve.

To get a feel for the two quantities κ_g and κ_n in (14), consider a couple of surfaces. Draw a couple of pictures as you read the next two paragraphs. That will make it easy to follow what I am talking about, which is not much more than common spatial sense.

First, a plane flat as Kansas. Through P draw a curve as curvy as you like, and you can make κ_g as large as you like. But try as you may, $\frac{d\vec{t}}{dl}$ will stay in the plane by definition, and κ_n will remain stubbornly equal to 0. Evidently, κ_g does not tell us about the curvature of the surface, merely the curvature of the curve.

Next, picture a sphere, and let P be Copenhagen, say. Following Gauss, consider a variety of curves going through Copenhagen. For example, think of the circle of constant latitude. Then $\frac{d\vec{t}}{dl}$ points toward the axis of the earth joining the north and south poles and can be written as in (14) with $\vec{e}$ pointing north along some street in Copenhagen and $\vec{n}$ pointing upward* at the sky (as always, independent of where we are). As we try different curves, κ_g and κ_n vary. If we choose the curve to be the circle of constant longitude (rather than latitude) going through Copenhagen, κ_g vanishes, while $|\kappa_n|$ is maximized, given by the inverse of the earth's radius. Indeed, $|\kappa_n|$ attains its maximum value for the two great circles going through Copenhagen. If you have trouble with this, try drawing a picture.

This example shows clearly that it is κ_n, not κ_g, that tells us about the curvature of the surface. You can further convince yourself by picturing other examples, such as the ridge you were walking on earlier. While there is an infinite number of surfaces with different global properties, if we focus on a local patch of the surface around a point P, there are only a couple prototypical surfaces, sphere-like or ridge-like, so to speak.

---

* With this convention (rather than pointing downward toward the center of the earth, as would be mathematically more natural), $\kappa_g > 0$ while $\kappa_n < 0$.

From curvature of curves to curvature of surface

Using (13) and (7), we have (suppressing terms not of interest to us)

$$\frac{d\vec{t}}{dl} = \cdots + t^\mu \frac{d\vec{e}_\mu}{dl} = \cdots + t^\mu \frac{\partial \vec{e}_\mu}{\partial x^\nu} t^\nu = \cdots + t^\mu (K_{\mu\nu}\vec{n}) t^\nu \tag{15}$$

Comparing with (14), we can extract

$$\kappa_n = K_{\mu\nu} t^\mu t^\nu \tag{16}$$

A digressive word about what appears to physicists as rather quaint terminology. Strip the dl off $t^\mu = \frac{dx^\mu}{dl}$ in κ_n and we encounter the combination $K_{\mu\nu} dx^\mu dx^\nu$, known to classical differential geometers as the second fundamental form.[7] Sounds pretty important. Then what do these guys call the first fundamental form? None other than our beloved infinitesimal distance squared: $g_{\mu\nu} dx^\mu dx^\nu$.

Next, differentiate $\vec{t} \cdot \vec{n} = 0$ to obtain (using (14))

$$\vec{t} \cdot \frac{d\vec{n}}{dl} = -\vec{n} \cdot \frac{d\vec{t}}{dl} = -K_{\mu\nu} t^\mu t^\nu = -\kappa_n \tag{17}$$

known as Weingarten's equation after Julius Weingarten (1836–1910).

Gauss's idea was to look at all curves passing through the point P. For each curve, calculate κ_n. Following the great man, we are supposed to find the extremal values of κ_n. So, let us extremize $K_{\mu\nu} t^\mu t^\nu$. But t^μ is not entirely free to vary: it has to satisfy $g_{\mu\nu} t^\mu t^\nu = 1$. Thus, we have a constrained extremization problem.

But we know how to deal with this: introduce a Lagrange multiplier[8] k. In other words, vary $K_{\mu\nu} t^\mu t^\nu - k(g_{\mu\nu} t^\mu t^\nu - 1)$ with respect to t^μ and set the result to 0, thus obtaining $(K_{\mu\nu} - k g_{\mu\nu}) t^\nu = 0$. Multiplying by $g^{\lambda\mu}$, we obtain an equation

$$(g^{\lambda\mu} K_{\mu\nu} - k\delta^\lambda_\nu) t^\nu = 0 \tag{18}$$

for the eigenvalues of the 2-by-2 matrix $M^\lambda_{\ \mu} \equiv g^{\lambda\mu} K_{\mu\nu}$. Contracting (18) with $t_\lambda \equiv g_{\lambda\rho} t^\rho$, we find $k = K_{\mu\nu} t^\mu t^\nu = \kappa_n$. In other words, the two eigenvalues k_1 and k_2 give the extremal values of κ_n.

As usual, the eigenvalues are determined by

$$\det(g^{-1}K - kI) = 0 \tag{19}$$

which (since $g^{-1}K$ is a 2-by-2 matrix) amounts to the quadratic equation $k^2 - \mathrm{tr}(g^{-1}K)k + \det(g^{-1}K) = 0$. Thus, the product of the eigenvalues is given by

$$\mathcal{G} \equiv \det(g^{-1}K) = \frac{\det K}{\det g} \tag{20}$$

and the sum by

$$\mathcal{S} \equiv \mathrm{tr}(g^{-1}K) \tag{21}$$

($ B ' = : D ! A " 1!

Alas for Nordström, he chose the wrong road.* Nature does not† make use of this possibility. Incidentally, he did this work[5] before Einstein formulated his theory of general relativity.

After special relativity was established, which after all was to make mechanics compatible with electromagnetism and its Lorentz invariance, Einstein was not the only one to realize that Newtonian gravity (1) also had to be made compatible with Lorentz invariance. Others in the race included Max Abraham (1875–1922) and Gustav Mie (1869–1957).

A less traveled road to Einstein gravity

> Compared with understanding gravity, the special theory of relativity was mere child's play.
>
> —A. Einstein writing to Arnold Sommerfeld, 1912

While ρ becomes a component of the tensor $T^{\mu\nu}$, the left hand side of $\partial^2\Phi = 4\pi G\rho$, for the equation to make sense, is also compelled to be a component of a tensor. We are thus forced to promote $\Phi(x)$ to a symmetric tensor field $h^{\mu\nu}(x)$ and write

$$\partial^2 h_{\mu\nu} = 8\pi G T_{\mu\nu} \tag{3}$$

where we have defined $h_{00} = -2\Phi$ to agree with our earlier discussion.

After the preceding chapter, it does not take much to guess that the field $h_{\mu\nu}$ will rather naturally turn out to be the deviation of the metric $g_{\mu\nu} = \eta_{\mu\nu} + h_{\mu\nu}$ from the Minkowski metric. Thus, once we decide not to wander off with Nordström, we are practically committed to curved spacetime. Indeed, as soon as we write down (3), we are led inexorably to Einstein gravity, as was shown by Stanley Deser, collaborating with David Boulware and echoing various earlier and later works of Suraj Gupta, Robert Kraichnan,[6] Richard Feynman,[7] Steve Weinberg,[8] and others.

I merely sketch how we will end up with Einstein gravity, suppressing indices for clarity. The action that would lead to (3) has the form $S_1 \sim \int d^4x(\frac{1}{G}\partial h\partial h + hT)$, with the (invisible) indices contracted by $\eta_{\mu\nu}$. Indeed, $\delta S_1 \sim \int d^4x(\frac{1}{G}\partial h\partial\delta h + \delta hT) \sim \int d^4x(-\frac{1}{G}\partial^2 h + T)\delta h = 0$, giving us $\frac{1}{G}\partial^2 h \sim T$. I must confess that living the unindexed life has its charms.

Keep on iterating

But this action can't be the end of the story. The very fact that the field $h_{\mu\nu}(x)$ is endowed with dynamics—that it can wriggle in spacetime—means that it carries energy and mo-

---

* Had Nature chosen this road, you wouldn't have to learn Riemannian geometry to master gravity.

† This is one of my favorite examples of the need to read with sophistication Einstein's dictum about making physics as simple as possible. Simple does not necessarily mean less math. Nature couldn't care less about how much or how little math you learned in school.

mentum. In S_1, we include in $T^{\mu\nu}$ only the contribution of the matter fields. Here the word "matter" is used in the same sense as in chapter VI.4 and includes anything but the gravitational field $h_{\mu\nu}$. We are now forced to include the contribution of $h_{\mu\nu}$ to $T^{\mu\nu}$ as well.

In chapter VI.4, we learned, given an action, how to determine its contribution to $T^{\mu\nu}$, even if the action is given merely in flat spacetime. We pretend momentarily that $\eta_{\mu\nu}$ is actually $g_{\mu\nu}$, we vary $g_{\mu\nu}$ to obtain $T^{\mu\nu}$, and then quickly set $g_{\mu\nu}$ back to $\eta_{\mu\nu}$, doing all this in our heads.

Apply this procedure to the term $\frac{1}{G}\partial h \partial h$ in S_1. Since this term carries 6 indices (which we have suppressed), there are actually 3 "invisible" ηs lurking in this term, in the schematic form $\sim \frac{1}{G}\eta\eta\eta\partial h\partial h$. Promoting $\eta_{\mu\nu}$ to $g_{\mu\nu}$, varying $g_{\mu\nu}$, and then setting $g_{\mu\nu}$ back to $\eta_{\mu\nu}$, we obtain a contribution to $T^{\mu\nu}$ of the schematic form $\frac{1}{G}\eta\eta\partial h\partial h$, where two indices are left dangling to match the $\mu\nu$ indices on $T^{\mu\nu}$. In other words, we have to shift $hT \to h(T + \frac{1}{G}\eta\eta\partial h\partial h)$. Including this contribution, we are forced to the action $S_2 \sim \int d^4x(\frac{1}{G}\partial h\partial h + hT + \frac{1}{G}h\partial h\partial h)$. (Our notation is evidently such that after every step, the letter T in the schematic form of the action once again includes only the contribution of the matter fields. We also suppress the many ηs lurking in the action.)

You see how the game goes: we keep on iterating. The term $\frac{1}{G}h\partial h\partial h$ in S_2 will now force us to include a term of the form $\frac{1}{G}h\partial h\partial h$ in T. Hence we are led by the nose to the action $S_3 \sim \int d^4x(\frac{1}{G}\partial h\partial h + hT + \frac{1}{G}h\partial h\partial h + \frac{1}{G}h^2\partial h\partial h)$.

Before you can shout "Here comes S_4!", you see that the action will iterate to an infinite series $S \sim \int d^4x\{\frac{1}{G}(\partial h\partial h + h\partial h\partial h + h^2\partial h\partial h + \cdots) + hT\}$. This much is easy to understand and makes sense physically, as I will explain presently. The hard part is to show, as Deser and company did, that the series $\frac{1}{G}(\partial h\partial h + h\partial h\partial h + h^2\partial h\partial h + \cdots)$ sums to the Lagrangian $\frac{1}{G}\sqrt{-g}R$ in Einstein gravity.*

In other words, the claim is that, upon substituting $g_{\mu\nu} = \eta_{\mu\nu} + h_{\mu\nu}$ into the Einstein-Hilbert Lagrangian and expanding in h, we will obtain the series we found by iterating. But in a sense this is hardly surprising, since general covariance forces us to the Einstein-Hilbert Lagrangian uniquely (as we saw in chapter VI.1).

In chapter V.2, we extolled the far-reaching power of the equivalence principle. If we know the action governing any interaction in flat Minkowskian spacetime, we immediately know the action governing that interaction in curved spacetime, in the presence of gravity: all we have to do, we learned, is to promote $\eta_{\mu\nu}$ to $g_{\mu\nu}$. But there is one interaction we cannot apply this wondrous stupendous trick to, so take back the word "any" in the preceding sentence. That very special interaction is the gravitational interaction itself! We knew gravity only in Newtonian, not Minkowskian, spacetime. What we have learned in this chapter is that if we try to construct the gravitational action in Minkowskian spacetime iteratively, we end up with the Einstein-Hilbert action in curved spacetime.

Instead of working with the action, we could also have worked with the equation of motion (3). Our task would then be to find a combination, involving two derivatives and the metric, with which to replace $\partial^2 h_{\mu\nu}$ on the left hand side, as we had already anticipated way way back in part II. Gauss, Riemann, and Ricci solved this highly nontrivial problem for us.

---

* To keep things simple, we did not mention that starting with hT, we generate an infinite series that will also sum up appropriately.

Geometry emerges

This discussion underlines the importance of the geometrical view of special relativity that we have emphasized in part III, in contrast to the view of special relativity as a series of apparent paradoxes. We could certainly work through the theory of special relativity applying the Lorentz transformation to various apparent paradoxes, without once mentioning the word "geometry." But that would be impoverishing physics.

Imagine yourself in a galaxy far far away, where people have never heard of Einstein gravity. But people know about the Newtonian equation (1) $\nabla^2\Phi(\vec{x}, t) = 4\pi G\rho(\vec{x}, t)$, and Lorentz invariance has just been discovered. Suppose you then try to make this equation Lorentz invariant, following the road less traveled outlined here, and thus promoting Φ to $h_{\mu\nu}$. If you had understood special relativity in terms of the geometry of spacetime (that is, understood $\eta_{\mu\nu}dx^\mu dx^\nu$ as the generalized distance between two nearby points), then you would naturally interpret $(\eta_{\mu\nu} + h_{\mu\nu})dx^\mu dx^\nu$ as an even more generalized distance between two nearby points. Geometry of curved spacetime naturally emerges. But the poor sap who knows special relativity as a series of paradoxes may have a hard time seeing curved spacetime.

The graviton interacts with itself

The physics behind the infinite series $\frac{1}{G}(\partial h\partial h + h\partial h\partial h + h^2\partial h\partial h + \cdots)$ is easy to understand with a minimal knowledge[9] of quantum field theory. You have no doubt heard, and I have already mentioned, that when we quantize the electromagnetic field, we obtain the photon, and when we quantize the gravitational field, we obtain the graviton. A huge difference between the photon and the graviton is that the photon couples to charged fields, such as the electron field, but is not charged itself. In contrast, the graviton couples to anything carrying energy and momentum, and since it certainly carries energy and momentum, it couples to itself. In the electromagnetic action given in chapter IV.2, the photon couples to the charged fields that comprise the electromagnetic current J^μ via the term $A_\mu J^\mu$ in the action. Similarly, in the Einstein-Hilbert action, the graviton couples to matter fields that comprise the energy momentum tensor $T^{\mu\nu}$ via the term $h_{\mu\nu}T^{\mu\nu}$. But in addition, there are an infinite[10] number of terms of the form $h \cdots h\partial h\partial h$ describing the complicated interactions of many gravitons with one another. This partly accounts for the intractability of quantum gravity at present.

To say all this in a slightly different way, we recall from chapter VI.4 that $T^{\mu\nu}$ is not locally conserved, in contrast to the electromagnetic current J^μ. The physics behind this fact is the ability of the gravitational field to exchange energy momentum with $T^{\mu\nu}$.

Appendix 1: From electrostatics to Maxwell

It is instructive to repeat for electromagnetism what we did in this chapter. Suppose we start with electrostatics, with Poisson's equation $\nabla^2\Phi(\vec{x}, t) = \rho(\vec{x}, t)$ determining the electrostatic potential Φ in terms of the charge density ρ. Indeed, it is essentially the same equation as (1) that we started this chapter with.

($ ' 211 " L %

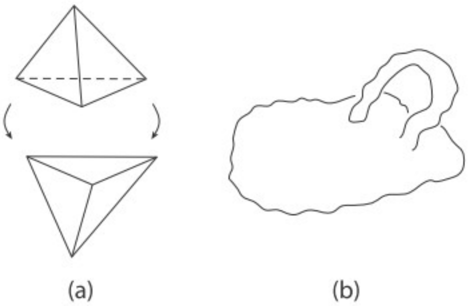

Figure 1 (a) Gluing 2 tetrahedra together. (b) A spherical blob grows a trunk.

What about the Einstein-Hilbert action? Let's try $S = \int R_{\alpha\beta} * (e^\alpha e^\beta)$. Again, the answer is easy to guess. We need a d-form to integrate over, involving 1 power of the curvature 2-form and no power of derivative. To obtain a d-form, we multiply the curvature 2-form by a $(d-2)$-form: the only possibility in this context is the star of the 2-form $e^\alpha e^\beta$. Again, between us friends, do you doubt this? Okay, let's check (but, to save writing and to spare you the stream of indices, only for 4-dimensional spacetime):

$$\begin{aligned} R_{\alpha\beta} * \left(e^\alpha e^\beta\right) &= \left(R_{\alpha\beta\omega\psi} dx^\omega dx^\psi\right)\left(\epsilon_{\rho\sigma}^{\ \ \mu\nu}\sqrt{-g}\, e^\alpha_\mu e^\beta_\nu dx^\rho dx^\sigma\right) \\ &= R_{\mu\nu\omega\psi}\epsilon_{\rho\sigma}^{\ \ \mu\nu}\sqrt{-g}\, dx^\omega dx^\psi dx^\rho dx^\sigma = R_{\mu\nu\omega\psi}\epsilon_{\rho\sigma}^{\ \ \mu\nu}\sqrt{-g}\,\epsilon^{\omega\psi\rho\sigma} d^4x \\ &= R_{\mu\nu\omega\psi} g^{\mu\omega} g^{\nu\psi}\sqrt{-g}\, d^4x = \sqrt{-g}\, d^4x\, R \end{aligned} \tag{16}$$

(using the generalization of (6) and again ignoring overall numerical factors), as expected.

Appendix 3: Topological invariants: Euler characteristic, Gauss-Bonnet theorem, and all that

We are now ready to look at some celebrated invariants in topology. Our discussion will be heuristic rather than rigorous, hitting some highlights rather than being exhaustive. I keep the discussion as elementary as possible.

I suspect that many readers probably first encountered the Euler characteristic, like me, in a popular book of mathematics. For me, it was a real eye opener. First, let us look at the empirical data. The cube has 8 vertices or corners, 12 edges (4 on the top, 4 on the bottom, and 4 on the side), and 6 faces. Hence, $V = 8$, $E = 12$, $F = 6$. Next, the tetrahedron has 4 vertices, 6 edges (3 on the bottom and 3 on the side), and 4 faces, that is, $V = 4$, $E = 6$, $F = 4$. We see that the combination, $\chi = V - E + F$, known as the Euler characteristic, is equal to 2 in both cases. (Note that in the sum, we add the number of geometrical entities, vertices, edges, and faces, with an alternating sign according to whether the dimension of the entity is even or odd.) The joke is that theoretical physicists would proclaim this to be a theorem at this point, but in fact it is easy to prove. Let me give a proof that would satisfy most physicists (but not mathematicians) and is suitable for elementary school children.

Glue another tetrahedron to the tetrahedron we have, producing a 6 faced "diamond-shaped" object. See figure 1a. We gain 4 faces (the four of the second tetrahedron) but lose 2 faces (the two that are glued together). Thus, $\Delta F = +4 - 2 = 2$. Similarly, we can see that $\Delta V = +4 - 3 = 1$ and $\Delta E = +6 - 3 = 3$. Hence, we have $\Delta\chi = \Delta V - \Delta E + \Delta F = 1 - 3 + 2 = 0$. Now we can glue zillions of these tetrahedra together to approximate any object we like. At every gluing, the Euler characteristic does not change. Hence $\chi = 2$ for any spherical-looking blob. The discussion makes clear that we are counting the V, E, and F on the surface. (The interior of the object, consisting of the faces we have glued together and their edges and vertices, has been "lost forever," so to speak.) Throughout, we will be studying a surface or a 2-manifold, not the 3-dimensional blob enclosed by the surface.

The Euler characteristic is evidently a topological quantity. We can lengthen and shorten the edges of the tetrahedra we are gluing together without changing V, E, and F.

Suppose we now go beyond deforming the spherical blob to changing its topology. We show presently that χ "measures" the topology of the object.

By gluing more tetradehedra on, we can make the spherical blob grow a trunk like that of an elephant. Let us slowly extend the trunk back toward another part of the blob, sort of like an elephant about to scratch its back with its trunk. The Euler characteristic χ remains equal to 2, until we glue the tetrahedron at the tip of the trunk to a tetrahedron on the back of the elephant. See figure 1b. Now we lose 2 faces, 3 vertices, and 3 edges, and thus $\Delta\chi = \Delta V - \Delta E + \Delta F = -3 + 3 - 2 = -2$. The resulting surface has the topology of a torus and Euler characteristic $\chi = 2 - 2 = 0$.

Growing another trunk and attaching it somewhere else causes the Euler characteristic χ to decrease further, with $\Delta\chi = -2$ every time we do it. We have thus derived the general result $\chi = V - E + F = 2(1 - g)$, where g denotes the genus ($g = 0$ for the sphere, $g = 1$ for the torus, and so on). Some people call the genus the number of "holes." (The torus is said to have 1 hole, but as we will soon see, in this context, the word "genus" or "handle" is preferable to the word "hole.") The Euler characteristic χ is manifestly a topological invariant, independent of the size or "shape" of the surface, and only dependent on its genus.

A trivial generalization is to punctured surfaces. (In everyday parlance, a punctured sphere is a sphere with a hole in its surface, like a rapidly shrinking balloon with a hole in it. This is one reason why the use of the word "hole" for genus or handle, as indulged in by some, is ill advised.) Since we can puncture a surface by removing a triangular face from the surface (so that $\Delta V = 0$, $\Delta E = 0$, and $\Delta F = -1$ and hence $\Delta\chi = -1$), we have, more generally,

$$\chi = 2 - 2g - h \tag{17}$$

with h the number of holes or punctures in the surface.[7]

Another way of proving (17) is to start with $\chi = 2$ for a spherical surface, and to punch any number of holes in it, thus obtaining $\chi = 2 - h$. Deforming the surface to bring 2 holes near each other and then to glue them together, we decrease h by 2 and increase the genus by 1. Hence we have (17). This derivation also makes clear the relative factor of 2 in the coefficients of g and h in χ.

We obtain what is known as a triangulation of the surface. (Indeed, that is what surveyors do: they triangulate the surface of the earth.) At the level of rigor of physics, any surface can be approximated to arbitrary accuracy by making the triangles small enough. In other words, we physicists would take the continuum limit without further ado.

At the same level of rigor, we can also approximate spacetime by a large number of discrete elements. This represents the first step in a program to discretize Einstein gravity and to put it on the computer for numerical analysis.*

That we used tetrahedra is not essential. Take the tetrahedron we started with. Call the vertices on the triangle on its "base" A, B, and C. Pick a point X on the edge joining A and B, and draw a line connecting X to the other vertex C. Then $\Delta V = 1$, $\Delta E = 2$, and $\Delta F = 1$, and so $\Delta\chi = 0$. By "pulling" on the point X, we can deform the tetrahedron, if we feel like it, to a pyramid with a square base. As another example, we can pick a triangle on the surface we are studying and draw a line from one side of the triangle to another side, so that we divide the triangle into a smaller triangle and a quadrilateral. In the process, $\Delta V = 2$, $\Delta E = 3$, and $\Delta F = 1$, and so again $\Delta\chi = 0$. You can make up your own "moves" and show that instead of triangles, the surface could be composed of polygons with any number of sides you like.

Indeed, Descartes had already published, in his progymnasmata to the study of solids, a theorem on angular deficits that foreshadowed the Euler characteristic. Here is what Descartes said. At each vertex of a cube, 3 squares meet. The 3 angles at the vertex add up to $3(\frac{1}{2}\pi) = \frac{3}{2}\pi$. The amount by which this is less than 2π is known as the angular deficit, in this case equal to $(2 - \frac{3}{2})\pi = \frac{1}{2}\pi$. The total angular deficit, namely the sum of the angular deficits at each of the 8 vertices, is then equal to $8(\frac{1}{2}\pi) = 4\pi$. Descartes stated that the total angular deficit of any polyhedron topologically equivalent to the sphere is equal to 4π.

Let's try it for a tetrahedron. At each vertex, 3 equilateral triangles meet, with angles adding up to $3(\frac{\pi}{3}) = \pi$, so that the deficit equals $(2 - 1)\pi = \pi$. There are 4 vertices, and so the total deficit is indeed 4π. We have verified 2 cases, so it is surely a theorem. We are proud physicists, but still, perhaps a third example would be good.

So consider the dodecahedron with 12 pentagonal faces. Since there are $E = (12 \times 5)/2 = 30$ edges, according to Euler's theorem, the number of vertices equals $V = 2 + E - F = 2 + 30 - 12 = 20$. The 12 pentagons have $12 \times 5 = 60$ vertices, and hence $60/20 = 3$ pentagons meet at each vertex. For a regular polygon with n sides, the angle α at each vertex is given by $n\alpha + 2\pi = n\pi$ (to see this, divide the polygon into n triangles), that is, $\alpha = (n-2)\pi/n$. In particular, for a pentagon, we have $\alpha = \frac{3}{5}\pi$. The angular deficit at each vertex is then $\left(2 - 3\left(\frac{3}{5}\right)\right)\pi = \frac{1}{5}\pi$. Thus, the total angular deficit equals to $20 \times \frac{1}{5}\pi = 4\pi$. Descartes was right!

---

* Lattice gravity is a thriving subject of research. Historically, this first step is known as the Regge calculus.

Let's now show that the total angular deficit is topologically invariant. Consider some triangulated surface as described earlier, and visualize it as a wire framework. (For ease of presentation, let the faces be triangles. Thus, for the cube mentioned above, simply divide the squares by their diagonals.) Pick an edge AB, shared by two triangles ABC_1 and ABC_2. Call the 6 angles contained in these 2 triangles α_j, β_j, γ_j, with $j = 1, 2$, using an almost self-evident notation (for example, α_1 is the angle of ABC_1 at the vertex A, γ_1 is the angle of ABC_1 at the vertex C_1, and so on). Now imagine lengthening the edge AB slightly, thus increasing γ_j and decreasing α_j and β_j. Thus, the change in the angular deficit at the vertex A is $-(\delta\alpha_1 + \delta\alpha_2)$. But since the angles in a triangle have to add up to π, $\delta(\alpha_j + \beta_j + \gamma_j) = 0$. The angular deficit at the vertices A, B, C_1, and C_2 all vary, but the total angular deficit stays the same: it is a topological invariant, as Descartes taught us.

Here is the previous proof dressed up to make it look more sophisticated. Label the vertices by p. At vertex p, a set $s(p)$ of triangles meet. The sum of the angles meeting at vertex p is then $\sum_{i \in s(p)} \alpha_i$, with α_i the angle extended by the ith triangle at that vertex. The total angular deficit is then $\sum_p \left(2\pi - \sum_{i \in s(p)} \alpha_i\right)$. Let us now deform the surface infinitesimally by lengthening or shortening each of the zillions of edges. The variation in the total angular deficit is equal to $-\sum_p \sum_{i \in s(p)} \delta\alpha_i$. Rearranging to sum over 1 triangle at a time, we see that this vanishes, since the sum of the angles in each triangle is constrained to add up to π.

With this background explanation of what the Euler characteristic χ is, we now return to the subject of this appendix and of this chapter. Can we write χ as an integral? In other words, how do we calculate χ, originally defined to be $V - E + F$, in the continuum limit where V, E, and F are not defined?

We are given a closed surface, that is, a 2-manifold M without boundary (in other words, we are setting $h = 0$ for simplicity). What is a 2-form that we could integrate over M? The curvature 2-form $R^{\alpha\beta}$ comes to mind; so let's try $\int_M \varepsilon_{\alpha\beta} R^{\alpha\beta}$. (It is also instructive to try the other possibility: $e^\alpha e^\beta$. It turns out that $\int_M \varepsilon_{\alpha\beta} e^\alpha e^\beta$ is the area of the surface, as you might have guessed from the fact that it does not contain any derivative.) We first work out the integrand in terms of a more elementary notation:

$$\begin{aligned} \varepsilon_{\alpha\beta} R^{\alpha\beta} &= \varepsilon_{\alpha\beta} R^{\alpha\beta}_{\mu\nu} dx^\mu dx^\nu = \varepsilon_{\alpha\beta} e^\alpha_\rho e^\beta_\sigma R^{\rho\sigma}_{\mu\nu} dx^\mu dx^\nu \\ &= (\det e)\varepsilon_{\rho\sigma} R^{\rho\sigma}_{\mu\nu} \varepsilon^{\mu\nu} d^2x = 2d^2x\sqrt{g}\,\delta^\mu_\rho \delta^\nu_\sigma R^{\rho\sigma}_{\mu\nu} = d^2x\sqrt{g}R \end{aligned} \tag{18}$$

(In the next to last step, we used (6).)

We have known, for quite a while now, that for a sphere of radius a, the scalar curvature $R = 2/a^2$. The area is $\int_M d^2x\sqrt{g} = 4\pi a^2$. Thus, the radius cancels out in the integral $\int_M \varepsilon_{\alpha\beta} R^{\alpha\beta} = 2\int_M d^2x\sqrt{g}R$, and this integral is indeed, as we might suspect, topological in character, equal to some constant like 16π.

The scalar curvature of a torus was calculated back in exercise I.6.2 and again in exercise I.5.16; it assumes both positive and negative values. I will let you check that the integral gives 0 for a torus. We claim that, up to some overall factor, this integral gives the Euler characteristic χ.

In fact, Descartes' theorem is just the statement, up to some overall constant, that the Euler characteristic χ equals 2 for a surface with the topology of the sphere. Go back to the spherical-looking blob. Under the microscope, we see that the surface is formed out of zillions of triangles. Inside any triangle, we have a flat surface; the surface curvature is concentrated on the edges and at the vertices. Indeed, the angular deficit measures our intuitive understanding of curvature: that which we cannot iron flat is curvature. The smaller the angular deficit is at a vertex, the less that vertex sticks out. When the angular deficit vanishes, the surface around that vertex is flat. The angular deficit "measures" the curvature.

The generalization to a 4-manifold M almost immediately suggests itself. Let's parallel the discussion embodied in (18) and integrate the 4-form $\varepsilon_{\alpha\beta\gamma\delta} R^{\alpha\beta} R^{\gamma\delta}$ over M. As in the discussion above, the characteristic length a of M will cancel out in the integral $\int_M \varepsilon_{\alpha\beta\gamma\delta} R^{\alpha\beta} R^{\gamma\delta}$. I will let you have the fun of working this out in an exercise. That this integral is a topological invariant[8] is known as the Gauss-Bonnet theorem in the physics literature.

In the interest of keeping this appendix to a manageable size, I have not proven why the 2 integrals mentioned here are topological invariant,[9] but instead, have "merely" shown you why they must be so (in the spirit of what the American Mathematical Society said about my field theory textbook, as quoted in a footnote in chapter V.6).

Exercises

1 Check Descartes' theorem for the icosahedron, constructed out of 20 equilateral triangular faces. Hint: Use Euler's theorem.

(/B / B A " 1! 7! ! " 5 !

18 Change coordinates by $u = \log r,\ v = \theta$, and we obtain $ds^2 = (dr^2 + r^2 d\theta^2)$. The space is just the plane in disguise.

I.6 Curved Spaces: Gauss and Riemann

4 With no loss of generality, we can pick the point P to be $(x, y) = (0, y_*)$. A particular set of locally flat coordinates (u, v) is given by $x = y_*(u + uv + \cdots)$, $y = y_*(v + \frac{1}{2}(v^2 - u^2) + \cdots)$, where the dots represent terms cubic and higher in u, v. We could of course trivially rotate (u, v) (and also translate) to obtain another set of locally flat coordinates.

5 From $g_{11} = (1 + \mu^2 u^2)$, we have $B_{11,22} = 0$. Similarly, $B_{22,11} = 0$. From $B_{12,12} = \frac{1}{2}\mu\nu$. So $2B_{12,12} - B_{11,22} - B_{22,11} = \mu\nu$, which is indeed the intrinsic curvature.

8 We have $ds^2 = dx^2 + dz^2/\left(pz^{\frac{p-1}{p}}\right)^2$. For example, for $z = y^2$, $g_{zz} = 1/(4z)$ blows up at $z = 0$.

10 Let one line segment go from the point x to $x + (\Delta x)_1$, and the other to $x + (\Delta x)_2$. The angle between the two line segments is given by

$$\cos\theta = (\Delta x)_1 \cdot (\Delta x)_2 / \sqrt{((\Delta x)_1 \cdot (\Delta x)_1)((\Delta x)_2 \cdot (\Delta x)_2)}$$

(defining $(\Delta x)_1 \cdot (\Delta x)_2 \equiv g_{\mu\nu}(\Delta x)_1^\mu (\Delta x)_2^\nu$ and generalizing the standard high school formula for the scalar dot product). Suppose we now calculate the angle with the metric $\tilde{g}$: the factors of Ω evidently cancel between the numerator and the denominator.

11 Solution by counting. We can choose D functions, but we have to satisfy $\frac{1}{2}D(D+1) - 1$ conditions. We have enough freedom for $D = 2$, but not for $D > 2$.

13 $R = \frac{x+y}{2x^2y^2}$

I.7 Differential Geometry Made Easy, But Not Any Easier!

2 We calculate the components of $\vec{V}$ along the two basis vectors, namely $\vec{V} \cdot \vec{e}_\mu(y)$, and then use these two components to form a linear combination of the two basis vectors. These words translate into an expression for $\vec{V}$ projected into the tangent plane: $\vec{V}_{\rm P}(y) \equiv (\vec{V} \cdot \vec{e}_\mu(y)) g^{\mu\nu}(y)\vec{e}_\nu(y)$, where $g^{\mu\nu}(y)$ is the inverse of the 2-by-2 matrix $g_{\mu\nu}(y)$ defined by $g^{\mu\nu}(y)g_{\nu\lambda}(y) = \delta^\mu_\lambda$. (For the sphere, $g_{\mu\nu} = \begin{pmatrix} 1 & 0 \\ 0 & \sin^2\theta \end{pmatrix}$ and $g^{\mu\nu} = \begin{pmatrix} 1 & 0 \\ 0 & 1/\sin^2\theta \end{pmatrix}$.) To see that the inverse is needed here, take the dot product of $\vec{V}_{\rm P}(y)$ and a basic vector $\vec{e}_\lambda(y)$:

$$\vec{V}_{\rm P}(y) \cdot \vec{e}_\lambda(y) = (\vec{V} \cdot \vec{e}_\mu(y)) g^{\mu\nu}(y) \vec{e}_\nu(y) \cdot \vec{e}_\lambda(y) = (\vec{V} \cdot \vec{e}_\mu(y)) g^{\mu\nu}(y) g_{\nu\lambda}(y) = (\vec{V} \cdot \vec{e}_\mu(y))\delta^\mu_\lambda = (\vec{V} \cdot \vec{e}_\lambda(y))$$

In other words, $(\vec{V}_{\rm P}(y) - \vec{V}) \cdot \vec{e}_\lambda(y) = 0$, which is just another way of saying that $\vec{V}_{\rm P}(y)$ and $\vec{V}$ differ by a vector normal to the surface. In other words, we subtracted out the component of $\vec{V}$ normal to the surface from $\vec{V}$ to obtain $\vec{V}_{\rm P}(y)$.

3 Multiply the two eigenvalue equations (for $i = 1, 2$)

$$(K_{\mu\nu} - k_i g_{\mu\nu}) t_i^\nu = 0$$

by t_j^μ (with $j \neq i$) and subtract one from the other. We obtain $(k_1 - k_2) g_{\mu\nu} t_1^\mu t_2^\nu = 0$. For those readers who have studied quantum mechanics, does this remind you of the proof of wave function orthogonality?

6 Take the dot product: $\vec{e}_\rho \cdot \vec{e}_{\mu,\nu} = g_{\rho\lambda}\Gamma^\lambda_{\mu\nu} = \Gamma_{\rho\cdot\mu\nu}$. Interchange $\rho \leftrightarrow \mu$: $\vec{e}_\mu \cdot \vec{e}_{\rho,\nu} = \Gamma_{\mu\cdot\rho\nu}$. Add to obtain $\partial_\nu(\vec{e}_\rho \cdot \vec{e}_\mu) = \partial_\nu g_{\rho\mu} = \Gamma_{\rho\cdot\mu\nu} + \Gamma_{\mu\cdot\rho\nu}$, which we can solve for Γ using I.4.15.

II.1 The Hanging String and Variational Calculus

2 Once again, we can solve $\nabla^2\Phi = GM\delta^{(3)}(\vec{x})$ by dimensional analysis. It is also easy to verify the solution explicitly. By rotational invariance, Φ can only depend on $r^2 \equiv \sum_{i=1}^D x^i x^i$. Differentiate this to obtain $r\,dr = \sum_{i=1}^D x^i dx^i$, so that $\frac{\partial r}{\partial x^i} = \frac{x^i}{r}$. Then we have

$$\sum_{i=1}^{D} \frac{\partial}{\partial x^i}\frac{\partial}{\partial x^i}\frac{1}{r^p} = \sum_{i=1}^{D}\frac{\partial}{\partial x^i}\left(-\frac{p x^i}{r^{p+2}}\right) = \frac{p(p+2-D)}{r^{p+2}}$$

We see that $\Phi \propto 1/r^p$ with $p = D-2$ solves the equation for $\vec{x}$ away from the origin. The potential goes like $1/r^{D-2}$, and so the force law is an inverse $(D-1)$ law.

3 Varying S with respect to b gives $a' = 0$, and varying it with respect to a gives $(r(1-b))' = 0$. Fitting to the boundary conditions at spatial infinity gives $a = 1$ and $b = 1 - \frac{2M}{r}$.

5 Describe the desired curve by $y(x)$, with y the vertical axis. Released at rest at $y = 0$, the bead attains a speed of $v(y) = \sqrt{2gy}$ after falling a distance of y (with the coordinate y chosen to point downward). We see that the transit time (in suitable units) is given by

$$T = \int \sqrt{\frac{dx^2 + dy^2}{y}} = \int dx \left[\frac{1}{y}\left(1 + \left(\frac{dy}{dx}\right)^2\right)\right]^{\frac{1}{2}}$$

You could proceed from here, derive the Euler-Lagrange equation, solve for $y(x)$, and “rival” Newton more than 300 years later. Note that in spite of my remark in the text, in this context, the notation $y(x)$ seems quite natural.

Here is the instructive part of the problem. We could just as well have chosen y as the variable and solved for $x(y)$. Then

$$T = \int dy \left[\frac{1}{y}\left(1 + \left(\frac{dx}{dy}\right)^2\right)\right]^{\frac{1}{2}}$$

You can verify that, in contrast to the case with the previous choice, the second order differential equation can now be integrated trivially to yield the first order differential equation

$$\left(\frac{dx}{dy}\right)^2 = \frac{y}{y^* - y}$$

with y^* an integration constant. You could solve this easily with the change of variable $y = y^* \sin^2\theta$.

Moral of the story: in solving variational problems, it pays to choose the independent variable wisely.

II.2 The Shortest Distance between Two Points

6 Varying the stated quantity, we obtain $\frac{d}{d\lambda}\left(2g_{\sigma\nu}\frac{dX^\nu}{d\lambda}\right) = (\partial_\sigma g_{\mu\nu})\frac{dX^\mu}{d\lambda}\frac{dX^\nu}{d\lambda}$ almost instantly, but this is just (16).

8 Simply plug $g_{\mu\sigma} = e^{2\Omega}\delta_{\mu\sigma}$ into (24) to obtain $\frac{d}{dl}\left(e^{2\Omega}\delta_{\mu\sigma}V^\mu\right) = \partial_\sigma\Omega$ (since $g_{\mu\nu}V^\mu V^\nu = 1$). Noting that $\frac{d}{dl}e^{2\Omega} = 2V^\nu\partial_\nu\Omega e^{2\Omega}$, we find, after cleaning up a bit,

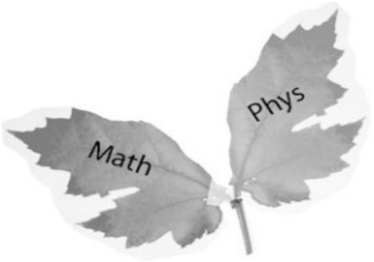

Fig. 3.1 A symbolic assessment by C.N. Yang that Mathematics and Physics have a common root

3.2 A Historical Outline

One spring in the late seventies, C.N. Yang, the father of gauge-theories and one among the most extraordinary scientific minds of the XXth century, was invited by Scuola Normale di Pisa to give the traditional yearly series of Fermian Lectures. It was just the eve of the 1983 experimental discovery of the W and Z bosons, which finally confirmed that gauge theories are indeed the language adopted by Nature to express the fundamental forces binding matter together and driving the evolution of the physical world. Yang chose to start his recollection of gauge-theories and his personal assessment of the entire subject from a symbolic picture of the kind shown in Fig. 3.1.

Two leaves depart from the same stem: one is Mathematics, the other is Physics. The two leaves live parallel lives but have a common root and, as it happens in non-Euclidian geometry, parallels can and indeed do intersect. They frequently intersect and, equally frequently, interchange the role of guiding pivot. Examples are numberless both in recent and less recent history of science. This is a relevant but somehow trivial observation.

The most profound allusion in the typical Chinese symbolism of Yang's picture is the common stem of the two leaves. Mathematics and Physics were not that much socially and academically separated in the XIXth as they became in the XXth century and were further unified by a common denominator: the shared philosophical attitude of both the mathematician and the physicist, the latter assessing himself a natural philosopher.

The common root of Modern Mathematics and Modern Theoretical Physics is most prominently evident in the case of the concepts of *connections* and *metrics* which constitute the main topics of the present chapter. From the physical side these mathematical notions encode all the *fundamental interactions* among *elementary matter constituents*. From the mathematical side they are the corner stones of Differential Geometry, Algebraic Topology and allied subjects.

The historical developments of both the notion of a *connection* and the notion of a *metric* are quite long, spreading over more than a century. They are strongly intertwined and involve both Physics and Mathematics in an alternate and entangled fashion.

Two fundamental geometrical problems are at the basis of both notions: the problem of *length* and the problem of *parallel transport*, namely how can we measure distances in a general continuous space and how do we assess the parallelism of two lines going through different points of that space. It turns out that these two apparently different problems are intimately related. Such a relation is the reason why connections and metrics, although genuinely different and independent mathematical notions can be, under certain conditions, related in a one-to-one fashion. The case where connection and metric are one-to-one related corresponds to Gravity and is the play-ground of General Relativity, while the case where the connection stands on his own feet is the case of non-gravitational interactions and encodes all the rest of Physics.

Historically the first notion of connection that was discovered is that of the *metric connection* named after its systematizer, the Italian mathematician Levi Civita. The *Levi Civita connection* is that appropriate to a Riemannian manifold, namely to a manifold equipped with a metric and it is analytically described by the 3-index symbols $\{{}^{\mu}_{\nu\rho}\}$, introduced in the XIXth century by their German inventor, Elwin Bruno Christoffel. The development of such a notion is embedded in the development of Riemannian geometry, embracing the fall of the XIXth century and the dawn of the XXth, which is a mathematical tale strongly intertwined with the physical tale of Einstein's quest for General Covariance and the Theory of Gravity.

It took several decades in the first half of the XXth century and the work of several mathematicians to single out the notion of a *connection on a principal fibre bundle*, purified from association with a metric. In a completely independent way in 1954 Yang and Mills introduced the physical notion of non-Abelian gauge fields which extends to all Lie groups G the structure of the electromagnetic theory based on the simplest of all such groups, namely $\mathrm{U}(1)$. In the course of due time the mathematical notion of a connection and the physical one of a Yang-Mills field were recognized to be identical.

Let us sketch the main outline of this crucial, century long intellectual development.

3.2.1 Gauss Introduces Intrinsic Geometry and Curvilinear Coordinates

The first appearance of a metric is in the 1828 essay of Gauss (see Fig. 3.2) on curved surfaces. Written in Latin, the *Disquisitiones Generales circa superficies curvas* [1] contains the major revolutionary step forward that was necessary to overcome the precincts of Euclidian geometry and found a new *differential science* of spaces able to treat both flat and curved ones. Up to Gauss' paper, Geometry was either formulated abstractly in terms of Euclidian axioms or analytically in terms of *Cartesian coordinates*. By Geometry it was meant the study of global properties of plane figures like triangles, squares and other polygons, or solids like the regular polyhedra. All such objects were conceived as immersed in an external space where it was implicitly assumed that one could always define the absolute distance $d(A,B)$ between any two given points A and B. Distance is the basic brick of the whole Euclidian building and it is calculated as the length of the segment with end-

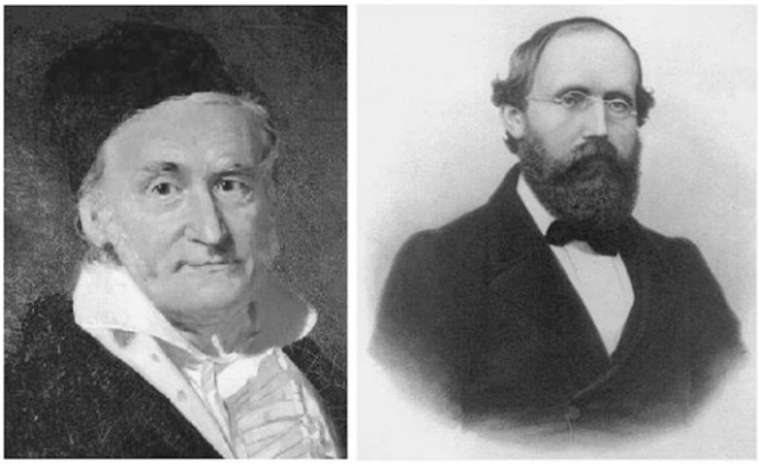

Fig. 3.2 Carl Friedrich Gauss (1777–1855) on the *left* and Georg Friedrich Bernhard Riemann (1826–1866) on the *right*. Gauss, *the King of Mathematicians*, was Professor at the University of Göttingen for many decades up to the very end of his long life. His contributions to all fields of Mathematics were enormous and most profound. Bernhard Riemann, another genious and a giant of human thought, had a very short and not too happy life. He was Gauss' student both at the level of Diploma and of *Habilitationsschrift*. The whole of his work is contained in no more than 11 papers for a total of little more than 200 pages. Yet each of his contributions was a milestone in Mathematics and set the path for century long future developments. The foundations of Riemannian geometry were laid in the 16 page long dissertation of his Habilitation. Riemann had important ties with the Scuola Normale di Pisa and died in Italy at the age of 39

points in A and B, lying on the unique straight line which goes through any such pair of distinct points.

Curved surfaces were obviously known before Gauss, yet their shape and properties were conceived only through their immersion in three-dimensional space, considered unique and absolute, as pretended by Immanuel Kant who promoted Euclidian geometry to an a priori truth lying at the basis of any sensorial experience. Gauss revolutionary starting point was that of reformulating the geometrical study of surfaces from an intrinsic rather than extrinsic viewpoint. He wondered how a little being, confined to live on the surface, might have perceived the geometry of his world. Rather than viewing the global shape of the surface M, unaccessible to his observations, the little creature would have explored its local properties in the vicinity of a point $p \in M$.

In order to study curved surfaces in these terms, Gauss understood that it was necessary to abandon Cartesian coordinates as a system of point identification. In analytic geometry every point $p \in \mathbb{E} \equiv \mathbb{R}^3$ of Euclidian space is singled out by a triplet of real numbers X, Y, Z which determine the distance of p from the three coordinate axes. As long as the points of the surface M are particular points of $\mathbb{E}$, they admit the labeling in terms of three Cartesian coordinates, yet in such a description there is an excess of superfluous information. Why three coordinates when we are talking about a two-dimensional surface? Two should suffice. Gauss

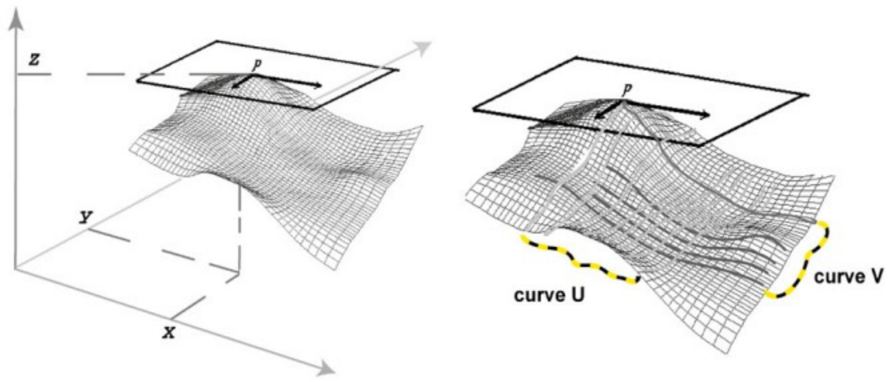

Fig. 3.3 The points p of a curved surface M can be labeled with the three Cartesian coordinates X, Y, Z of the Euclidian space in which M is immersed. Yet this is a redundant information. The two Gaussian coordinates u and v are given through the construction of two systems of curves U and V on the surface

was the first to grasp the notion of curvilinear coordinates and invented *Gaussian coordinates*. A very simple but revolutionary idea.

On the surface M let us consider a family of curves U such that each element of the family never intersects any other element of the same family, at least in the neighborhood $\mathscr{U}_p$ of the point p (for instance the lighter curves in Fig. 3.3) and such that the family covers the entire considered neighborhood. Let us next introduce a second family of curves V, with the same properties among themselves, yet such that each element of the family V intersects all elements of the U family at least in the neighborhood $\mathscr{U}_p$ (for instance the darker curves Fig. 3.3). Once such systems of curves have been constructed, any point $q \in \mathscr{U}_p$ in the neighborhood of p can be localized by stating on which U-curve and on which V-curve it lies. Assuming that u and v are the real parameters respectively enumerating the U and V curves, the pair of real numbers (u, v) provides the new (*Gaussian*) system of coordinates to label surface points. Using these coordinates we no longer need to make any reference to the exterior space in which M is immersed that might also be non-existing!

By introducing *curvilinear Gaussian coordinates* the King of Mathematicians freed the study of surfaces from their immersion in the external Euclidian space $\mathbb{E}$ but he immediately had to cope with a new fundamental problem. Having abolished from the list of one's mathematical instruments the straight line segments that join any two points A and B of the surface M, how can we calculate their distance? The great intuitions of Gauss were the *tangent plane* $\mathrm{T_p}M$ and the linear element ds^2, namely the metric.

Defining the absolute distance between two points A and B was no longer possible but also not interesting. In the external Euclidian space, the distance between A and B is the length of the segment which joins them, but which relevance has this datum for the little creature confined to live on the surface M, if such a segment does not lie on it? For the little two-dimensional being the only interesting datum is

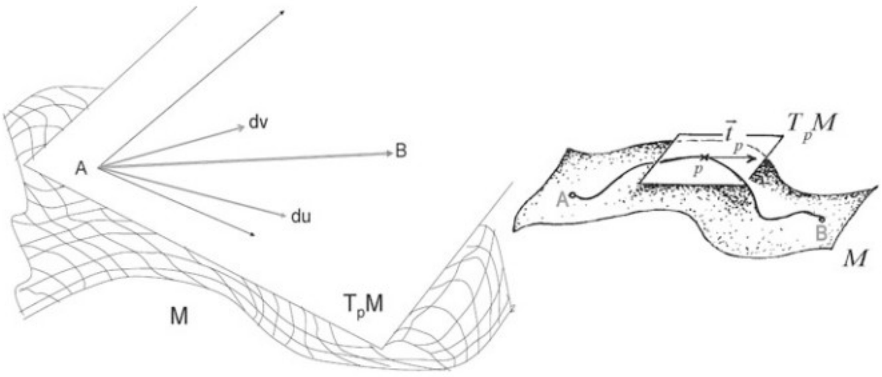

Fig. 3.4 The tangent plane to a point p of a surface M is a two-dimensional Euclidian space $\mathbb{E}^2$ where the notion of distance is defined. In the tangent plane which approximates infinitesimal regions of the surface surrounding p, we can define the line element as the Euclidian distance between two infinitesimally close points of the surface

the length of a road going from A to B: the length of any possible road with such a property! The small ant has exactly the same needs as any contemporary car-driver who wants to start on a journey. Both need to know the length of all possible paths from their origin to their destination.

Hence the problem addressed by Gauss was to give an answer to the following question: *Can we define the length of any curve departing from* $p \in M$ *and arriving at* $q \in M$ *in terms of data completely intrinsic to the surface* M*?*

Gauss' answer was positive and based on the change of perspective at the basis of the new *differential geometry*.

Let us reformulate the initial question whether we might define the absolute distance between two arbitrary points $A, B \in M$ of the surface, adding the extra condition that A and B should be only infinitesimally apart from each other. Analytically this means that if the Gaussian coordinates of A are (u, v), then those of B should be $(u + du, v + dv)$ where du and dv are infinitesimal. Gauss crucial observation is that a very small portion of the surface M around any point $p \in M$ can be approximated by a portion of the tangent plane to the surface at the point p, namely T_pM. Smaller the considered region of M better the approximation (see Fig. 3.4). This being the case we observe that Euclidian geometry makes sense in the tangent plane. Gauss remarked that the distance of two infinitesimally close points can be defined as the length of the infinitesimally short segment which joins them and which lies in the tangent plane.

Recalling Pithagora's theorem one might be tempted to say that the square length of the segments joining A and B, named ds^2, is the sum of the squared differences of the Gaussian coordinates, namely: $ds^2 = du^2 + dv^2$. Yet this is not necessarily true. In order to apply Pithagora's theorem it is required that the axes **u** and **v** be orthogonal, which is generically false. Indeed a priori it is by no means guaranteed that the curve u and the curve v, meeting at point A, should intersect there at right angle. In order to calculate ds^2 one has therefore to find the components dx and

dy of the infinitesimal segment AB in an orthogonal system of axes $\mathbf{x}$ and $\mathbf{y}$. Once these components are known one can apply Pithagora's theorem and write $ds^2 = dx^2 + dy^2$. The components dx and dy depend on the Gaussian shifts du and dv linearly:

$$\begin{pmatrix} dx \\ dy \end{pmatrix} = \begin{pmatrix} a(u,v) & b(u,v) \\ c(u,v) & d(u,v) \end{pmatrix} \begin{pmatrix} du \\ dv \end{pmatrix} \tag{3.2.1}$$

with matrix coefficients that vary from place to place on the surface, namely are functions of the Gaussian coordinate u, v. Taking this into account Gauss wrote the line element in the following way:

$$ds^2 = F(u,v)\,du^2 + G(u,v)\,dv^2 + H(u,v)\,du\,dv \tag{3.2.2}$$

where $F = a^2 + c^2$, $G = b^2 + d^2$, $H = 2ab + 2cd$.

Formula (3.2.2), written in 1828 provided the first example (a two-dimensional one) of a Riemannian metric, although Riemann was at that time only a two-year old child.

3.2.2 Bernhard Riemann Introduces n-Dimensional Metric Manifolds

The name of Riemann is associated in Mathematics with so many different and fundamental objects that the contemporary student is instinctively led to think about the scientific production of this giant of human thought as composed by a countless number of papers, books and contributions. Actually the entire corpus of Riemann's works is constituted only by 225 pages distributed over 11 articles published during the life-time of their author to which one has to add the 102 pages of the 4 posthumous publications. Among the latter there are the 16 pages of the *Ueber die Hypothesen, welche der Geometrie zu Grunde liegen* [2] which, in 1854, was debated by the candidate in front the Göttingen Faculty of Philosophy as *Habilitationsschrift*. The habilitation to teach courses was the traditional first step in the academic career foreseen by most European universities all over their very long history. In XIXth century Germany the procedure to access habilitation consisted of the writing of a dissertation on a topic chosen by the Faculty from a list of three proposed by the candidate. Typical time allowed for the preparation of such a dissertation was a couple of months and in the case of Riemann it amounted to exactly seven weeks.

Obsessed the whole of his short life by extreme poverty and by a very poor health that eventually led him to death from pulmonary consumption at the quite young age of thirty-nine, the shy and meek Bernhard Riemann, who was nonetheless quite conscious of his own talents, had already profoundly impressed Gauss with his diploma thesis. Written in 1851 and entitled *Grundlagen für eine allgemeine Theorie der Functionen einer veränderlichen complexen Grösse* which can be translated as *Principles of a General Theory of the Functions of one complex*

"Standard Candles"
If we know how luminous an object is then we can translate it's apparent brightness into it's distance.
Gauss Law states that the flux through any spherical surface around the source is constant.
Dilution of Brightness by Distance
d = 1
d = 2
d = 3
$\ell_{apparent} = \frac{\ell_{absolute}}{d^2}$

Fig. 4.6 The concept of standard candle is based on Gauss Law of fluxes which is satisfied by any type of massless radiation like the electromagnetic one. Since the flux through any spherical surface that surrounds the source is constant, it follows that the apparent luminosity decreases, with respect to the absolute one, with the square of the distance from the surface. If we happen to know the absolute luminosity then, by measuring the apparent one, we can easily evaluate the distance which separates our terrestrial environment from the observed object

Fig. 4.7 Henrietta Leavitt (1868–1921) was completely deaf. This notwithstanding she was one of the first women who made a scientific career in Astronomy. After graduation from the Radcliffe College, an allied institution of Harvard University, she obtained a job from the Harvard Observatory as a human-computer, namely as a human resource for those calculations that at that time, deprived of electronic computers, had to be done by hand. In 1912 she made her great discovery about variable Cepheides. She died from cancer in 1921. Proposed for the Nobel Prize by Mittag-Leffler she could not get it since she had already died at the time of assignment

The union of (6.1.2) with (6.1.3) constitutes the Neveu Schwarz algebra [7] which is a first example of a *super Lie Algebra*. The novelty that entitles it to the new qualifier "*super*" is the presence of a grading that splits the set of all generators in two classes, the *even* ones (in our case the L_n) and the *odd* ones (in our case the $G_{n+\frac{1}{2}}$). The algebra is specified by providing the *commutators* of the *even* operators with the *even* ones that necessarily produces another *even* operator, of the *even*s with the *odd*s that produces an *odd* and finally the *anti-commutator* of two *odd*s that necessarily produces an *even*.

Chronologically the Neveu Schwarz superalgebra was not really the very first, since a few months before, also in 1971, Pierre Ramond had found another very similar extension of the Virasoro algebra adding to it a set of *odd generators* G_n that are in correspondence with the integer numbers. Ramond superalgebra [4] is obtained by adjoining to (6.1.2) the following commutation, anti-commutation relations:

$$\begin{aligned} [L_m, G_n] &= \left(\frac{1}{2}m - n\right) G_{m+n} \\ \{G_m, G_n\} &= 2L_{n+m} + \frac{c}{3}\left(m^2 - \frac{1}{4}\right)\delta_{m+n,0} \\ [c, G_n] &= 0 \end{aligned} \tag{6.1.4}$$

Which algebra was the right one for superstrings? Both were right since they have a common origin in an extension of Nambu string theory by means of a new fermionic field that lives on the world-sheet traced by the string while propagating through space-time. The evolution history of the string, for instance that drawn in Fig. 6.3 or in Fig. 6.4 is described by giving the coordinate X^μ of the ambient space as functions $X^\mu(\sigma, \tau)$ of the two Gaussian coordinates $\{\sigma, \tau\}$ that label the world-sheet points. So doing we can regard the world-sheet itself as a two-dimensional space-time and the functions $X^\mu(\sigma, \tau)$ as a set of scalar fields living on it. Adopting this point of view why not consider, besides spin 0 fields also new fermionic fields of spin $\frac{1}{2}$ living in the same space-time? Let us do it and let us introduce as many new fields of this type as there were scalar fields: let us name such newcomers $\Psi^\mu(\sigma, \tau)$. What has it happened at the end of such a procedure? A surprising miracle! The little field theory that we have constructed on the world-sheet has the following marvelous properties:

- It is *supersymmetric* since it is invariant under a set of appropriate transformations that exchange the bosonic fields $X^\mu(\sigma, \tau)$ with the fermionic ones $\Psi^\mu(\sigma, \tau)$.
- It is anomaly free and quantum consistent no longer in a $D = 26$ space-time, rather in a significantly smaller one $D = 10$.
- The states encompassed in the spectrum of this quantum theory divide in two sectors, one named **NS** realizes the Neveu Schwarz algebra (6.1.2)+(6.1.3), the second named **R** realizes the Ramond algebra (6.1.2)+(6.1.4). Both sectors are necessary to construct Veneziano amplitudes for bosonic and fermionic particles.

6.1.2 Supersymmetry

While trying to insert fermions into the structure of Veneziano amplitudes, a new algebraic structure had been discovered, *supersymmetry*, which was destined to mark heavily the development of Theoretical Physics in the subsequent years. Actually in the same 1971 year, the supersymmetry algebra had been constructed in a completely different context by two Russian scientists, Golfand and Likhtman [1, 2], whose almost tragic personal story is a sort of emblem of the incredible contradictions of Soviet times, also in relation with pure science.[3] Results similar to those of Golfand and Likhtman were obtained also in Kharkov, by other two Soviet scientists, Volkov and Akulov [5] who constructed a non-linear field theoretical realization of the same super Poincaré Lie algebra discovered in Moscow.

If we analyse the meaning of the operators in the Virasoro algebra and in its extensions we understand the following: the operators L_n correspond to a mode-expansion of the stress-energy tensor, namely of the Noether current of translations P_μ, while the fermionic operators G_n correspond to the mode-expansion of a spinor-vector current J^α_μ. Which symmetry is such a Noether current associated with? The answer is unique: to some new symmetry generator Q^α which transforms as a spinor under the Lorentz group and whose anti-commutator with itself must be proportional to the translation generator P_μ.

In $D = 4$ the super Lie Algebra corresponding to such a symmetry, contains $\mathscr{N}$ of such spinor generators, named supercharges, and has the following general structure:

$$\begin{aligned}
&[J_{\mu\nu}, J_{\rho\sigma}] = -\eta_{\mu\rho} J_{\nu\sigma} + \eta_{\nu\rho} J_{\mu\sigma} - \eta_{\nu\sigma} J_{\mu\rho} + \eta_{\mu\sigma} J_{\nu\rho} \\
&[J_{\mu\nu}, P_\rho] = -\eta_{\mu\rho} P_\nu + \eta_{\nu\rho} P_\mu \\
&[J_{\mu\nu}, \overline{Q}_{A\beta}] = -\frac{1}{4}\overline{Q}_{A\alpha}(\gamma_{\mu\nu})^\alpha{}_\beta \\
&\{\overline{Q}_{A\alpha}, \overline{Q}_{B\beta}\} = \mathrm{i}\big(\mathscr{C}\gamma^\mu\big)_{\alpha\beta} P_\mu \delta_{AB} - \mathscr{C}_{\alpha\beta} Z_{AB}; \quad (A, B = 1, \ldots, \mathscr{N}) \\
&[Z_{AB}, \text{anything}] = 0
\end{aligned} \tag{6.1.5}$$

---

[3] Born in Kharkov in 1922, Yuri Abramovich Golfand got his mathematical-physical education in that Ukrainian city. Later, since 1951, he joined the Tamm group at the Lebedev Physical Institute of the Soviet Academy of Sciences in Moscow (FIAN), an institution that collected seven Nobel Prizes in Physics in the course of sixty years. Golfand and his student Likhtman conducted there, at the end of the 1960s, the studies that led them to discover the super Poincaré Lie algebra and to construct its first field theoretical realizations, published in 1971 after a long procedure of checks and inspections by the Soviet censorship authorities (see [10] for a detailed account of these facts). The next year, in the course of a routine campaign of personnel cuts, Yuri Golfand was fired from FIAN and decided to apply for an exit visa to Israel. This put him in a very bad light in front of Soviet authorities who refused the visa and treated him as a renegate. For 7 years he lived unemployed and was readmitted to FIAN only in 1980. Golfand obtained permission to emigrate to Israel only in 1990 and there he lived his last four years in Haifa, where he died in 1994. Because of his association with the renegate Golfand, also Likhtman had very difficult times with Soviet authorities and could never get a proper academic position.

*D 1 3 3

the frontiers of current research in gravitational theories, little by little absorbing a remarkable wealth of geometrical lore and of consciousness about its physical meaning.

Hopefully our reader should by now be convinced that the geometrical seeds first implanted in the XIXth century by Gauss and Riemann, not only inspired Einstein and, through his mind, produced a beautiful and so far fully verified theory, but have still a lot to say about Gravity. Whether supersymmetric or not, Gravitation is certainly the most fundamental interaction among the fundamental ones, it governs the structure of the Universe and it is a manifestation of Geometry. Which geometry the humans will still debate for a long time.

The Gaussian Constant in Celestial Mechanics

The asteroid Ceres had been discovered in 1803, but was soon lost as its path took it into the Sun's glare. The tools then available to astronomers were not so well developed as to determine the whole orbit of a thing from just a few observations. Then a young man named Karl Friedrich Gauss developed a method to determine such orbits. His method was used by astronomers to recover Ceres after its passage around the Sun. It was a stunning success and Gauss became instantly famous. Gauss evolved into one of the greatest mathematicians of all time, and contributed brilliantly to a broad range of problems. Of interest to us here is what became known as the *Gaussian constant*.

Gauss sought a constant for use with Kepler's Third Law that would be valid for all objects in any orbit around the Sun, and would make orbital calculations simpler. He derived the constant k that bears his name in his famous 1809 work, *Theory of Motion of the Heavenly Bodies Moving About the Sun in Conic Sections,* sometimes referred to by its shortened Latin title, *Theoria Motus*. Gauss used the Earth's orbit around the Sun as his reference. He took the distance between the Earth and Sun as the unit distance, and the Sun's mass as one unit.

Earlier we saw how when we changed units the equations became much simpler. The mass unit was one solar mass; the distance unit was one astronomical unit (AU). The secondary mass was assumed to be a particle of near-zero mass is orbiting the Sun. When the unit of time was in seconds, the inertial constant became this:

$$\underbrace{G = \frac{4\pi^2}{P^2}}_{G \text{ where units are solar masses, AU and seconds}}$$

When the year is the time unit (such that $P = 1$) the constant further simplified to this:

$$\underbrace{G = 4\pi^2}_{G \text{ where units are solar masses, AU and years}}$$

If, on the other hand, we use *days* as our unit of time, as Gauss did, then we have a constant that will tell us orbital periods of planets in days, which can also be very useful. In Gauss' day the year's length was not as precisely known as it is today, and with a slight adjustment for the mass of the Moon, he arrived at the value for $\sqrt{G}$[4]:

$$\sqrt{G} = .01720209895$$

---

[4] In Gauss' day the period of revolution of the earth was taken as 365.2563835 days. The combined mass of the Earth-Moon system was assumed by Gauss to be 1/354710 of the Sun's mass.

Gauss called this value k so,

$$k = .01720209895$$

This is the *Gaussian constant* or the *Gaussian gravitational constant*. Thus, with these units (solar masses, AU and days),

$$\underbrace{G = k^2}_{G \text{ where units are solar masses, AU and days}}$$

This value of k is used today in celestial mechanics for the solar system, where the mass and distance units are solar and AU, respectively, and where the time units desired are days.[5] It has fundamental importance as an astronomical standard constant.

Use of the Gaussian constant can simplify calculations in celestial mechanics. And even though the values for mass of the Earth-Moon system and Earth's orbital period have been refined over the years since the early 1800s, the Gaussian constant has been adopted as a fundamental constant in astronomy.

Using the Gaussian Constant to Find Heliocentric Periods

For bodies of negligible secondary mass orbiting the Sun, where the units are AU and days, Kepler's equation in terms of the Gaussian constant can be written as:

$$P = \frac{2\pi}{k} a^{3/2}$$

Using the Gaussian constant, we can as an example find the orbital period of Mars (neglecting its own mass), given that its semi-major axis is about 1.52 AU (or, more precisely, 1.52371034 AU)[6] from the Sun:

$$P = \frac{2\pi}{.01720209895} (1.52371034)^{3/2}$$

$$P = 686.99 \text{ days}$$

which is 1.881 years. This is an easy method to get quite accurate results in celestial mechanics calculations.

For bodies of more considerable mass, the equation reverts to this general form (where the 1 is the Sun's mass in solar mass units):

---

[5] The modern astronomical unit has been redefined (a little) to, in effect, take out the mass adjustment Gauss made in determining his constant.

[6] See http://ssd.jpl.nasa.gov

$$P = \frac{2\pi}{k\sqrt{1+m}} a^{3/2}$$

where m is the mass of the body in heliocentric orbit, in solar masses. The Gaussian constant was derived from bodies orbiting the Sun, and is commonly used for such bodies. It applies to *any* body: planet, comet, asteroid, or spacecraft in solar orbit. It was derived from the particular facts of the Earth-Sun system, because they were known, but the same constant could just as easily have been derived from another planet's data in the solar system.

Applying the Gaussian Constant to Find Heliocentric Orbital Velocities

The Gaussian constant is expressed in terms of solar masses, astronomical units and days. For finding the period of heliocentric orbits, this is very useful. Later we will be calculating velocities in heliocentric orbits. The usual result in such calculations is kilometers per second. So it would seem the AU/days units for the Gaussian constant would not be much of a time-saver. However, we can derive a conversion factor for such purposes. For the conversion we divide 1 AU in meters by the length of the day, which is 86,400 s. Hence the Gaussian AU/day units can become meters per second. To find its value, we divide

$$\underbrace{\frac{\text{AU}}{\text{Day}}}_{\text{Units for Gaussian constant k}} \quad \rightarrow \quad \underbrace{\frac{\text{AU in kilometers}}{\text{Day in seconds}}}_{\text{Conversion factor when seeking result in km/s}}$$

Inserting the correct values for the numerator and denominator,

$$\frac{149,597,871 \times 10^{8}}{86,400}$$

$$\underbrace{1731.46}_{\text{Conversion factor from AU/days to km/ sec}}$$

---

[7] The precise result is 1731.45684 which can be used where more precision is desired.

This number is good to remember.[7] To see how this is useful, recall the circular velocity in a heliocentric orbit is given by

$$v = \sqrt{\frac{Gm_\odot}{a}}$$

Using the units for the Gaussian constant k (where mass units are solar, time units are days and distances are in AU) the equation becomes,

$$v = \frac{k}{\sqrt{a}}$$

To take the example of Mars again, its *mean* velocity should be,

$$v = \frac{.01720209895}{\sqrt{1.5237}}$$

$$v = .0139358.\mathrm{AU}/\mathrm{day}$$

These are awkward units! Converting to kilometers per second, multiply the result by the conversion factor derived above and we obtain, for a mean orbital velocity of Mars, the value,

$$1731.46 \times .0139358 = 24.1\,\mathrm{km}/\,\mathrm{sec}$$

We used two constants, the Gaussian constant and a conversion factor. Combining these into one "modified" Gaussian constant for a heliocentric orbit, and calling the result the Greek letter kappa, we get

$$\kappa = 1731.46k$$
$$\kappa = 29.785$$

We will use this number frequently in heliocentric velocity calculations.[8] The equation for mean velocity in kilometers per second thus becomes,

$$v = \frac{\kappa}{\sqrt{a}}$$

---

[8] The result for κ to more decimal places is 29.78469189. We will use the rounded value for the instructional purposes of this book.

8 Conserved quantities in the Einstein-Gauss-Bonnet gravity

8.1 Superpotentials and currents in the EGB gravity

8.1.1 Action and field equations in the EGB gravity

In the present chapter we develop and apply the results of the previous chapter to Einstein-Gauss-Bonnet (EGB) gravity. This modification of general relativity is the one of the most well-known of all modified gravitational theories. From the one side, it is the second order of the Lovelock type theories, Lagrangians of which are polynomials of the curvature tensors leaving the field equations second order [299]. From the other side, the EGB theory is the low energy limit of some string theories.

The action of the n-dimensional EGB theory with a bare cosmological term Λ_0 is

$$\begin{aligned} S &= -\frac{1}{2\kappa}\int d^n x \mathscr{L}_{EGB} + \int d^n x \mathscr{L}^M \\ &= -\frac{1}{2\kappa}\int d^n x \sqrt{-g}\,[R - 2\Lambda_0 + \alpha L_{GB}] + \int d^n x \mathscr{L}^M\,, \end{aligned} \tag{8.1.1}$$

where $\alpha > 0$, we restrict ourselves to $\Lambda_0 \le 0$, and the Gauss-Bonnet combination is

$$L_{GB} = R^2_{\mu\nu\rho\sigma} - 4R^2_{\mu\nu} + R^2\,, \tag{8.1.2}$$

see, for example, [126]. Thus $\mathscr{L}_{EGB}$ plays the role of $\mathscr{L}^G$ in (7.2.1), or in (7.2.60). Below, the subscripts "$_E$" is related to the pure Einstein part of the action (8.1.1), and the subscript "$_{GB}$" is related to the Gauss-Bonnet part connected with the α-correction.

The equations of motion that follow from (8.1.1) are

$$\mathscr{E}_{\mu\nu} = \kappa \mathscr{T}_{\mu\nu}\,, \tag{8.1.3}$$

where

$$\mathscr{E}_{\mu\nu} \equiv \frac{\delta}{\delta g^{\mu\nu}}\mathscr{L}_{EGB} = \sqrt{-g}\left[\left(R_{\mu\nu} - \tfrac{1}{2}g_{\mu\nu}R + g_{\mu\nu}\Lambda_0\right) + \alpha H_{\mu\nu}\right]\,; \tag{8.1.4}$$

$$\begin{aligned} H_{\mu\nu} \equiv 2\Big[&RR_{\mu\nu} - 2R_{\mu\sigma\nu\rho}R^{\sigma\rho} - R_{\mu\sigma\rho\tau}R_\nu{}^{\sigma\rho\tau} - 2R_{\mu\sigma}R_\nu{}^\sigma \\ &- \tfrac{1}{4}g_{\mu\nu}\left(R^2_{\tau\lambda\rho\sigma} - 4R^2_{\rho\sigma} + R^2\right)\Big]\,, \end{aligned} \tag{8.1.5}$$

and $\mathscr{T}_{\mu\nu}$ is the standard matter energy-momentum defined as in (1.3.21). The expression $H_{\mu\nu}$ is a result of varying L_{GB}, and $H_{\mu\nu} \equiv 0$ if $n \le 4$.

DOI 10.1515/9783110351781-008

The equations (8.1.3) are the variant of the equations (7.2.3) for the case of the EGB gravity. The equations (8.1.3) are also

$$\mathscr{E}_{\mu\nu} = 0 \tag{8.1.6}$$

in the vacuum case.

8.1.2 Three types of superpotentials

In deriving concrete expressions for conserved quantities in the EGB gravity, we change the order of the presentation used in Sections 7.1 and 7.2, where currents have been described firstly. Indeed, considering an abstract theory, it is more natural to begin the construction from currents, then to continue the construction of superpotentials. Here, inversely, we begin from superpotentials, and finish with the currents. The reasons are as follow. First, anyway we keep in mind the principal scheme of construction in Chapter 7 and already have at hand the basic general formulae for such a construction. Second, historically superpotentials have been more popular and more desirable in applications because they give a direct way for constructing conserved charges. Third, superpotential expressions are significantly simpler than the expressions for currents.

The canonical prescription

At first, one has to define the KBL type Lagrangian for the EGB gravity. Following to (7.2.15), we derive it as

$$\mathscr{L}_{KBL} = -\frac{1}{2\kappa}\left(\mathscr{L}^{c}_{EGB} - \bar{\mathscr{L}}^{c}_{EGB} + \partial_\alpha \mathscr{D}^\alpha\right) . \tag{8.1.7}$$

Following the recommendation (7.2.18), we construct the canonical superpotential in the EGB gravity,

$$\boldsymbol{j}^{*\alpha\beta}_{C}(\xi) = \boldsymbol{i}^{*\alpha\beta}(\xi) - \bar{\boldsymbol{i}}^{*\alpha\beta}(\xi) + \boldsymbol{i}'^{\alpha\beta}(\xi) . \tag{8.1.8}$$

From the beginning we construct the *starred* expressions, coefficients for which are derived in Appendix C. Possibilities of the developed approaches in Section 7.2 permit us to construct families of superpotentials easily. Here we use these possibilities by applying concrete expressions in the EGB case. Thus, the pure Noether's canonical starred superpotential of the general form (7.1.46) in EGB gravity acquires the concrete form:

$$\begin{aligned}
\boldsymbol{i}^{*\alpha\beta} = {} & \frac{1}{\kappa}\left(\mathfrak{g}^{\rho[\alpha}\bar{\nabla}_\rho \xi^{\beta]} + \mathfrak{g}^{\rho[\alpha}\Delta^{\beta]}_{\rho\sigma}\xi^\sigma\right)\\
& - 2\alpha\frac{1}{\kappa}\left\{\Delta^{\rho}_{\lambda\sigma}\mathscr{R}_{\rho}{}^{\lambda\alpha\beta} + 4\Delta^{\rho}_{\lambda\sigma}g^{\lambda[\alpha}\mathscr{R}^{\beta]}_{\rho} + \Delta^{[\alpha}_{\rho\sigma}g^{\beta]\rho}\mathscr{R}\right\}\xi^\sigma\\
& - 2\alpha\frac{1}{\kappa}\left\{\mathscr{R}_{\sigma}{}^{\lambda\alpha\beta} + 4g^{\lambda[\alpha}\mathscr{R}^{\beta]}_{\sigma} + \delta^{[\alpha}_{\sigma}g^{\beta]\lambda}\mathscr{R}\right\}\bar{\nabla}_\lambda\xi^\sigma ,
\end{aligned} \tag{8.1.9}$$

(' $ '$ = 7!) 9 3

a testament. All the terms, parameters, contribute, in a highly non-trivial way, to the masses which are only defined at a given constant curvature background. Let us consider the three and the four dimensional cases as two explicit examples as they offer interesting limits and some other special theories.

The case of $n = 3$ dimensions

The masses of the spin-2 and spin-0 modes respectively read

$$m_g^2 = -\frac{1}{\kappa\beta} - 4\left(1 + 3\frac{\alpha}{\beta}\right)\Lambda, \qquad m_s^2 = \frac{1}{(8\alpha + 3\beta)\kappa} - \frac{4(3\alpha + \beta)}{(8\alpha + 3\beta)}\Lambda, \tag{9.2.76}$$

which were also found with the usual canonical analysis in [210] for the de Sitter case. It is also important to note that, since there is no massless graviton these are the 3 degrees of freedom in 3 dimensions. This fact has remarkable consequences, for the choice $8\alpha + 3\beta = 0$, the scalar mode decouples and one can make the massive spin-2 mode unitary. This theory is called the "New Massive Gravity" (NMG) theory noted above [39] which is a theory of massive spin-2 graviton at the non-linear level. [2]

The case of $n = 4$ dimensions

The masses of the spin-2 and spin-0 modes respectively read

$$m_g^2 = -\frac{1}{\kappa\beta} - 2\left(1 + 4\frac{\alpha}{\beta}\right)\Lambda, \qquad m_s^2 = \frac{1}{2(3\alpha + \beta)\kappa}. \tag{9.2.77}$$

It is interesting to note that only in four dimensions, for (A)dS backgrounds, the massless mode does not receive a correction from the background. In addition to these two modes, there is the Einsteinian massless spin-2 graviton which altogether make up the 8 degrees of freedom whose flat space versions were given by Stelle [423]. An often studied sub-case of quadratic gravity is the Weyl-square corrected Einstein's gravity for which $3\alpha + \beta = 0$ in four dimensions. In this case the scalar mode decouples but the theory has a massive spin-2 ghost. In addition, if one drops out the Einstein term and keeps only the quadratic part, one has the so called conformal gravity [309, 389] since the combination $R_{\mu\nu}^2 - \frac{1}{3}R^2$ is equal to the Weyl-square up to a boundary term.

Einstein-Gauss-Bonnet theory

For the Einstein-Gauss-Bonnet (Einstein-GB) theory in n dimensions, since $\alpha = \beta = 0$, both massive modes decouple and only the massless mode survives as expected since the field equations are second order. But there is a constraint on the theory for unitarity since the effective Newton's constant now reads

---

[2] As a side remark, let us note that NMG suffers from bulk-boundary unitarity clash, namely the theory does not have a unitary boundary conformal field theory in its 2 dimensional boundary of AdS_3 as one of its central charges of the double copy of the Virasoro algebra turns out to be negative. This unitarity clash seems to persist in all extensions of NMG with massive spin-2 gravitons [212].

$$\frac{1}{\kappa_{\text{eff}}} \equiv \frac{1}{\kappa} + \frac{4\Lambda\,(n-3)\,(n-4)}{(n-1)\,(n-2)}\gamma = \frac{1}{\kappa} + 4\Lambda k, \tag{9.2.78}$$

which must be positive to get a positive kinetic energy for the massless graviton or equivalently, to get attractive gravity and this condition must be compatible with the existence of a maximally symmetric solution that is $1 + 8k\kappa\Lambda_0 \geq 0$. This theory arises in low energy string theory [71, 477].

Critical gravity

Critical gravity corresponds to the decoupling of the massive spin-0 mode with the choice $4\alpha(n-1)+\beta n = 0$ while tuning the cosmological constant in such a way that the massive spin-2 mode also decouples. The resulting theory is a higher derivative theory with an action of the form [123, 300]

$$S = \int d^n x\, \sqrt{-g}\left(\frac{1}{\kappa}\,(R - 2\Lambda_0) + \alpha R^2 - \frac{4\,(n-1)}{n}\alpha R^{\mu\nu}R_{\mu\nu} + \gamma\chi_{\text{GB}}\right), \tag{9.2.79}$$

where the bare cosmological constant must be tuned as

$$\Lambda_0 = -\frac{n^2\,(n-1)\,(n-2)\,\left[(n-1)\,(n-2)\,\alpha + (n-3)\,(n-4)\,\gamma\right]}{8\kappa\left[(n-1)\,(n-2)^2\,\alpha + n\,(n-3)\,(n-4)\,\gamma\right]^2}. \tag{9.2.80}$$

Even though this theory seems promising as a possible ghost-free, perhaps renormalizable gravity theory, it turns out this is not the case. The theory has asymptotically non-AdS logarithmic modes [3, 215] which are of the wave-type and arise as both exact and as perturbative solutions. It was shown in [381] that they are ghosts and truncation of these modes renders the Hilbert space trivial, devoid of anything but the vacuum. Hence the above discussion teaches us something important: for $n \geq 4$ one must have $\beta = 0$ to avoid the massive spin-2 ghost, $n = 3$ is the exceptional case.

9.3 Particle spectrum of $f(R_{\mu\nu\sigma\rho})$ gravity in (A)dS

Now we turn our attention to the following more general theory with f an arbitrary analytic function of the Riemann tensor

$$S = \int d^n x\, \sqrt{-g} f\left(R^{\mu\nu}_{\alpha\beta}\right). \tag{9.3.1}$$

In this formulation, with two up and two down indices on the Riemann tensor, the (inverse) metric is not needed for contractions and this simplifies the ensuing discussion a little bit. For example, in this notation, the Einstein-Hilbert action (up to a multiplicative constant) simply reads

way, progression from the dipole to the full quadrupole case would have added a third evolution equation and all three would have involved time derivatives of quadrupole components. Each successive approximation would add a further equation in this way, and a complete solution of the variational equation would have an infinite set of equations, each involving time derivatives of an infinite set of moments.

In Newtonian mechanics there would only be two evolution equations, those for momentum and angular momentum. Mathisson's new mechanics should aim at maintaining this simplicity. This would require eliminations between the full set of equations to leave only two, those governing momentum and angular momentum. The issue is whether or not this can be achieved, and if so how it can be done.

The final issue concerns the supplementary condition (18). Equation (17) is of second order in $S^{\alpha\beta}$. By use of (18) it can be put in a form that is of first order in $S^{\alpha\beta}$ but then it becomes second order in v^α. The set of equations (15), (17) and (18) then has solutions corresponding to arbitrary initial values of position, velocity, spin *and acceleration*. This is greater freedom than classical mechanics allows.

If the equations of motion are considered to represent a point particle then it is a matter of fact whether (18) is or is not satisfied. In a second paper [12] in 1937, Mathisson showed that this additional freedom in the solutions provides a classical analogue of the *zitterbewegung* of the quantum theory of the electron. But if the equations of motion are to represent an extended body then the supplementary condition selects the world line used to represent its position. It is no longer a matter of fact, but of choice, whether (18) holds. The freedom to specify an initial acceleration is now a defect. It does not correspond to a physical freedom but merely to the failure of (18) to determine a unique world line. It points to the need for a different supplementary condition that does not admit such solutions.

5 The Unphysical Solutions

The unphysical solutions allowed by the supplementary condition (18) are present also in special relativity. In this context they were studied by a number of authors in the period 1939–1950. It was noted above that they must be avoided when modelling an extended body. To achieve this, their origin needs to be properly understood. The following account is based on the work of Pryce [13] and Møller [14] and uses a Minkowskian coordinate system in the flat spacetime of special relativity.

Consider an extended body with symmetric energy-momentum tensor $T^{\alpha\beta}$ that satisfies the conservation equation (3). Given a spacelike hypersurface Σ that spans the body and a point z not necessarily on Σ, let

$$p^\alpha \equiv \int_\Sigma T^{\alpha\beta} \mathrm{d}\Sigma_\beta \tag{26}$$

and

$$S^{\alpha\beta} \equiv 2\int_{\Sigma}(x^{[\alpha} - z^{[\alpha}(s))T^{\beta]\gamma}\mathrm{d}\Sigma_{\gamma}. \tag{27}$$

The difference between their values for two different choices of Σ can be converted by Gauss's theorem to volume integrals. The integrands then vanish by the conservation equation for $T^{\alpha\beta}$ and because it is symmetric. These quantities are therefore independent of the choice of Σ. As the definition of p^{α} does not involve z, it follows that p^{α} is constant while $S^{\alpha\beta}$ becomes a function only of the point z. These properties have led to them becoming the generally accepted definitions of momentum and angular momentum (spin) for an isolated body in special relativity. Generalisations to more complex situations such as general relativity or the presence of external forces need to reduce to these in this special case.

Let z move along an arbitrary timelike world line L parameterised as $z(s)$ by proper time s and let $v^{\alpha} = \mathrm{d}z^{\alpha}/\mathrm{d}s$, which satisfies $v^{\alpha}v_{\alpha} = 1$. Differentiate (27) with respect to s, holding Σ fixed as the values of the integrals do not depend on it. This gives

$$\frac{\mathrm{d}S^{\alpha\beta}}{\mathrm{d}s} = 2p^{[\alpha}v^{\beta]} \tag{28}$$

from which

$$p^{\alpha} = Mv^{\alpha} + v_{\beta}\frac{\mathrm{d}S^{\alpha\beta}}{\mathrm{d}s} \tag{29}$$

where $M \equiv p^{\alpha}v_{\alpha}$. Since p^{α} is constant, (29) gives

$$\frac{\mathrm{d}}{\mathrm{d}s}\left(Mv^{\alpha} + v_{\beta}\frac{\mathrm{d}S^{\alpha\beta}}{\mathrm{d}s}\right) = 0 \tag{30}$$

while (28) and (29) together give

$$\frac{\mathrm{d}S^{\alpha\beta}}{\mathrm{d}s} + v^{\alpha}v_{\gamma}\frac{\mathrm{d}S^{\beta\gamma}}{\mathrm{d}s} - v^{\beta}v_{\gamma}\frac{\mathrm{d}S^{\alpha\gamma}}{\mathrm{d}s} = 0. \tag{31}$$

These are precisely the forms taken in flat spacetime by Mathisson's equations (15) and (17) in his dipole approximation, but now they are exact and the supplementary condition (18) has not yet been imposed. The variables also agree, to the accuracy of his approximation. To see this, note first that $m^{\alpha\beta\gamma} = M^{\alpha\beta\gamma}$ in the notation of (24) when quadrupole and higher contributions are neglected, and that the definition (27) of $S^{\alpha\beta}$ corresponds to $S^{\alpha\beta} = 2M^{[\alpha\beta]\gamma}v_{\gamma}$ to this accuracy. But (14) gives $2m^{[\alpha\beta]\gamma}v_{\gamma} = S^{\alpha\beta}$, so it follows that the two tensors $S^{\alpha\beta}$ are in agreement. The vector v^{α} is the unit tangent to L in both cases and in order for the right hand side of (29) to be constant with both definitions of M, these must also agree.

This agreement enables the origin of the unphysical solutions arising from the supplementary condition (18) to be studied in a context where the equations of motion are exact. First suppose that z is any point on some L that satisfies (18). Choose Σ in (27) to be the hyperplane $v_\alpha(x^\alpha - z^\alpha) = 0$ through z. For this choice, $\mathrm{d}\Sigma_\alpha$ is parallel to v_α so that $\mathrm{d}\Sigma_\alpha = v_\alpha v^\gamma \mathrm{d}\Sigma_\gamma$. Hence (18) with (27) gives

$$z^\alpha(s) = \int x^\alpha T^{\beta\gamma} v_\beta v_\gamma v^\delta \mathrm{d}\Sigma_\delta \Big/ \int T^{\beta\gamma} v_\beta v_\gamma v^\delta \mathrm{d}\Sigma_\delta, \tag{32}$$

showing that z^α is a centre of mass for the mass (or energy) density $T^{\alpha\beta} v_\alpha v_\beta$ in the instantaneous rest frame. It follows that for a body with positive energy density throughout, i.e., $T^{\alpha\beta} v_\alpha v_\beta > 0$ for all choices of timelike v^α, L lies within the body (suitably interpreted if spacelike cross-sections of the body are not convex).

This is a restriction on the solutions for L but it does not make L unique. To study the non-uniqueness in more detail, let

$$K^{\alpha\beta} \equiv 2 \int x^{[\alpha} T^{\beta]\gamma} \mathrm{d}\Sigma_\gamma \tag{33}$$

so that (27) gives

$$S^{\alpha\beta}(s) = K^{\alpha\beta} - 2z^{[\alpha}(s) p^{\beta]}. \tag{34}$$

This shows that there is a unique world line parameterised by a scalar λ, given by

$$z^\alpha = \lambda p^\alpha + \frac{p_\beta K^{\alpha\beta}}{p^\gamma p_\gamma}, \tag{35}$$

on which

$$p_\beta S^{\alpha\beta} = 0. \tag{36}$$

If the Minkowskian coordinate system is chosen so that this line is the time axis then it is also given by $z^\alpha = \lambda p^\alpha$, so (34) gives $S^{\alpha\beta}(s) = K^{\alpha\beta}$ and (36) becomes

$$p_\beta K^{\alpha\beta} = 0. \tag{37}$$

Let Latin indices take values 1, 2, 3 and let m be the magnitude of p^α, so $m^2 = p^\alpha p_\alpha$. Then with these coordinates $p^i = 0$, $p^0 = m$ and hence from (37) also $K^{i0} = 0$. From (34) the supplementary condition (18) can be put in the form

$$v_\beta \left(K^{\alpha\beta} - 2z^{[\alpha}(s) p^{\beta]} \right) = 0. \tag{38}$$

This has only three linearly independent components, which can be taken as those with $\alpha = 1, 2, 3$, since multiplication by v_α gives an identity. It is therefore equivalent to

$$v_j K^{ij} - m z^i v_0 = 0 \tag{39}$$

in the chosen Minkowskian coordinates. Since K^{ij} is antisymmetric it can be represented by a three-dimensional vector K_i such that $K^{ij} = \epsilon^{ikj} K_k$ where ϵ^{ijk} is the three-dimensional Levi-Civita symbol. If $t \equiv x^0$ is coordinate time then $v^i/v^0 = \mathrm{d}z^i/\mathrm{d}t$. These results enable (39) to be expressed in three-dimensional vector notation as

$$m\mathbf{z} - \frac{\mathrm{d}\mathbf{z}}{\mathrm{d}t} \times \mathbf{K} = 0. \tag{40}$$

Since $\mathbf{K}$ is constant, the time derivative of (40) shows that $\mathrm{d}\mathbf{z}/\mathrm{d}\mathbf{t}$ and $\mathbf{K}$ are orthogonal. The vector product of (40) with $\mathbf{K}$ therefore gives

$$\frac{\mathrm{d}\mathbf{z}}{\mathrm{d}t} = \frac{m}{\mathbf{K}^2}\mathbf{K} \times \mathbf{z}. \tag{41}$$

This corresponds to motion about the origin in a circle with angular velocity m/K, where $K = |\mathbf{K}|$, in a plane perpendicular to $\mathbf{K}$. From (40) the radius of the circle is vK/m where $v = |\mathrm{d}\mathbf{z}/\mathrm{d}t|$. Units here have the velocity of light $c = 1$ so since L is timelike, $v < 1$. The possible circular motions therefore all lie in a disc of radius K/m in this plane and centred on the origin, but all such motions give an L that satisfies the supplementary condition, so confirming the non-uniqueness claimed above. For a body with positive energy density throughout, it was seen above that all choices of L that satisfy the supplementary condition lie within the body, suitably interpreted. It follows that this disc lies within the body, which gives a minimum size for such a body when its spin is nonzero.

A different perspective arises if the Eqs. (30) and (31) are taken in isolation, so that the quantities M and $S^{\alpha\beta}$ are considered to be properties of the body rather than constructs from the energy-momentum tensor. This is the situation when the equations of motion are used to model a point particle whose motion satisfies (18) as a matter of physical fact. The same results hold but they need to be cast in terms of M and $S^{\alpha\beta}$ rather than m and K. With the same choice of Minkowskian coordinate system used above, (34) gives $S^{ij} = K^{ij}$ but whereas $K^{i0} = 0$, S^{i0} is not zero. From (18),

$$S^{i0} = -S^{ij} v_j/v_0 = -K^{ij} v_j/v_0 = -\epsilon^{ikj}\frac{\mathrm{d}z_j}{\mathrm{d}t}K_k. \tag{42}$$

But $\mathrm{d}\mathbf{z}/\mathrm{d}t$ and $\mathbf{K}$ are orthogonal three-dimensional vectors and $S_{i0} = -S^{i0}$ due to the form of the metric tensor, so

$$S^{i0}S_{i0} = -(vK)^2. \tag{43}$$

With the magnitude S of the spin tensor $S^{\alpha\beta}$ defined by $S^2 = S^{\alpha\beta}S_{\alpha\beta}/2$, (43) gives

$$S^2 = K^2(1 - v^2). \tag{44}$$

Also

$$M \equiv p^{\alpha} v_{\alpha} = m v_0 = m/\sqrt{1 - v^2} \tag{45}$$

so

$$\frac{vK}{m} = \frac{vS}{M(1 - v^2)} \tag{46}$$

which gives the radius of the circular orbit in terms of S and M as required. But whereas $v < 1$, which gave a limiting size to the radius, $v/(1 - v^2)$ is unbounded as $v \to 1$. With this perspective there is no limit on the size of the circular orbits. As described above, the initial acceleration of the particle can be arbitrary and it is this choice that determines which orbit is followed.

This form of solution to the Eqs. (30) and (31) in flat spacetime was first given by Weyssenhoff and Raabe [15]. Mathisson [12] had earlier given a solution in the non-relativistic approximation that he had used to provide a classical analogue of the *zitterbewegung* of the electron. But as discussed in the preceding section, when the equations are used to model an extended body then these unphysical solutions must be avoided. The above analysis provides the clue to their avoidance, for it was seen that (36) *does* determine a unique world line. So in special relativity, if (36) is adopted as the supplementary condition in place of (18) then unphysical solutions are avoided. The issue in a curved spacetime is to find appropriate meanings for p^{α} and $S^{\alpha\beta}$. This will be addressed in Sect. 21.

6 The Period 1950–1970

At his death in 1940, Mathisson [9] had been studying his variational equation in special relativity for a body under the influence of external forces, maybe looking for clues as to how to progress further with it in general relativity. This work led to a paper by Shanmugadhasan [16] in 1946 that continued this development in special relativity. The multipole approach to equations of motion in general relativity went dormant, however, until the appearance of a paper by Papapetrou [17] in 1951 entitled "Spinning test-particles in general relativity. I", a title that does not show anything like the same vision as did Mathisson's.

Papapetrou defined a set of non-covariant moment integrals identical to those of Bielecki et al. [8] given as (24) above. He continued by developing equations of motion in terms of these quantities and other similarly defined ones, also non-covariant, constructing combinations of them along the way that he subsequently proved did transform as tensors. This was done first for a particle in which only the monopole moment is retained, and then when the dipole moment is also retained, which he calls a pole-dipole particle. In this way he finally arrives at the Eqs. (15) and (17) first obtained by Mathisson. Mathisson's paper [1] of 1937 is given as a reference, but with the statement that it gives a discussion of the pole-dipole particle in special relativity. Since Papapetrou's paper of 1951 in Proceedings of the Royal and a is the largest dimension of the body. Thus, when $\lambda \ll 1$, i.e. when the curvature is not too strong compared to the scale of the size of the body,[13] $P^{\hat{\alpha}}_{\text{Dix}} \simeq P^{\hat{\alpha}}$. The two schemes are actually indistinguishable in a pole-dipole approximation, where only terms to linear order in x are kept in the integrals defining the moments; the resulting equations of motion are the same (compare Eqs. (43), (49) of [25] with Eqs. (6.31) and (6.32) of [11], or Eqs. (7.1) and (7.2) of [26]), both schemes leading to the well known Mathisson-Papapetrou equations (the latter derived using less sophisticated formalisms). These conclusions are natural, for the metric in Riemann normal coordinates is (e.g. [27]) of the form $g_{\hat{\alpha}\hat{\beta}} = \eta_{\hat{\alpha}\hat{\beta}} + \mathcal{O}(\|\mathbf{R}\|x^2)$; hence the assumption $\lambda \ll 1$ amounts to say that, *for the computation* of P^α and $S^{\alpha\beta}$, one may, to a good approximation, take the spacetime as nearly flat throughout the body.

The Dependence of the Particle's Momenta on Σ

The momenta (1) and (2) depend, in general, on the spacelike hypersurface $\Sigma(z,u) \equiv \Sigma(z(\tau),u)$ on which the integration is performed, see e.g. [11, 25, 26]. This is so even in flat spacetime; when forces and torques act on the body, it is clear that $P^\alpha(z,u)$, $S^{\alpha\beta}(z,u)$ depend on $z^\alpha(\tau)$, and also on the argument u^α of Σ. Curvature brings additional complications, as u^α is no longer a "free vector", and Σ itself is in principle point dependent. Herein we shall show that, in the absence of electromagnetic field ($F^{\alpha\beta} = 0$), and under the assumption $\lambda \ll 1$ made above, for hypersurfaces $\Sigma(z,u)$ *through a point* z^α *within the body*'s convex hull, the u^α dependence of the momentum and angular momentum is negligible.

Denote by $\boldsymbol{\xi} = dx^{\hat{\alpha}}$ a particular basis 1-form of the Riemann normal coordinate system $\{x^{\hat{\alpha}}\}$; $P^{\boldsymbol{\xi}} \equiv P^\alpha \xi_\alpha$ is thus the $\boldsymbol{\xi}$ component of P^α. From definition (1), and since ξ_α has constant components, we may write the $\boldsymbol{\xi}$ component of the momentum as the integral of a vector $A^\alpha \equiv T^{\alpha\beta}\xi_\beta$ on a 3-surface,

$$P^{\boldsymbol{\xi}}(z,u) = \xi_{\hat{\alpha}} \int_{\Sigma(z,u)} T^{\hat{\alpha}\hat{\beta}} d\Sigma_{\hat{\beta}} = \int_{\Sigma(z,u)} T^{\hat{\alpha}\hat{\beta}} \xi_{\hat{\alpha}} d\Sigma_{\hat{\beta}} = \int_{\Sigma(z,u)} A^\beta d\Sigma_\beta \ .$$

Take $u^\alpha = P^\alpha/M$, and consider another vector u'^α at the same point z^α; the $\boldsymbol{\xi}$ component of the difference between the momenta computed in the hypersurfaces $\Sigma(z,u')$ and $\Sigma(z,u)$, $\Delta P^{\boldsymbol{\xi}} \equiv P^{\boldsymbol{\xi}}(z,u') - P^{\boldsymbol{\xi}}(z,u)$ is, from an application of the Gauss theorem (see Fig. 7),

$$\Delta P^{\boldsymbol{\xi}} = \int_{\Sigma(z,u)} A^\beta d\Sigma_\beta - \int_{\Sigma(z,u')} A^\beta d\Sigma_\beta = \int_{V_{Left}} A^\beta{}_{;\beta} dV - \int_{V_{Right}} A^\beta{}_{;\beta} dV \ .$$

---

[13] For example, in the case of the Schwarzschild spacetime, $\|\mathbf{R}\| \sim m_S/r^3$, $\lambda = (m_S/r)(a^2/r^2)$; since $m_S/r < 1$ for any point outside the horizon, $\lambda \ll 1$ is guaranteed just by taking the size of the body much smaller than its the distance to the source, $r^2 \gg a^2$.

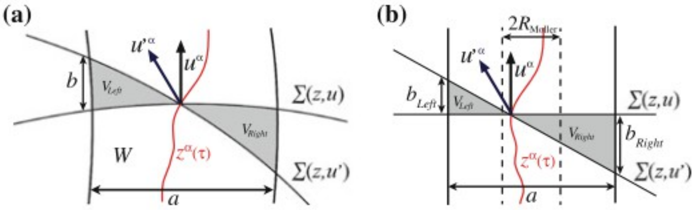

Fig. 7 *Shadowed regions* V_{Left} and V_{Right} are the 4-volumes delimited by the hypersurfaces $\Sigma(z,u')$, $\Sigma(z,u)$, and the boundary of the body's worldtube, of convex hull W. u^α is chosen parallel to P^α. **a** Curved spacetime; **b** flat spacetime

Here V_{Left} and V_{Right} denote the shadowed regions of Fig. 7 (where $A^\alpha \neq 0$), i.e. the "left" and "right" 4-volumes delimited by $\Sigma(z,u')$, $\Sigma(z,u)$ and the boundary of the body's worldtube. Now, using the conservation law $T^{\alpha\beta}_{\ \ \ ;\beta} = 0$, one notes that

$$A^\beta_{\ ;\beta} = T^{\alpha\beta}_{\ \ \ ;\beta}\xi_\alpha + T^{\alpha\beta}\xi_{\alpha;\beta} = T^{\alpha\beta}\xi_{\alpha;\beta};$$

thus

$$\Delta P^{\boldsymbol{\xi}} = \int_{V_{Left}} T^{\alpha\beta}\xi_{\alpha;\beta}dV - \int_{V_{Right}} T^{\alpha\beta}\xi_{\alpha;\beta}dV.$$

Since $\boldsymbol{\xi}$ is a basis 1-form, $\xi_{\hat{\alpha},\hat{\beta}} = 0$, and

$$\xi_{\hat{\alpha};\hat{\beta}} = -\Gamma^{\hat{\gamma}}_{\hat{\alpha}\hat{\beta}}\xi_{\hat{\gamma}} = \mathcal{O}(\|\mathbf{R}\|x);$$

therefore

$$|\Delta P^{\boldsymbol{\xi}}| \lesssim \|\mathbf{R}\| \int_V T^{\hat{0}\hat{0}}|x|dV = \|\mathbf{R}\| V \left\langle T^{\hat{0}\hat{0}}|x| \right\rangle,$$

where $V \equiv V_{Left} + V_{Right}$, $\langle\cdot\rangle$ denotes the average on the shadowed region of Fig. 7a, and we noted that $T^{\hat{0}\hat{0}}$ is the largest component of $T^{\alpha\beta}$ and always positive. Since $b < av(u',u)$ (see Fig. 7), with $v^\alpha(u',u)$ defined by Eq. (9), and $v(u',u) < 1$, then $\langle|x|\rangle < a$; moreover (assuming $\partial_{\hat{0}} = \mathbf{u}$ at z), $V\left\langle T^{\hat{0}\hat{0}}\right\rangle < Mav(u',u)$; hence we get

$$|\Delta P^{\boldsymbol{\xi}}| \lesssim M\lambda v(u',u) = \|\mathbf{P}\|\lambda v(u',u)\ , \tag{70}$$

showing that ΔP^α is negligible[14] compared to P^α under the restriction above on the strength of the gravitational field, $\lambda \ll 1$ (the same under which the different

---

[14] The inequality (69) means not only that the components of $\Delta\mathbf{P}$ in the system $\{x^{\hat{\alpha}}\}$ (where $P^{\hat{i}} = 0$) are much smaller than M, but also much smaller than the typical spatial momentum in other frames. For instance, in normal coordinates $\{x^{\alpha'}\}$ comoving with u'^α, one has $|P^{i'}| \sim \gamma(u',u)v(u',u)M$ and $|\Delta P^{i'}| \lesssim |\Delta P^{\boldsymbol{\xi}}|\gamma(u',u)$, thus $|\Delta P^{i'}| \ll |P^{i'}|$ when $\lambda \ll 1$.

*D & 1 ! = "! ! A! "! < !

multipole schemes become equivalent, and one can take local Lorentz coordinates as nearly rectangular throughout the extension of the body; see also footnote 13). In the application in Sect. 3.4—Schwarzschild spacetime, far field limit—we can write

$$|\Delta P^{\boldsymbol{\xi}}| \lesssim \frac{M m_S}{r^3} a^2 v(u', u) \simeq \| P_{\text{hidI}} \| \frac{a}{R_{\text{Moller}}} \frac{a}{r} v(u', u)$$

where P^{α}_{hidI} is the inertial hidden momentum *of the CP condition*, Eq. (57) (P^{α}_{hidI} is zero or negligible for the other solutions). Thus ΔP^{α} is negligible compared to P^{α}_{hidI} under the condition $\frac{R_{\text{Moller}}}{a} \gg \frac{a}{r} v(u', u)$, which is reasonable in a problem where the particle's spin is worth taking into account (e.g. in the problem of nearly circular motion in Sect. 3.4 this amounts to taking $\omega_{\text{body}} \gg \omega_{\text{orbit}}$, where ω_{body} and ω_{orbit} are the body's rotation and orbital angular velocities).

Through an analogous procedure, one can show that the dependence of $S^{\alpha\beta}$ on u^{α} is negligible in this regime. Let $\mathscr{J}^{\hat{\alpha}\hat{\beta}\hat{\gamma}} \equiv 2x^{[\hat{\alpha}}T^{\hat{\beta}]\hat{\gamma}}$, so that $S^{\hat{\alpha}\hat{\beta}} = \int_{\Sigma(z,u)} \mathscr{J}^{\hat{\alpha}\hat{\beta}\hat{\gamma}} d\Sigma_{\hat{\gamma}}$; and consider the two basis *spatial* 1-forms $\boldsymbol{\xi}$ and $\boldsymbol{\eta}$. Constructing the vector $\mathscr{J}^{\gamma} \equiv \mathscr{J}^{\alpha\beta\gamma}\xi_{\alpha}\eta_{\beta}$, we can write the $\boldsymbol{\xi} \otimes \boldsymbol{\eta}$ component of $S^{\alpha\beta}$ as $S^{\boldsymbol{\xi\eta}}(z, u) = \int_{\Sigma(z,u)} \mathscr{J}^{\beta} d\Sigma_{\beta}$. By the Gauss theorem,

$$\begin{aligned} \Delta S^{\boldsymbol{\xi\eta}} = \int_{V_{Left}} \mathscr{J}^{\beta}_{\ ;\beta} dV - \int_{V_{Right}} \mathscr{J}^{\beta}_{\ ;\beta} dV \ \sim \ \|\mathbf{R}\| \int_V x^2 |\vec{J}| dV = \|\mathbf{R}\| V \langle |\vec{J}| x^2 \rangle \\ < \|\mathbf{R}\| a^2 V \langle |\vec{J}| \rangle = \lambda V \langle |\vec{J}| \rangle \lesssim \lambda a^4 v(u', u) \langle |\vec{J}| \rangle \ , \end{aligned}$$

where $J^{\hat{i}} = T^{\hat{0}\hat{i}}$. In the second relation again we used $\Gamma^{\hat{\gamma}}_{\hat{\alpha}\hat{\beta}} = \mathcal{O}(\|\mathbf{R}\| x)$. Since $S = \mathcal{O}(a^4 \langle |\vec{J}| \rangle)$, cf. Eq. (13), we see that indeed when $\lambda \ll 1$, $\|\Delta S^{\boldsymbol{\xi\eta}}\| \ll S$.

The Case with Electromagnetic Field

When $F^{\alpha\beta} \neq 0$, the conservation law is $T^{\alpha\beta}_{\ \ ;\beta} = F^{\alpha\beta} j_{\beta}$ (denoting by $T^{\alpha\beta}$ *the particle's* energy momentum tensor). Consider for simplicity flat spacetime, and let $\boldsymbol{\xi}$ be a basis 1-form of a *global* Lorentz system; then $T^{\alpha\beta}_{\ \ ;\beta}\xi_{\alpha} = (T^{\alpha\beta}\xi_{\alpha})_{;\beta} \equiv A^{\beta}_{\ ;\beta} = F^{\alpha\beta} j_{\beta}\xi_{\alpha}$. Note that $f^{\alpha} \equiv F^{\alpha\beta} j_{\beta}$ is the Lorentz force density. It follows (see Fig. 7b)

$$\Delta P^{\boldsymbol{\xi}} = \int_{V_{Left}} A^{\beta}_{\ ;\beta} dV - \int_{V_{Right}} A^{\beta}_{\ ;\beta} dV = \xi_{\alpha} \left(V_{Left} \langle f^{\alpha} \rangle_{Left} - V_{Right} \langle f^{\alpha} \rangle_{Right} \right) .$$

We have $V_{Left} = V^{(3)}_{Left} b_{Left}/2$, $V_{Right} = V^{(3)}_{Right} b_{Right}/2$ (where $V^{(3)}$ denote 3-volumes orthogonal to u^{α}). Herein we allow z^{α} to be any point within the worldtube of centroids; it follows that

Electromagnetic forces and torques defined in this way first arise at dipole order. The (monopole) Lorentz force depends—unlike any other electromagnetic terms—on $\dot{z}_s^a$. It has therefore been separated out explicitly in (192). There is no similarly velocity-dependent electromagnetic torque.

Defining the force to exclude the Lorentz force has the advantage that if ψ^a is Killing and preserves $\hat{F}_{ab}$, the associated conservation law implies that

$$\hat{F}_a \psi^a + \frac{1}{2} \hat{N}_{ab} \nabla^a \psi^b = 0. \tag{195}$$

This does not involve q, and is directly analogous to the scalar result (106).

4.3.5 Center of Mass

The electromagnetic laws of motion (192)–(194) depend on both the foliation $\{\mathfrak{B}_s\}$ and the worldline $\mathcal{Z}$. Center of mass conditions may be used to fix these structures as described in Sect. 3.8. An evolution equation for the center of mass position γ_s can then be obtained by differentiating $\hat{p}_a \hat{S}^{ab} = 0$. The result differs slightly from (111) due to the additional velocity-dependence associated with the Lorentz force. Adapting the methods of [31], the electromagnetic momentum-velocity relation may be shown to be

$$\hat{m}\dot{\gamma}_s^a = \hat{p}^a - \hat{N}^a{}_b u^b - \frac{\hat{S}^{ab}[\hat{m}\hat{F}_b + (\hat{p}^c - \hat{N}^c{}_h u^h)(q\hat{F}_{bc} - \frac{1}{2}R_{bcdf}\hat{S}^{df})]}{\hat{m}^2 - \frac{1}{2}\hat{S}^{pq}(q\hat{F}_{pq} - \frac{1}{2}R_{pqrs}\hat{S}^{rs})} \tag{196}$$

when s has been chosen such that $\dot{\gamma}_s^a \hat{p}_a = -\hat{m}$ and u^a is the unit timelike vector satisfying $\hat{p}^a = \hat{m} u^a$.

Although a precise set of assumptions which imply this are not known, it is assumed here that the center of mass condition (111) admits a unique timelike solution in a sufficiently broad class of physical systems. Inspection of (196) shows that a breakdown of the center of mass condition must occur whenever

$$\hat{m}^2 - \frac{1}{2}\hat{S}^{bc}\left(q\hat{F}_{bc} - \frac{1}{2}R_{bcdf}\hat{S}^{df}\right) = 0. \tag{197}$$

This is sufficient but not necessary. While the $q = 0$ case was dismissed in Sect. 3.8 as unlikely to be physically relevant, the charged case is potentially more interesting. Consider an electron[24] in a magnetic field of order B. Setting $q = e$, $\hat{m} = m_e$, $R_{abc}{}^d = 0$, and $\hat{S} = \hbar/2$, the denominator in (196) can diverge when $B \sim 2m_e^2/e\hbar \sim 10^{14}$ Gauss. This may be viewed as the field strength at which an electron's dipole energy $\hbar B/2$ becomes comparable to its rest mass. Quantum mechanically, it is also the field strength at which the separation between (Landau) energy levels becomes comparable to the rest mass energy. Indeed, this is the scale at which quantum electrodynamics is expected to become dominant. Although systems with 10^{14} Gauss magnetic fields are far from direct laboratory experience, such fields are believed to exist around some neutron stars [45]. Even in somewhat smaller magnetic fields, hidden momentum effects predicted by the classical theory can become very large. Whether or not this has qualitative consequences for neutron star astrophysics is an open question.

---

[24] It is unclear that there is any sense in which an electron's behavior can be modeled using equations derived for classical extended charges. Nevertheless, the example appears to be suggestive.

If the center of mass can be defined and the classical laws of physics remain valid, (196) may be combined with (192)–(194) to yield very general laws of motion. As in the scalar case, $\hat{S}^{ab}$ can also be reduced to a single spin vector $\hat{S}^a$ satisfying (113). Similarly, the mass varies according to (114). Unlike in the scalar case, matter coupled to electromagnetic fields can change mass only at dipole and higher orders. Such effects are related to changes in a body's internal energy due to work performed by (or against) the ambient fields [24].

4.3.6 Monopole Approximation

In simple cases, the laws of motion governing an extended charge distribution may be truncated at monopole order. Within this approximation, $\hat{F}_a = \hat{N}_{ab} = 0$ and (192) reduces to

$$\frac{\mathrm{D}\hat{p}^a}{\mathrm{d}s} = q\hat{F}^a{}_b\dot{\gamma}_s^b + \frac{1}{2}R_{bcd}{}^a\hat{S}^{bc}\dot{\gamma}_s^d, \qquad \frac{\mathrm{D}\hat{S}_{ab}}{\mathrm{d}s} = 2\hat{p}^{[a}\dot{\gamma}_s^{b]}. \tag{198}$$

Contracting the second of these equations with $\hat{S}_{ab}$ while using (110) again shows that $\hat{S}^2 := \hat{S}^a\hat{S}_a =$ (constant). An object which is initially not spinning therefore remains non-spinning in this approximation. Consider these cases for simplicity. The momentum-velocity relation then reduces to $\hat{p}^a = \hat{m}\dot{\gamma}_s^a$, the mass remains constant, and the body accelerates via the Lorentz force law

$$\hat{m}\ddot{\gamma}_s^a = q\hat{F}^a{}_b\dot{\gamma}_s^b \tag{199}$$

in the effective electromagnetic field $\hat{F}_{ab}$. The effective field always satisfies the vacuum Maxwell equations. It is generically distinct from the physical field F_{ab} which governs the acceleration of nearby test charges.

In many cases of interest, it is useful to model F_{ab} as the sum of some external field F_{ab}^{ext} and the retarded field associated with a body's charge distribution:

$$F_{ab} = F_{ab}^{\mathrm{ext}} + 2\int_{\mathfrak{W}} \nabla_{[a}G^{-}_{b]b'}J^{b'}\mathrm{d}V'. \tag{200}$$

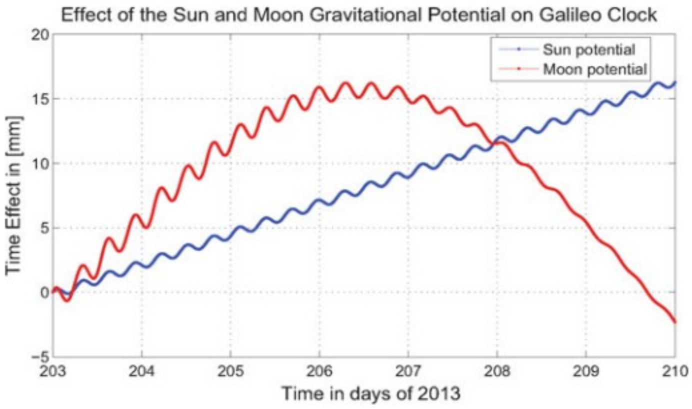

Fig. 18.9 Accumulated time along the orbit of the Galileo E11 satellite due to the gravitational potential of Sun and Moon for a selected period of 6 days with low Sun elevation $4^\circ > \beta > -2^\circ$ above the orbital plane. When the Sun is in the Galileo orbital plane, the satellite orbit spans about 2×29600 km per orbit revolution in the Sun’s gravitational field (max.-min. distance to the Sun). The maximum is reached for a Moon elevation of 28.5°

18.5 Environmental Effects on the Galileo Clock Parameters

In this section, we discuss the impact of the in-orbit environment (magnetic field and temperature variations) on the Galileo clock performance. Magnetic field perturbations can be estimated by using the magnetic sensitivity coefficient of $<3 \times 10^{-13}$/G (one gauss equals 10^{-4} tesla) in fractional frequency, as measured during ground tests (Boving et al. 2009) and (Rochat et al. 2012). Magnetic filed variations along the Galileo orbit were calculated by using the International Geomagnetic Reference Field (IGRF) model (International Association of Geomagnetism and Aeronomy et al. 2010) in the direction of the satellite X, Y and Z axes. The time accumulated along the orbit was obtained by integrating the fractional frequency variations due to the ambient magnetic field (see Fig. 18.11). Considering that the magnetic field is in the order of 300–550 nT along the Galileo orbit (days 100–116 in 2013), the contribution of magnetic perturbations to the estimated residual clock parameters is in the order of several millimeters. However, assuming the orientation of the Galileo maser cavity along the satellite X-axis (that never faces the Sun), the maximum effect of the magnetic field is below 0.8 mm, see Fig. 18.11. When applied as a correction, the standard deviation of the residual clock parameters in Fig. 18.7 was improved by only 0.1 mm. We can therefore conclude that the impact of magnetic field variations on the Galileo clock parameters is very small and negligible. In addition, shielding of the satellite further reduces their effect. However, this would not be the case if the same clock were placed in a LEO orbit, where the magnetic field strength is higher by two orders of magnitude.

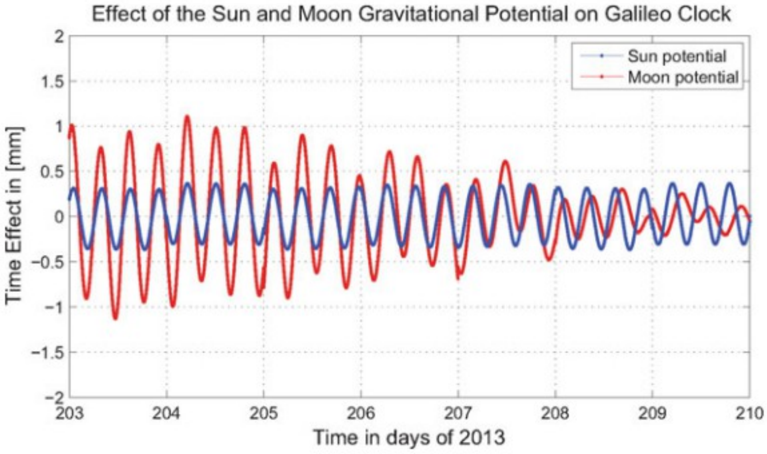

Fig. 18.10 Accumulated time along the orbit of the Galileo E11 satellite due to the gravitational potential of Sun and Moon after removing daily time offset and drift. One can clearly see a distinct twice per revolution effect for the Sun potential. After removing daily time offset and time drift, the remaining effect on the residual clock parameters is below 0.4 mm for the Sun and up to 1 mm for the Moon potential

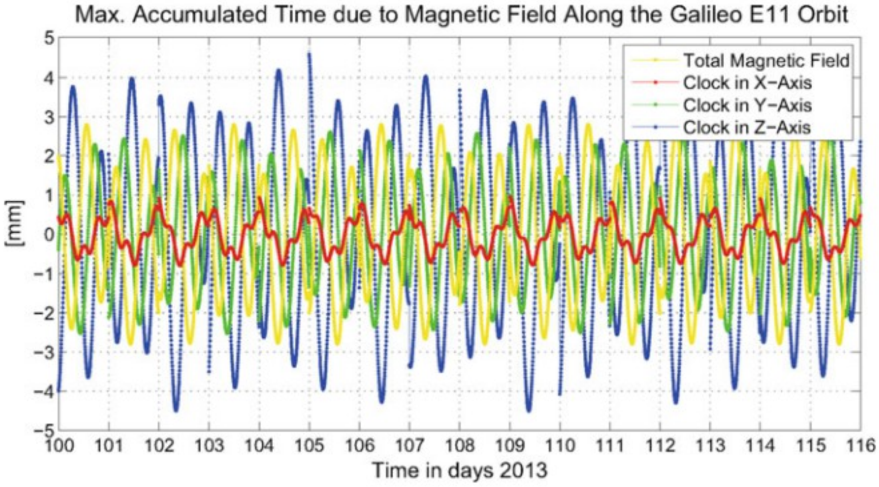

Fig. 18.11 Maximum accumulated time in (mm) along the orbit of Galileo E11 satellite assuming a maximum magnetic sensitivity coefficient of $3 \times 10^{-13}/\text{Gauss}$. The magnetic field along the X, Y and Z satellite axes was calculated using the IGRF model giving a magnetic field variation of 300–550 nT along the orbit. Assuming the orientation of the H-maser cavity along the X satellite axis (never faces Sun), the maximum effect of the magnetic field on residual clock parameters is below 0.8 mm. Along the Z axis, the effect is about three times higher. Daily bias and drift were removed

Unfortunately, no public data is available on the in-orbit temperature at the clock reference point, therefore not much can be said about thermal perturbations. Boving et al. (2009) reported a thermal sensitivity coefficient of the Galileo H-maser as measured on the ground of $\leq 2 \times 10^{-14}/\,^{\circ}\mathrm{C}$. The cavity temperature of the Galileo H-maser is stabilized by a two-stage thermal control and an additional electronic Automatic Cavity Tuning (ACT) system is used to optimize the cavity frequency pulling effect caused by the residual thermal drift (Mattioni et al. 2002). From Mattioni et al. (2002), one can see that, for platform temperature variations of 5 °C, the cavity thermal control stabilizes the temperature within 3 m°C.

Temperature variations at the PHM reference point on-board the Galileo satellite are expected to have two different periods, the orbital period and the period of the stabilization loop. An analysis of the Allan deviation and PSD curves in Figs. 18.7 and 18.8, reveals no perturbation at the orbital period nor for periods shorter than 1000 s that could be attributed to temperature effects. This allows us to conclude that the temperature stability at the PHM reference point is at the level of a few tenths of a Kelvin.

corresponds to an angular scale of about 1° and we need to explain the absence of order one anisotropies on the angular scales of the full sky). Thus the first requirement on a successful early universe scenario is that the horizon at late times be much larger than the Hubble radius.

In order to be able to have a causal mechanism of structure formation, scales that are currently observed in cosmology must originate in the early universe with a wavelength smaller than the Hubble radius. This is the second requirement.

Third, the scales that we observe today must propagate for a long time at super-Hubble lengths. This is in order that the fluctuations are squeezed and enter the Hubble radius at late times as standing waves. This is required in order to provide an explanation for the observed acoustic oscillations in the angular power spectrum of the CMB.

Finally, the generation mechanism that acts on sub-Hubble scales must yield a nearly scale-invariant spectrum of cosmological perturbations.

The inflationary universe scenario provides a simple realization of these four criteria. However, there are alternative realizations as explained in the following section.

4.3 Paradigms of Early Universe Cosmology

4.3.1 Cosmological Inflation

Cosmological inflation (Brout, Englert, and Gunzig, 1978; Fang, 1980; Guth, 1981; Sato, 1981) assumes that space underwent a period of almost exponential expansion during a finite time interval in the very early universe, starting at some time t_i and ending at a time t_R.[4] The first model of inflation was based on a modified gravitational action (Starobinsky, 1980) where higher curvature terms dominate at early times and lead to accelerated expansion. Later models assumed that the accelerated expansion of space is realized in the context of Einstein gravity, but assuming the presence of a slowly rolling (Albrecht and Steinhardt, 1982; Linde, 1982, 1983) scalar field whose energy-momentum tensor is dominated by the scalar field potential energy. After the end of inflation at time t_R, the evolution of the universe is like in SBB cosmology.

Figure 4.5 represents a spacetime sketch of inflationary cosmology. The vertical axis is time, the horizontal axis denotes physical spatial distance. The solid curve labeled H^{-1} represents the Hubble radius, the dashed line is the horizon, and the curve labeled k represents the physical wavelength of a fluctuation mode.

During the phase of accelerated expansion for $[t_i < t < t_R]$, the horizon is growing very fast while the Hubble radius increases only slowly. For almost exponential

---

[4] The subscript R stands for *reheating* since at this time the conditions of a hot early universe must be created.

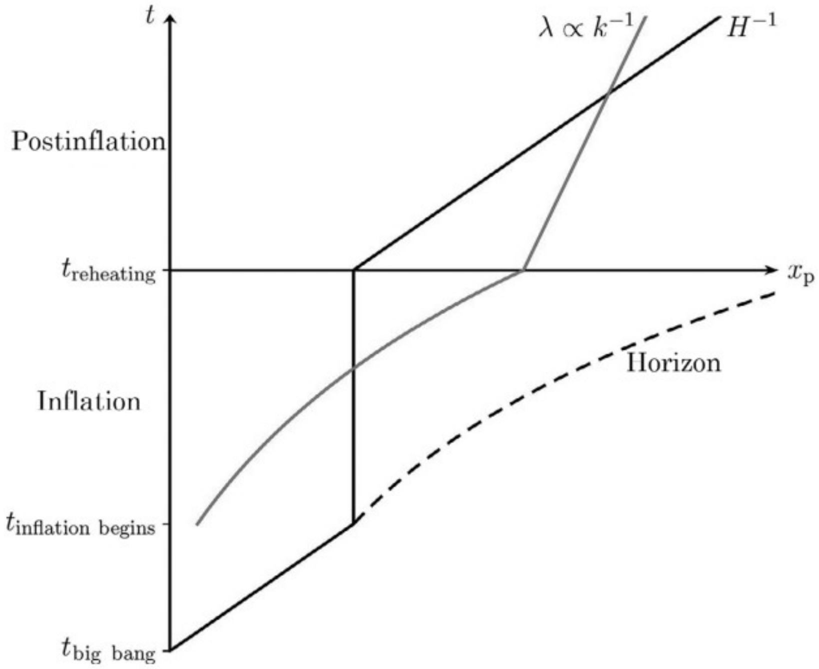

Figure 4.5 Space-time sketch of inflationary cosmology. The vertical axis is time, the horizontal axis is physical distance. The curve labeled H^{-1} is the Hubble radius, and the curve labeled k is the physical wavelength of the fluctuation on a particular (comoving) scale. Note that during the period inflation both the wavelength of a fluctuation and the horizon grow exponentially (for exponential inflation), which is indicated by the curvature of the lines. After the end of inflation, the wavelength grows as $a(t) \sim t^{1/2}$ which is indicated by the near linearity of the curve.

expansion the horizon increases nearly exponentially while the Hubble radius is almost constant. Only a very short interval of accelerated expansion is needed to solve the horizon problem (the horizon needs to increase by a factor of greater than 100 relative to the Hubble radius).

If the energy scale of inflation corresponds to the scale of particle physics Grand Unification (an energy scale of about 10^{16} GeV), then about 60 e-foldings of exponential expansion are required in order that scales that we observe now in cosmology had a wavelength smaller than the Hubble radius at the beginning of the inflationary period. In this case, the second of the general criteria for a successful early universe cosmology is satisfied.

As is evident from Figure 4.5, the wavelength of fluctuations is larger than the Hubble radius for a long time. Hence the squeezing of the fluctuations that is required in order to obtain the acoustic oscillations in the CMB angular power spectrum is realized.

Finally, as initially argued in Starobinsky (1979) for gravitational waves and in Mukhanov and Chibisov (1981) for the curvature perturbations, the power spectrum of fluctuations will be approximately invariant of scale. This is a consequence of the time-translation invariance of the phase of exponential expansion (Press, 1980; Sato, 1981). It is usually assumed that fluctuations originate as quantum vacuum perturbations at early times during the inflationary phase. This assumption can be justified since, in the absence of interactions with the agent driving the accelerated expansion, any initial fluctuations are redshifted away, leaving the matter in a vacuum state. If the agent driving inflation interacts with matter, it is possible to realize inflation while maintaining the dominance of thermal fluctuations. This is the *warm inflation* scenario (Berera, 1995).

The scale invariance of the spectrum of curvature fluctuations can also be seen using the general formalism described in the previous section. The curvature fluctuation variable, starting out with a deep blue vacuum spectrum on sub-Hubble scales, gets squeezed on super-Hubble scales. Large wavelength fluctuations exit the Hubble radius earlier and are thus squeezed more. For almost exponential inflation the squeezing is just right to turn the initial vacuum spectrum into a scale-invariant one. To see this, consider first the Hubble crossing condition:

$$a^{-1}(t_H t(k))k = H. \tag{4.11}$$

Before $t_H(k)$, the amplitude of v_k is constant, afterwards it increases as z. Thus the power spectrum of ζ at some late time t is:

$$\begin{aligned} P_\zeta(k,\eta) &= k^3 z^{-2}(\eta)\left(\frac{z(\eta)}{z((\eta_H(k))}\right)^2 |v_k(t_i)|^2 \\ &\simeq \frac{1}{2}\left(\frac{a(t_H(k))}{z(t_H(k))}\right)^2 H^2. \end{aligned} \tag{4.12}$$

The k-dependence has canceled out, and we thus obtain a scale-invariant spectrum.

Gravitational waves evolve as curvature fluctuations, with the function $z(\eta)$ being replaced by $a(\eta)$. Hence inflationary cosmology predicts a scale invariant spectrum of gravitational waves whose amplitude is suppressed compared to that of curvature fluctuations by the slow-roll parameter ϵ, which gives the ratio between z and a during the inflationary phase.

Of the early universe scenarios discussed here, inflationary cosmology is the only one that predicted (as opposed to postdicted) various observational results, e.g., the spatial flatness of the universe, the almost scale invariance of the spectrum of cosmological perturbations, and the near Gaussianity of this spectrum. In fact, inflation predicted (Mukhanov and Chibisov, 1981) a slight red tilt of the spectrum, a tilt that has now been established by the recent CMB observations (see, e.g., Ade et al. [2014]). Inflation predicts a nearly scale-invariant spectrum of gravitational waves (Starobinsky, 1979) with a slight red tilt. Note that, whereas the tilt of the spectrum of cosmological perturbations can be made blue by complicating the scalar field model of inflation, the spectrum of gravitational waves has a red tilt unless the matter that is responsible for inflation violates standard energy conditions.[5]

A drawback of the inflationary scenario is the *trans-Planckian problem* for cosmological perturbations (Brandenberger and Martin, 2001; Martin and Brandenberger, 2001). (See e.g., Brandenberger and Martin [2013] for a review with an extended list of references.) If the period of inflation lasts only slightly longer than the minimal amount of time it needs to in order to solve the flatness and structure formation problems of SBB cosmology, then the wavelengths of the fluctuation modes that we observe today are smaller than the Planck length at the beginning of inflation. We do not understand the physics on these wavelengths, and hence it is unclear if the initial conditions for the fluctuations that are used are well justified. Some other problems of inflationary cosmology are discussed in later sections.

4.3.2 Matter Bounce

Another paradigm to obtain successful structure formation is the *matter bounce* scenario (Wands, 1999; Finelli and Brandenberger, 2002). It is assumed that there is new physics[6] that resolves the cosmological singularity. Time runs from $-\infty$ to ∞. The universe begins in a contracting phase that is the mirror inverse of the expanding standard big bang cosmology evolution, which is to say that at very early times during contraction, a dark energy component may dominate, followed by a period of matter-dominated contraction, followed by a radiation-dominated phase, and then a nonsingular bounce. The bounce point (minimal value of the scale factor) is $t = 0$.

Figure 4.6 presents a sketch of the resulting spacetime diagram. The vertical axis is time, the horizontal axis represents comoving spatial distance. The Hubble radius is symmetric about $t = 0$. The perpendicular curve indicates the wavelength of a fluctuation. Since there is no origin of time, the horizon is infinite and there is no horizon problem. As obvious from the figure, all scales originate inside the Hubble

---

[5] At this point, we have not yet observed a stochastic background of gravitational waves, and observing the small tilts predicted by various early universe models will be very challenging.

[6] The new physics could be string theory, loop quantum gravity, or some effective field theory that corresponds to Einstein gravity coupled to some matter that violated the usual Hawking–Penrose energy conditions. For a review of bouncing cosmologies see, e.g., Brandenberger and Peter (2017). I am emphasizing here ways to obtain a spectrum of cosmological fluctuations in agreement with observations, and the specific dynamics of the bounce phase has little to say about this issue.

It's a common misconception that Einstein the genius physicist must also have been a great mathematician. He was not. Responding to his cry for help, his friend Marcel Grossman directed him to the work of the great German mathematician Carl Friedrich Gauss and his student, Bernhard Riemann. Einstein was introduced to the Riemann curvature tensor, the definitive mathematical expression for the curvature of a generalized geometry, in any set of coordinates. This was the connection that would later bring the sixteen-year-old Smolin from architecture to general relativity.

But the Riemann tensor didn't quite fit the bill, and as Einstein struggled to find a way to generalize it, he got 'lost' in the algebra, for two years making mistakes and following alleys that each in turn proved to be blind.

He eventually found the generalization required to make the field equations conform satisfactorily to the demands of the physics. The result is a set of equations which connect the curvature of spacetime—on the left-hand side—with the distribution and flow of mass-energy on the right-hand side. He presented his equations to the Prussian Academy of Sciences in Berlin in a series of four lectures which concluded on 25 November 1915.

From the beginning of his journey to the gravitational field equations of general relativity, Einstein was aware of four potential empirical tests.

Actually, the first is not so much a test, more the resolution of a mystery. We've known since the work of Johannes Kepler in the seventeenth century that a planet moves in an elliptical orbit around the Sun. But the planetary orbits are not exact ellipses. If they were, each planet's point of closest approach to the Sun (which is called the *perihelion*) would be fixed, the planet always passing through the same point with each and every orbit. But astronomical observations show that with each orbit the perihelion shifts slightly, or *precesses*.

Much of the observed precession is caused by the cumulative gravitational pull of all the other planets in the Solar System, effects which can be predicted using Newton's law. For the planet Mercury, lying closest to the Sun, this 'Newtonian precession' is predicted to be 532 arc-seconds per century.* However, the observed precession is rather more, about 574 arc-seconds per century, a difference of 42 arc-seconds. Though small, this difference accumulates and is equivalent to one 'extra' orbit every three million years or so.

Newton's gravity can't account for this small difference and other explanations—such as the existence of another planet, closer to the Sun than Mercury (named Vulcan)—were suggested. Astronomers searched for it in vain. Einstein was delighted to discover that the field equations of general relativity predict a further 'relativistic' contribution of 43 arc-seconds per century, due to the curvature of spacetime around the Sun in the vicinity of Mercury.† This discovery gave Einstein the strongest emotional experience of his life in science: 'I was beside myself with joy and excitement for days.'[10]

Perhaps the most famous prediction of general relativity concerns the bending of starlight passing close to the Sun. Once again, it's not the 'bending' per se that represents a novel prediction, but rather its extent. Newton's gravity suggests that light grazing the surface of the Sun should bend through 0.85 arc-seconds.‡ But the curvature of spacetime predicted by general

---

* A full circle is 360°, and an arc-minute is one-sixtieth of 1°. An arc-second is then one-sixtieth of an arc-minute. So 532 arc-seconds represents about 0.15 of a degree.

† The perihelia of other planets are also susceptible to precession caused by the curvature of spacetime, but as these planets are further away from the Sun the contributions are much less pronounced.

‡ Newton favoured a 'corpuscular' theory in which light is imagined to consist of individual particles. It's therefore not difficult to imagine why such 'bullets' of light might be affected by the gravitational pull of a large object such as a star.

Einstein was well versed in the geometries of things that curve. We know well enough that the Earth is finite—it has a mass that can be estimated (it's about six million billion billion kilograms). And, although from any human vantage point on its surface the Earth looks flat, we know that it is spherical, and so has no edge. The Earth is finite but unbounded.

So, in Einstein's universe spacetime curves back on itself like the surface of a sphere, and contains a finite amount of mass-energy. Note that the 'sphere' in question is a sphere in four spacetime dimensions (what mathematicians refer to as a 3-sphere or, more generally, a hypersphere—see Figure 11). The surface of

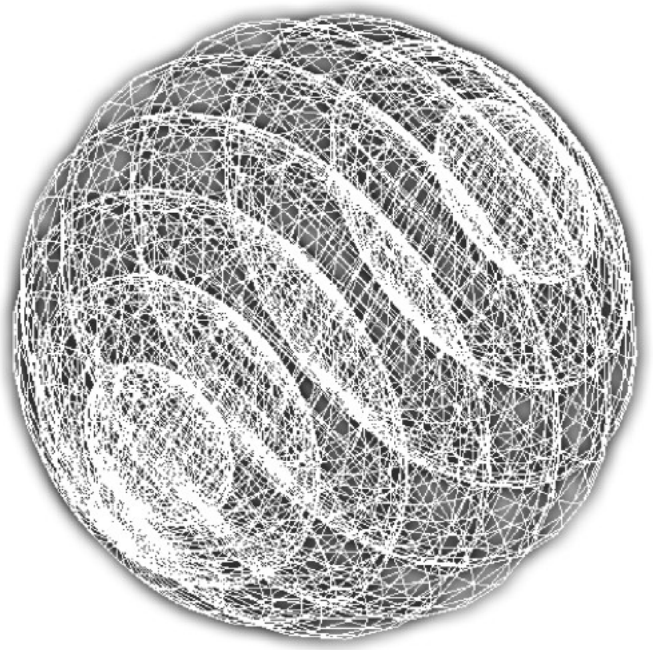

Figure 11. This representation of a 3-sphere (or hypersphere) is a projection into three-dimensional space, showing the structure as a stack of regular spheres (2-spheres), which is then projected onto two dimensions.

the Earth, in contrast, is a 2-sphere, a sphere in three-dimensional space. If it were possible for us to set off together across Einstein's universe on a journey along a straight path, we would eventually find ourselves returning to our point of departure.

Curiously, this was not the first example of a finite, but unbounded universe. Carlo Rovelli was delighted to discover that Einstein had been anticipated by the great Italian poet Dante Alighieri, who had studied at the University of Bologna in the fourteenth century. In *Paradiso*, the third and final part of the *Divine Comedy*, Dante describes his ascent to the Empyrean, the abode of God and the angels. Confronted with the challenge of describing the universe at its very edge, he fixes on the same solution that Einstein would choose, five hundred years later: 'Dante embeds the model in four dimensions, which does, as we know, solve the problem.'[2]

Einstein now had to deal with a more stubborn second problem. Gravity pulls objects together but it doesn't push them apart. Unlike electricity or magnetism, gravity doesn't have opposite charges or opposite poles, which attract *and* repel. Put another way, mass-energy curves spacetime only in ways which cause objects to move towards each other, never away.

Newton well understood where this leads. The mutual gravitational attraction between all the objects in an infinite universe would cause the universe to collapse in on itself. He had no choice but to invoke the ultimate solution, arguing in the *Mathematical Principles* that God had placed the stars sufficiently far apart to prevent such a catastrophic collapse from happening.[3]

Several centuries of astronomy had certainly produced no evidence that all the stars in the universe are rushing towards each other and in 1917 plain common sense suggested that the universe is surely *static*, not dynamic—we don't call them 'fixed stars' for nothing. But, just as in Newton's gravity, there was nothing in Einstein's field equations that would help to hold the universe steady. Einstein needed a physical mechanism that would do much the same job that Newton had asked of God.

His solution was to introduce a rather unsatisfactory 'fudge'. The left-hand side of the gravitational field equations describes the extent of spacetime curvature that will determine the motions of all the mass-energy, which is summarized on the right-hand side. Despite their extraordinary success, Einstein concluded that his equations were still 'unbalanced'. To engineer a static universe, he attempted to balance the equations by introducing a new term on the left-hand side, imbuing spacetime with a curious kind of antigravitational force, a negative gravitational pressure which builds in strength over long distances, counteracting the effects of the curvature caused by all the mass-energy on the right-hand side.

The new term is now characterized by a parameter Λ (Greek lambda), which is referred to as the 'cosmological constant'. By carefully selecting the value of Λ, Einstein found that he could achieve perfect balance: a static universe. He admitted that he 'had to introduce an extension to the field equations that is not justified by our actual knowledge of gravitation'.[4] But at the time it must have seemed like a neat solution. The cosmological constant didn't alter the way general relativity works over short distances, so all the theory's successful predictions were preserved.

However, Einstein had also made some significant errors. Not only was there no evidence or even a real theoretical justification for the cosmological constant, it actually doesn't do what Einstein claimed. The universe that he described in his 1917 paper is actually not static and is instead rather unstable. The modified field equations still didn't completely exclude the possibility that the universe might contract or expand.

Fourteen years later, Einstein's universe was overtaken by events.

A point mass M at a position $\mathbf{r}' = \mathbf{r}_0$ represents a mass density

$$\rho(\mathbf{r}') = M\delta(\mathbf{r}' - \mathbf{r}_0). \tag{1.20}$$

Substitution into Eq. (1.17) gives the potential of the point mass

$$\boxed{\phi(\mathbf{r}) = -\frac{GM}{|\mathbf{r} - \mathbf{r}_0|}.} \tag{1.21}$$

1.5 Local form of Newton's Gravitational law

Newton's law of gravitation cannot be a relativistically correct law, because it permits action at a distance. A point mass at one place may then act instantaneously on a point mass at another remote position. According to the special theory of relativity, instantaneous action at a distance is impossible. An action which is instantaneous in one reference frame, is not instantaneous in another frame, moving with respect to the first. This is due to the relativity of simultaneity (see Ch. 2). *Instantaneous action at a distance can only exist in a theory with absolute simultaneity.* As a first step towards a relativistically valid theory of gravitation, we shall give a local form of Newton's law of gravitation.

We shall now show how Newton's law of gravitation leads to a field equation for gravity. Consider a continuous mass-distribution $\rho(\mathbf{r}')$. Equations (1.16) and (1.17) lead to

$$\boldsymbol{\nabla}\phi(\mathbf{r}) = G\int \rho(\mathbf{r}')\frac{(\mathbf{r} - \mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|^3}d^3r', \tag{1.22}$$

which gives

$$\nabla^2\phi(\mathbf{r}) = G\int \rho(\mathbf{r}')\boldsymbol{\nabla}\cdot\frac{(\mathbf{r} - \mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|^3}d^3r'. \tag{1.23}$$

Furthermore

$$\begin{aligned}\boldsymbol{\nabla}\cdot\frac{(\mathbf{r} - \mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|^3} &= \frac{\boldsymbol{\nabla}\cdot\mathbf{r}}{|\mathbf{r} - \mathbf{r}'|^3} + (\mathbf{r} - \mathbf{r}')\cdot\boldsymbol{\nabla}\frac{1}{|\mathbf{r} - \mathbf{r}'|^3}\\ &= \frac{3}{|\mathbf{r} - \mathbf{r}'|^3} + (\mathbf{r} - \mathbf{r}')\cdot\left(-3\frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|^5}\right) = 0, \quad \mathbf{r} \neq \mathbf{r}'.\end{aligned} \tag{1.24}$$

In general the volume of integration encompasses the point $\mathbf{r}' = \mathbf{r}$ where the field is measured. Thus, we have to find an expression for $\boldsymbol{\nabla}\cdot(\mathbf{r} - \mathbf{r}')/|\mathbf{r} - \mathbf{r}'|^3$ which is also valid at this point. Equation (1.24) indicates that $\boldsymbol{\nabla}\cdot(\mathbf{r} - \mathbf{r}')/|\mathbf{r} - \mathbf{r}'|^3$ is proportional to Dirac's δ-function. According to Eq. (1.19) the proportionality factor can be found by calculating the integral $\int \boldsymbol{\nabla}\cdot(\mathbf{r} - \mathbf{r}')/|\mathbf{r} - \mathbf{r}'|^3 d^3r'$. Using Gauss' integral theorem

$$\int_V \boldsymbol{\nabla}\cdot\mathbf{A}d^3r' = \oint_S \mathbf{A}\cdot d\mathbf{S}' \tag{1.25}$$

where S is the surface enclosing V, we get

$$\int_V \boldsymbol{\nabla}\cdot\frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|^3}d^3r' = \oint_S \frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|^3}\cdot d\mathbf{S}'. \tag{1.26}$$

Note that the gradient $\nabla\phi$ in Eq. (1.22) is directed away from the source. Thus the divergence of this vector in Eq. (1.23) must be positive. The direction of the surface element $d\mathbf{S}'$ in Fig. 1.3 is chosen to satisfy this criterion.

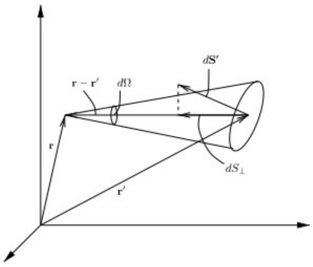

Figure 1.3: Definition of surface elements

With reference to Fig. 1.3 the solid angle element $d\Omega$ is defined by

$$d\Omega = -\frac{dS_\perp}{|\mathbf{r}-\mathbf{r}'|^2} \tag{1.27}$$

where

$$dS_\perp = \frac{\mathbf{r}-\mathbf{r}'}{|\mathbf{r}-\mathbf{r}'|}\cdot d\mathbf{S}'. \tag{1.28}$$

It follows that

$$d\Omega = -\frac{\mathbf{r}-\mathbf{r}'}{|\mathbf{r}-\mathbf{r}'|^3}\cdot d\mathbf{S}' \tag{1.29}$$

and

$$\int\limits_V \boldsymbol{\nabla}\cdot\frac{\mathbf{r}-\mathbf{r}'}{|\mathbf{r}-\mathbf{r}'|^3}d^3r' = \int d\Omega = \begin{cases} 4\pi, & P \text{ inside } V \\ 0, & P \text{ outside } V \end{cases} \tag{1.30}$$

Thus we get

$$\boldsymbol{\nabla}\cdot\frac{\mathbf{r}-\mathbf{r}'}{|\mathbf{r}-\mathbf{r}'|^3} = 4\pi\delta(\mathbf{r}-\mathbf{r}'). \tag{1.31}$$

Substituting this into Eq. (1.23) and using Eq. (1.19) with $f(\mathbf{r}) = 1$ we have

$$\boxed{\nabla^2\phi(\mathbf{r}) = 4\pi G\rho(\mathbf{r}).} \tag{1.32}$$

This Poisson equation is the local form of Newton's law of gravitation. Newton's 2nd law applied to a particle falling freely in a gravitational field gives the acceleration of gravity

$$\boxed{\mathbf{g} = -\boldsymbol{\nabla}\phi.} \tag{1.33}$$

Newton's theory of gravitation can now be summarized in the following way: *Mass generates a gravitational field according to Poisson's equation, and the gravitational field generates acceleration according to Newton's second law.*

Stoke's Theorem: *Let M be a smooth n-dimensional (oriented) compact manifold with intrinsic boundary ∂M, and let $\boldsymbol{\alpha}$ be an $(n-1)$-form. Then*

$$\boxed{\int\limits_M \mathbf{d}\boldsymbol{\alpha} = \int\limits_{\partial M} \boldsymbol{\alpha}.} \tag{6.71}$$

This is the generalisation of Gauss' law for vector calculus.

In particular we note that if $\partial M = 0$ then the integral vanishes. This is why any closed loop integral over an exact one-form yields zero, a loop has no boundary.

We will not get into details in this book, but we will just see how this law can be applied to the electromagnetic case.

Consider a bounded 3-dimensional region M which is purely spatial. From Stoke's theorem and Maxwell's equations we have

$$\int\limits_M \mathbf{d}\star\mathbf{F} = \int\limits_M \star\mathbf{J} = \int\limits_{\partial M} \star\mathbf{F}. \tag{6.72}$$

Since the region is purely spatial, so will its intrinsic boundary be. Thus

$$\int\limits_M \star\mathbf{J} = \int\limits_M \rho\mathbf{dx}^1\wedge\mathbf{dx}^2\wedge\mathbf{dx}^3 \equiv Q; \tag{6.73}$$

i.e. Q is the total charge inside the spatial region. On the other hand

$$\begin{aligned}\int\limits_{\partial M} \star\mathbf{F} &= \int\limits_{\partial M}\left(E_1\mathbf{dx}^2\wedge\mathbf{dx}^3 + E_2\mathbf{dx}^3\wedge\mathbf{dx}^1 + E_3\mathbf{dx}^1\wedge\mathbf{dx}^2\right)\\ &= \int\limits_{\partial M} \mathbf{E}\cdot\mathbf{dS},\end{aligned} \tag{6.74}$$

where $\mathbf{E}\cdot\mathbf{dS}$ can be interpreted as the electric flux out of the surface element $\mathbf{dS}$. Thus in all,

$$\int\limits_{\partial M} \mathbf{E}\cdot\mathbf{dS} = Q. \tag{6.75}$$

This is the famous Gauss' law in electromagnetism.

The corresponding law for the magnetic field is

$$0 = \int\limits_M \mathbf{dF} = \int\limits_{\partial M} \mathbf{F} = \int\limits_{\partial M} \mathbf{B}\cdot\mathbf{dS} \tag{6.76}$$

and can be interpreted as the lack of magnetic monopoles in electromagnetism.

Examples

Example 6.4 (The Electromagnetic Field outside a static point charge)
Let us investigate the electromagnetic field outside a point charge.

Assume that the field is a function of the radial coordinate, r, only. A pure static electric field can be generated by a field potential $A_0 = \varphi(r)$. Using

$$F_{\mu\nu} = \frac{\partial A_\nu}{\partial x^\mu} - \frac{\partial A_\mu}{\partial x^\nu}, \tag{6.77}$$

the only non-zero components of the field tensor are

$$F_{i0} = \frac{\partial \varphi}{\partial x^i} = \frac{\partial \varphi}{\partial r}\frac{x^i}{r} \tag{6.78}$$

using the chain rule and $r = \sqrt{(x^1)^2 + (x^2)^2 + (x^3)^2}$. The electric field is now just $E_i = F_{i0}$. If M is the interior of a spherical region so that ∂M is a sphere of radius r, the area surface element $\mathbf{dS}$ has components

$$(\mathbf{dS})_i = \frac{x^i}{r} \cdot r^2 d\Omega \tag{6.79}$$

Thus Gauss's law, eq. (6.75), gives

$$Q = \int\limits_{\partial M} \mathbf{E} \cdot \mathbf{dS} = \frac{\partial \varphi}{\partial r} r^2 \int d\Omega = \frac{\partial \varphi}{\partial r} 4\pi r^2 \tag{6.80}$$

which can be integrated to yield

$$\varphi(r) = -\frac{Q}{4\pi r} \tag{6.81}$$

We should note that even though this result was derived in Minkowski coordinates, the result is highly general. Around any point we can introduce geodesic normal coordinates (this will be shown later in this chapter). Hence, this result is valid for all spherically symmetric spacetimes. The only requirement is that the coordinate system is such that the area of a spherical surface with radius r is $4\pi r^2$.

Example 6.5 (Gauss' integral theorem)

Let us apply Stoke's theorem to the one-form $\boldsymbol{\alpha}$, and let $\mathbf{A}$ be the vector associated with this form. Define $\boldsymbol{\beta} = \star\boldsymbol{\alpha}$ so that according to equations (6.24) and (6.25) we have

$$\mathbf{d}\boldsymbol{\beta} = (\nabla \cdot \mathbf{A})\boldsymbol{\epsilon}. \tag{6.82}$$

According to Stoke's theorem

$$\int\limits_{M} \mathbf{d}\boldsymbol{\beta} = \int\limits_{M} (\nabla \cdot \mathbf{A})\boldsymbol{\epsilon} = \int\limits_{\partial M} \boldsymbol{\beta}. \tag{6.83}$$

Also

$$\boldsymbol{\beta} \;\; = \;\; \star\boldsymbol{\alpha} = \sqrt{|g|}\,\varepsilon_{\mu|\mu_1 \dots \mu_{n-1}|}\alpha^{\mu}\mathbf{dx}^{\mu_1} \wedge \dots \wedge \mathbf{dx}^{\mu_{n-1}}. \tag{6.84}$$

If we now assume that $x^1, \dots, x^{n-1}$ are coordinates on the surface ∂M, and that x^n is the orthogonal direction, then this can be written

$$\boldsymbol{\beta} \;\; = \;\; \sqrt{\frac{|g|}{g_{nn}}}\,\varepsilon_{1\dots(n-1)\hat{n}}\alpha^{\hat{n}}\mathbf{dx}^1 \wedge \dots \wedge \mathbf{dx}^{n-1}. \tag{6.85}$$

Thus

$$\int\limits_{\partial M} \boldsymbol{\beta} = \int\limits_{\partial M} \mathbf{A} \cdot \mathbf{dS} \tag{6.86}$$

where $\mathbf{dS} = \hat{\mathbf{n}}\sqrt{\frac{|g|}{g_{nn}}}dx^1 \dots dx^{n-1}$ is the invariant surface element. In this case Stoke's theorem takes the form

$$\boxed{\int\limits_{M} (\nabla \cdot \mathbf{A})\boldsymbol{\epsilon} = \int\limits_{\partial M} \mathbf{A} \cdot \mathbf{dS},} \tag{6.87}$$

which is *Gauss' integral theorem.*

The variation of $\mathbf{n}$ along the curve is now given by

$$\frac{d\mathbf{n}}{ds} = \frac{d\mathbf{b}}{ds} \times \mathbf{t} + \mathbf{b} \times \frac{d\mathbf{n}}{ds} = -\tau \mathbf{n} \times \mathbf{t} + \kappa \mathbf{b} \times \mathbf{n} \tag{7.11}$$

so

$$\boxed{\frac{d\mathbf{n}}{ds} = \tau \mathbf{b} - \kappa \mathbf{t}.} \tag{7.12}$$

Equations (7.6), (7.9) and (7.12) are called the *Serret-Frenet equations*.

7.2 Surfaces

Consider a two-dimensional surface embedded in three-dimensional Euclidean space. Let u and v be coordinates (or parameters) on the surface. Then, at every point on the surface the basis vectors

$$\mathbf{e}_u = \frac{\partial}{\partial u}, \qquad \mathbf{e}_v = \frac{\partial}{\partial v} \tag{7.13}$$

define a tangent plane of the surface.

The line element on the surface is

$$ds^2 = g_{\mu\nu} dx^\mu dx^\nu \tag{7.14}$$

where $x^1 = u$ and $x^2 = v$. This is often called *the first fundamental form* of the surface.

The directional derivative of $\mathbf{e}_\mu$ along $\mathbf{e}_\nu$ has generally one component in the tangent plane of the surface and one component orthogonal to the surface,

$$\boxed{\mathbf{e}_{\mu,\nu} = \Gamma^\alpha_{\ \mu\nu} \mathbf{e}_\alpha + K_{\mu\nu} \mathbf{n}} \tag{7.15}$$

where $\Gamma^\alpha_{\ \mu\nu}$ is the connection coefficients of the u, v system and $\mathbf{n}$ is the unit normal vector field on the surface. The coefficients $K_{\mu\nu}$ are defined by this equation. Since $\mathbf{e}_{\mu,\nu} = \frac{\partial^2}{\partial x^\mu \partial x^\nu} = \frac{\partial^2}{\partial x^\nu \partial x^\mu} = \mathbf{e}_{\nu,\mu}$ these coefficients are symmetric. Note also that the eq. (7.15) provides us with an interpretation of the covariant derivative and the connection coefficients $\Gamma^\alpha_{\ \mu\nu}$. The covariant derivative of a surface embedded in an Euclidean space is the ordinary derivative in Euclidean space, projected onto the tangent space of the surface.

The equation (7.15) is usually called *Gauss' equations*. Using

$$K_{\mu\nu} = \mathbf{e}_{\mu,\nu} \cdot \mathbf{n} \tag{7.16}$$

we can calculate the coefficients $K_{\mu\nu}$. Let now $\mathbf{u}$ be the tangent vector of a curve in the surface, parametrized by λ. Using equation (7.15) we have

$$\frac{d\mathbf{u}}{d\lambda} = u^\mu_{\ ;\nu} u^\nu \mathbf{e}_\mu + K_{\mu\nu} u^\mu u^\nu \mathbf{n}. \tag{7.17}$$

The λ-independent coefficient in front of $\mathbf{n}$, $K_{\mu\nu} dx^\mu dx^\nu$ is called *the second fundamental form* of the surface. Whereas the first fundamental form determines the intrinsic geometry of the surface, the second fundamental form reflects the extrinsic geometry, i.e. how the surface curves in the ambient three-dimensional Euclidean space in which it is embedded.

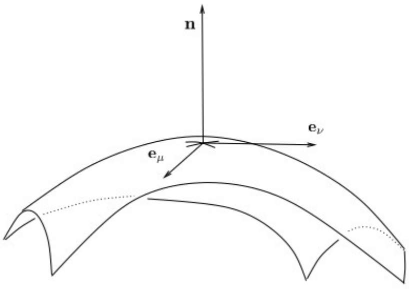

Figure 7.2: A two-dimensional surface embedded in three-dimensional Euclidean space

If λ is the arc-length, we can write equation (7.17) as

$$\frac{d\mathbf{u}}{d\lambda} = \kappa_g \mathbf{e} + \kappa_n \mathbf{n}, \quad \kappa_g \equiv |u^\mu{}_{;\nu} u^\nu \mathbf{e}_\mu|, \quad \kappa_n \equiv K_{\mu\nu} u^\mu u^\nu \tag{7.18}$$

where $\mathbf{e}$ is a unit vector. The quantities κ_g and κ_n are called *the geodesic curvature* and *the normal curvature* of the surface, respectively.

Since $\frac{d\mathbf{u}}{d\lambda}$ is orthogonal to $\mathbf{u}$ and $\mathbf{n}$, the unit vector $\mathbf{e}$ in the surface is given by

$$\mathbf{e} = \pm \mathbf{n} \times \mathbf{u}. \tag{7.19}$$

We see that the normal curvature can also be written

$$\kappa_n = \frac{d\mathbf{u}}{d\lambda} \cdot \mathbf{n}. \tag{7.20}$$

By differentiating $\mathbf{u} \cdot \mathbf{n}$ we get

$$\mathbf{u} \cdot \frac{d\mathbf{n}}{d\lambda} = -\kappa_n = -K_{\mu\nu} u^\mu u^\nu. \tag{7.21}$$

This is *Weingarden's equation*.

The geodesic and normal curvatures, taken separately, characterize the extrinsic geometry of the surface. We shall now find a quantity, called the Gaussian curvature, which is a measure of the intrinsic geometry of the surface.

At an arbitrary point on the surface we consider geodesic curves through the point with tangent vectors $\mathbf{u} = u^\mu \mathbf{e}_\mu$. In order to compare the normal curvature of the geodesics having different directions, we choose tangent vectors of unit length,

$$\mathbf{u} \cdot \mathbf{u} = g_{\mu\nu} u^\mu u^\nu = 1. \tag{7.22}$$

The directions with maximal and minimal values of the normal curvature are found by extremizing κ_n as given by eq. (7.18) with the constraint eq. (7.22). Thus we have to solve the variational problem δF for arbitrary u^μ, where

$$F = K_{\mu\nu} u^\mu u^\nu - k(g_{\mu\nu} u^\mu u^\nu - 1). \tag{7.23}$$

Here k is a Lagrange multiplier. Variation with respect to u^μ gives

$$\delta F = 2(K_{\mu\nu} - k g_{\mu\nu}) u^\nu \delta u^\mu. \tag{7.24}$$

Thus we must have

$$(K_{\mu\nu} - kg_{\mu\nu})u^\nu = 0. \tag{7.25}$$

This set of equations has non-trivial solutions whenever

$$\det\left(K_{\mu\nu} - kg_{\mu\nu}\right) = 0, \tag{7.26}$$

which yields the following quadratic equation for k

$$k^2 \det(g_{\mu\nu}) - k(g_{11}K_{22} - 2g_{12}K_{12} + g_{22}K_{11}) + \det(K_{\mu\nu}) = 0 \tag{7.27}$$

with solutions k_1 and k_2. These are the extremal values of k.

To see the meaning of k we multiply eq. (7.25) by u^μ and use eq. (7.18). This gives

$$k = \kappa_n. \tag{7.28}$$

The extremal values of k are called the *principal curvatures* of the surface. The *Gaussian curvature* of the surface is defined as

$$K = k_1 k_2. \tag{7.29}$$

From eq. (7.27) it follows that

$$\boxed{K = \frac{\det(K_{\mu\nu})}{\det(g_{\mu\nu})}.} \tag{7.30}$$

Let the directions corresponding to the principal curvatures be characterized by the vectors $\mathbf{u}$ and $\mathbf{v}$. From equation (7.25) and the symmetry of $K_{\mu\nu}$ follows

$$(k_1 - k_2)(\mathbf{u} \cdot \mathbf{v}) = 0. \tag{7.31}$$

For $k_1 \neq k_2$ this implies that $\mathbf{u}$ and $\mathbf{v}$ are orthogonal. The principal curvatures are found in orthogonal directions.

A positive Gaussian curvature means that the principal curvatures are of the same sign. The surface is locally similar to a distorted sphere, and the geometry is locally elliptic. If the Gaussian curvature vanishes, one of the principal curvatures have to vanish and the geometry is locally planar and the geometry is locally Euclidean. Finally, if the Gaussian curvature is negative the surface is locally saddle-shaped, i.e. like a hyperbolic surface. In this case the geometry is said to be locally hyperbolic.

In the following sections we will show that the Gaussian curvature represents a measure of the intrinsic geometry of the surface. This will be achieved by expressing it in terms of the components of the Riemann tensor, which we will introduce in the next section. Note however that curves have no intrinsic curvature.

7.3 The Riemann Curvature Tensor

In this section we will not restrict ourselves to two-dimensional surfaces, but describe spaces of arbitrary number of dimensions. We will introduce the important concept of curvature in an invariant way, described by the Riemann curvature tensor.

Consider two nearby points Q and P connected by a vector $\delta\lambda\mathbf{v}$ of infinitesimal length. Let $\mathbf{A}$ be a vector field. Then the difference between the vector field at Q, denoted $\mathbf{A}_Q$, and the vector $\mathbf{A}_P$ parallel-transported from P to Q (which is denoted $\mathbf{A}_{PQ}$) is to first order in $\delta\lambda$ given by the directional derivative at Q of $\mathbf{A}$ in the $\mathbf{v}$-direction

$$\delta\lambda\nabla_{\mathbf{v}}\mathbf{A} \approx \mathbf{A}_Q - \mathbf{A}_{PQ} \tag{7.32}$$

Thus

$$\mathbf{A}_{PQ} \approx (1 - \delta\lambda\nabla_{\mathbf{v}})\,\mathbf{A}_Q \tag{7.33}$$

To second order $\mathbf{A}_{PQ}$ is given by the first terms of the Taylor expansion

$$\mathbf{A}_{PQ} \approx \left(1 - \delta\lambda\nabla_{\mathbf{v}} + \frac{1}{2}\delta\lambda^2\nabla_{\mathbf{v}}\nabla_{\mathbf{v}}\right)\mathbf{A}_Q \tag{7.34}$$

We are now going to parallel-transport the vector $\mathbf{A}_P$ around the polygon shown in Fig.7.3. Parallel-transporting $\mathbf{A}_{PQ}$ from Q to R gives

$$\mathbf{A}_{PQR} \approx \left(1 - \delta\lambda\nabla_{\mathbf{u}} + \frac{1}{2}\delta\lambda^2\nabla_{\mathbf{u}}\nabla_{\mathbf{u}}\right)\left(1 - \delta\lambda\nabla_{\mathbf{v}} + \frac{1}{2}\delta\lambda^2\nabla_{\mathbf{v}}\nabla_{\mathbf{v}}\right)\mathbf{A}_R. \tag{7.35}$$

Proceeding around the polygon gives

$$\begin{aligned}\mathbf{A}_{PQRSTP} \;\approx\;& \left(1 + \delta\lambda\nabla_{\mathbf{u}} + \frac{1}{2}\delta\lambda^2\nabla_{\mathbf{u}}\nabla_{\mathbf{u}}\right)\left(1 + \delta\lambda\nabla_{\mathbf{v}} + \frac{1}{2}\delta\lambda^2\nabla_{\mathbf{v}}\nabla_{\mathbf{v}}\right)\\ \times\;& \left(1 - \delta\lambda^2\nabla_{[\mathbf{u},\mathbf{v}]}\right)\\ \times\;& \left(1 - \delta\lambda\nabla_{\mathbf{u}} + \frac{1}{2}\delta\lambda^2\nabla_{\mathbf{u}}\nabla_{\mathbf{u}}\right)\left(1 - \delta\lambda\nabla_{\mathbf{v}} + \frac{1}{2}\delta\lambda^2\nabla_{\mathbf{v}}\nabla_{\mathbf{v}}\right)\mathbf{A}_R.\end{aligned} \tag{7.36}$$

Thus, to second order, the change of the vector after parallel-transport around the polygon is

$$\delta\mathbf{A} = \mathbf{A}_{PQRSTP} - \mathbf{A}_P = \left([\nabla_{\mathbf{u}}, \nabla_{\mathbf{v}}] - \nabla_{[\mathbf{u},\mathbf{v}]}\right)\delta\lambda^2\mathbf{A}_P \tag{7.37}$$

In flat space there would be no such change of $\mathbf{A}$. This change is due to the curvature of the space. It can be shown that $\delta\mathbf{A}$ as given in eq. (7.37) is a vector which is linear in $\mathbf{A}$, $\mathbf{u}$ and $\mathbf{v}$ (see e.g. [vW81]). Thus $\delta\mathbf{A}$ may be expressed by a tensor of rank $\{^1_3\}$. This tensor $\mathbf{R}$ is called the *Riemann curvature tensor* and is defined by

$$\boxed{\mathbf{R}(\mathbf{u},\mathbf{v})\mathbf{A} \equiv \left([\nabla_{\mathbf{u}}, \nabla_{\mathbf{v}}] - \nabla_{[\mathbf{u},\mathbf{v}]}\right)\mathbf{A}.} \tag{7.38}$$

The components of this tensor are given by

$$\mathbf{e}_\mu R^\mu{}_{\nu\alpha\beta} = \left([\nabla_\alpha, \nabla_\beta] - \nabla_{[\mathbf{e}_\alpha,\mathbf{e}_\beta]}\right)\mathbf{e}_\nu \tag{7.39}$$

It follows that the Riemann curvature tensor is antisymmetric in $\mathbf{u}$ and $\mathbf{v}$ i.e. in α and β. We can therefore define a matrix of two-forms

$$\boxed{\mathbf{R}^\mu_\nu = \frac{1}{2}R^\mu{}_{\nu\alpha\beta}\boldsymbol{\omega}^\alpha \wedge \boldsymbol{\omega}^\beta} \tag{7.40}$$

$\mathbf{v}(P)$
Q

Figure 7.3: The vector $\mathbf{A}_P$ parallel transported around the polygon $PQRSTP$

which are called the *curvature forms*.

Equation (7.37) may now be written

$$\delta\mathbf{A} = \mathbf{e}_\mu R^\mu{}_{\nu\alpha\beta} A^\nu u^\alpha v^\beta. \tag{7.41}$$

The infinitesimal area of the polygon is to lowest order in $\mathbf{u}$ and $\mathbf{v}$

$$\Delta S^{\alpha\beta} = u^\alpha v^\beta - u^\beta v^\alpha. \tag{7.42}$$

Using the antisymmetry of $R^\mu{}_{\nu\alpha\beta}$ we may then write

$$\delta\mathbf{A} = \frac{1}{2} A^\nu R^\mu{}_{\nu\alpha\beta} \Delta S^{\alpha\beta} \mathbf{e}_\mu. \tag{7.43}$$

This shows that the change of a vector by parallel transport around a closed curve is proportional to the curvature of the space and to the area enclosed by the curve.

We shall now show how $R^\mu{}_{\nu\alpha\beta}$ may be expressed by the connection- and structure coefficients of a given basis. We find

$$\begin{aligned}
\mathbf{e}_\mu R^\mu{}_{\nu\alpha\beta} &= \left([\nabla_\alpha, \nabla_\beta] - \nabla_{[\mathbf{e}_\alpha,\mathbf{e}_\beta]}\right)\mathbf{e}_\nu \\
&= \left(\nabla_\alpha\nabla_\beta - \nabla_\beta\nabla_\alpha - c^\rho{}_{\alpha\beta}\nabla_\rho\right)\mathbf{e}_\nu \\
&= \left(\Gamma^\mu{}_{\nu\beta,\alpha} + \Gamma^\rho{}_{\nu\beta}\Gamma^\mu{}_{\rho\alpha} - \Gamma^\mu{}_{\nu\alpha,\beta} - \Gamma^\rho{}_{\nu\alpha}\Gamma^\mu{}_{\rho\beta} - c^\rho{}_{\alpha\beta}\Gamma^\mu{}_{\nu\rho}\right)\mathbf{e}_\mu
\end{aligned} \tag{7.44}$$

which implies that

$$\boxed{R^\mu{}_{\nu\alpha\beta} = \Gamma^\mu{}_{\nu\beta,\alpha} - \Gamma^\mu{}_{\nu\alpha,\beta} + \Gamma^\rho{}_{\nu\beta}\Gamma^\mu{}_{\rho\alpha} - \Gamma^\rho{}_{\nu\alpha}\Gamma^\mu{}_{\rho\beta} - c^\rho{}_{\alpha\beta}\Gamma^\mu{}_{\nu\rho}.} \tag{7.45}$$

The connection coefficients and structure coefficients are calculated from a basis vector field in the space considered, without reference to any higher dimensional space. Thus eq. (7.45) shows that the Riemann tensor describes the intrinsic geometry of space.

The curvature forms may now be written in component form as

$$\mathbf{R}^{\mu}{}_{\nu} = \left(\Gamma^{\mu}{}_{\nu\beta,\alpha} - \frac{1}{2} c^{\rho}{}_{\alpha\beta} \Gamma^{\mu}{}_{\nu\rho} + \Gamma^{\rho}{}_{\nu\beta} \Gamma^{\mu}{}_{\rho\alpha} \right) \boldsymbol{\omega}^{\alpha} \wedge \boldsymbol{\omega}^{\beta}. \tag{7.46}$$

Using equations (6.136) and (6.165) we find

$$\boxed{\mathbf{R}^{\mu}{}_{\nu} = \mathbf{d}\boldsymbol{\Omega}^{\mu}{}_{\nu} + \boldsymbol{\Omega}^{\mu}{}_{\lambda} \wedge \boldsymbol{\Omega}^{\lambda}{}_{\nu}.} \tag{7.47}$$

This is *Cartan's 2nd structural equation.*

We shall now deduce some identities fulfilled by the Riemann tensor. Using eqs. (6.118) and (6.144) we get

$$\begin{aligned} A^{\mu}{}_{;\beta\alpha} &= A^{\lambda} \Gamma^{\mu}{}_{\lambda\beta,\alpha} - A^{\lambda} \Gamma^{\tau}{}_{\lambda\alpha} \Gamma^{\mu}{}_{\tau\beta} - A^{\mu}{}_{;\lambda} \Gamma^{\lambda}{}_{\beta\alpha} + A^{\mu}{}_{,\beta\alpha} \\ &\quad + \left(A^{\lambda}{}_{;\alpha} \Gamma^{\mu}{}_{\lambda\beta} + A^{\lambda}{}_{;\beta} \Gamma^{\mu}{}_{\lambda\alpha} \right). \end{aligned} \tag{7.48}$$

The two latter terms are symmetric in α and β and do not contribute to the antisymmetric combination $A^{\mu}{}_{;\beta\alpha} - A^{\mu}{}_{;\alpha\beta}$. Hence, by using eqs. (7.45) and (6.134), we get

$$A^{\mu}{}_{;\beta\alpha} - A^{\mu}{}_{;\alpha\beta} = A^{\lambda} R^{\mu}{}_{\lambda\alpha\beta} - A^{\mu}{}_{;\lambda} T^{\lambda}_{\alpha\beta}. \tag{7.49}$$

Since this is a tensor equation it is valid in an arbitrary basis. Eq. (7.49) is called the *Ricci identity*. In Riemannian geometry it reduces to

$$\boxed{A^{\mu}{}_{;\beta\alpha} - A^{\mu}{}_{;\alpha\beta} = R^{\mu}{}_{\lambda\alpha\beta} A^{\lambda}.} \tag{7.50}$$

Combining this with eq. (6.163) leads to

$$\mathbf{d}^2 \mathbf{A} = \frac{1}{2} R^{\mu}{}_{\nu\alpha\beta} A^{\nu} \mathbf{e}_{\mu} \otimes \boldsymbol{\omega}^{\alpha} \wedge \boldsymbol{\omega}^{\beta} \tag{7.51}$$

By exterior differentiation of Cartan's first structural equation, eq. (6.180) combined with Cartan's second structural equation and Poincaré's Lemma, we find

$$\mathbf{R}^{\mu}{}_{\nu} \wedge \boldsymbol{\omega}^{\nu} = \mathbf{d}\mathbf{T}^{\mu} + \boldsymbol{\Omega}^{\mu}{}_{\nu} \wedge \mathbf{T}^{\nu}. \tag{7.52}$$

By means of eq. (6.216), this equation takes the form

$$\mathbf{R}^{\mu}{}_{\nu} \wedge \boldsymbol{\omega}^{\nu} = \mathbf{D}\mathbf{T}^{\mu}. \tag{7.53}$$

This is *Bianchi's first identity*. In Riemannian geometry it reduces to

$$\boxed{\mathbf{R}^{\mu}{}_{\nu} \wedge \boldsymbol{\omega}^{\nu} = 0.} \tag{7.54}$$

On component form this equation is

$$\boxed{R^{\mu}{}_{[\nu\alpha\beta]} = 0.} \tag{7.55}$$

By exterior differentiation of Cartan's second structural equation, and using Poincaré's Lemma, we get

$$\mathbf{d}\mathbf{R}^{\mu}{}_{\nu} = \mathbf{d}\boldsymbol{\Omega}^{\mu}{}_{\lambda} \wedge \boldsymbol{\Omega}^{\lambda}{}_{\nu} - \boldsymbol{\Omega}^{\mu}{}_{\lambda} \wedge \mathbf{d}\boldsymbol{\Omega}^{\lambda}{}_{\nu} = \mathbf{R}^{\mu}{}_{\lambda} \wedge \boldsymbol{\Omega}^{\lambda}{}_{\nu} - \boldsymbol{\Omega}^{\mu}{}_{\lambda} \wedge \mathbf{R}^{\lambda}{}_{\nu}, \tag{7.56}$$

which is more usually written

$$\mathbf{dR}^{\mu}{}_{\nu} + \mathbf{\Omega}^{\mu}{}_{\lambda} \wedge \mathbf{R}^{\lambda}{}_{\nu} - \mathbf{R}^{\mu}{}_{\lambda} \wedge \mathbf{\Omega}^{\lambda}{}_{\nu} = 0. \tag{7.57}$$

Applying eq. (6.214) to a matrix of two-forms this equation may be written

$$\boxed{\mathbf{DR}^{\mu}{}_{\nu} = 0.} \tag{7.58}$$

This is *Bianchi's second identity*. On component form this identity becomes

$$\boxed{R^{\mu}{}_{\nu[\alpha\beta;\gamma]} = 0.} \tag{7.59}$$

An additional symmetry of the Riemann tensor is most easily found by decomposing it in an orthonormal basis field. Applying eq. (6.169) and Cartan's second structural equation (7.47), we get

$$\boxed{R_{\mu\nu\alpha\beta} = -R_{\nu\mu\alpha\beta}} \tag{7.60}$$

The fourth and last symmetry of the Riemann tensor is found by applying geodesic normal coordinates. From eq. (7.45), (6.110) and (6.232) we then get

$$R_{\mu\nu\alpha\beta} = \frac{1}{2}(g_{\mu\beta,\nu\alpha} - g_{\mu\alpha,\nu\beta} + g_{\nu\alpha,\mu\beta} - g_{\nu\beta,\mu\alpha}). \tag{7.61}$$

It follows that

$$\boxed{R_{\mu\nu\alpha\beta} = R_{\alpha\beta\mu\nu}.} \tag{7.62}$$

The four symmetries of the Riemann tensor reduce its number of independent components in an n-dimensional space from n^4 to $\frac{1}{12}n^2(n^2-1)$, in four-dimensional space-time from 256 to 20.

We shall now construct a curvature tensor of rank $\{{0 \atop 2}\}$ by contraction of the Riemann tensor. Note first that

$$R^{\alpha}{}_{\alpha\mu\nu} = 0 \tag{7.63}$$

because of the antisymmetry in the first two indices. Furthermore

$$R^{\alpha}{}_{\mu\nu\alpha} = -R^{\alpha}{}_{\mu\alpha\nu}. \tag{7.64}$$

Thus there exists only one independent non-vanishing contraction of the Riemann tensor. This is called the *Ricci tensor* and is usually written

$$\boxed{R_{\mu\nu} = R^{\alpha}{}_{\mu\alpha\nu}.} \tag{7.65}$$

From eq. (7.62) follows that it is symmetrical. It has $\frac{1}{2}n(n+1)$ independent components in an n-dimensional space; 10 components in four-dimensional space-time.

Contraction of the Ricci tensor gives the *Ricci scalar*

$$\boxed{R = R^{\mu}{}_{\mu}.} \tag{7.66}$$

Let us calculate the divergence of the Ricci tensor. Contraction of Bianchi's second identity eq.(7.58) (μ with α), yields

$$\begin{aligned} R^{\mu}{}_{\nu\mu\beta;\gamma} + R^{\mu}{}_{\nu\gamma\mu;\beta} + R^{\mu}{}_{\nu\beta\gamma;\mu} &= \\ R_{\nu\beta;\gamma} - R_{\nu\gamma;\beta} + R^{\mu}{}_{\nu\beta\gamma;\mu} &= 0. \end{aligned} \tag{7.67}$$

Raising the index ν and contracting with γ leads to

$$R^{\nu}{}_{\beta;\nu} - R_{;\beta} + R^{\mu}{}_{\beta;\mu} = 0. \tag{7.68}$$

Hence the divergence of the Ricci tensor is

$$R^{\nu}{}_{\mu;\nu} = \frac{1}{2}\left(\delta^{\nu}{}_{\mu}R\right)_{;\nu}. \tag{7.69}$$

Thus the tensor

$$E^{\nu}{}_{\mu} = R^{\nu}{}_{\mu} - \frac{1}{2}\delta^{\nu}{}_{\mu}R \tag{7.70}$$

is divergence free. This is *Einstein's curvature tensor*. Its covariant components are

$$\boxed{E_{\mu\nu} = R_{\mu\nu} - \frac{1}{2}Rg_{\mu\nu}.} \tag{7.71}$$

It follows immediately that this tensor is symmetric.

In an n-dimensional space the vanishing of the divergence of the Einstein tensor represents n equations. Thus the Einstein tensor has $\frac{1}{2}n(n-1)$ independent components in general, and 6 independent components in four-dimensional space-time.

The Weyl Curvature Tensor

Let us now focus on the case where the dimension of the manifold is 4, like our four-dimensional spacetime. The symmetries of the Riemann tensor imply that the Riemann tensor has 20 independent components in four dimensions. The Ricci tensor, on the other hand, has only 10 independent components. The components of the Riemann tensor which is not captured in the Ricci part form what is called the *Weyl curvature tensor*.

In four dimensions the Weyl curvature tensor is defined by

$$C_{\alpha\beta\gamma\delta} = R_{\alpha\beta\gamma\delta} - g_{\alpha[\gamma}R_{\delta]\beta} + g_{\beta[\gamma}R_{\delta]\alpha} + \frac{1}{3}Rg_{\alpha[\gamma}g_{\delta]\beta}. \tag{7.72}$$

It possesses the same symmetries as the Riemann tensor,

$$C_{\alpha\beta\gamma\delta} = C_{\gamma\delta\alpha\beta}, \quad C_{\alpha\beta\gamma\delta} = -C_{\beta\alpha\gamma\delta}, \quad C_{\alpha[\beta\gamma\delta]} = 0,$$

and in addition, *contraction over any pair of indices yields zero*:

$$C^{\alpha}{}_{\beta\alpha\delta} = 0. \tag{7.73}$$

Hence, when contracting the Riemann tensor over two indices only the Ricci part of it will survive. This gives, as we will see later, a physical interpretation of the Weyl tensor. Einstein's equations, which will be introduced in the next chapter, will only involve the Ricci tensor and hence the Weyl tensor represents the *free gravitational field*. Thus even if the Ricci tensor is zero, there can be a free gravitational field encoded in the Weyl tensor. This property gives rise to many interesting phenomena; many of which will be discussed in this book. Two important examples are gravitational waves, and the Schwarzschild vacuum solution.

The definition of the Weyl tensor in any dimension, see section 18.4. This section also discusses some further properties of the Weyl tensor.

7.4 Extrinsic and Intrinsic Curvature

From eq. (7.45) it is seen that the components of the Riemann tensor may be calculated from the components of the metric tensor. They are defined in terms of basis-vectors in a space which has a curvature specified by the Riemann tensor. Thus the specification of the metric does not presuppose any embedding of the curved space in a higher-dimensional flat space. The Riemann curvature tensor represents intrinsic geometric properties of space, which may be measured by inhabitants of that space. (Such inhabitants are always assumed to be creatures with the same number of dimensions as that of the space they inhabit.) Therefore one says that the Riemann tensor is a measure of the *intrinsic* curvature of space.

In the case of a two-dimensional surface, say a balloon, the intrinsic geometry is measured by two-dimensional creatures on the surface, "flatlanders". In general, if the Riemann tensor in a space vanishes, the space is flat. For a two-dimensional surface this means that the surface may be rolled onto an Euclidean plane without any local changes of the geometry. If the surface is an elastic membrane, no stresses or strains are introduced by this "rolling out" of it. The intrinsic geometry of a cylindrical surface for example, is Euclidean, and has no intrinsic curvature.

However, as seen from an external Euclidean three-dimensional space, the cylindrical surface looks curved. The surface has external curvature. We shall now introduce a tensor measuring the external curvature of a space, which is embedded in a space of one more dimension.

In the following we shall consider a curved n-dimensional space $\mathcal{M}^n$ embedded in an $(n+1)$-dimensional space $\mathcal{M}^{n+1}$ which also may be curved. Such a space embedded in an space with one dimensional higher, is called a *hypersurface*. Furthermore, Greek indices are associated with $\mathcal{M}^{n+1}$ and Latin indices with $\mathcal{M}^n$.

A measure of the extrinsic curvature of a space is obtained by considering how the direction of the unit normal vector $\mathbf{N}$ to the hypersurface changes with position on the hypersurface. *The extrinsic curvature tensor* $\mathbf{K}$ is a tensor on $\mathcal{M}^n$ of rank $\{^0_2\}$ defined up to a sign ambiguity by

$$\boxed{K_{ab} = -\mathbf{e}_b \cdot \nabla_a \mathbf{n}} \tag{7.74}$$

where the covariant derivative is taken in the ambient space $\mathcal{M}^{n+1}$. Since $\mathbf{N}$ is orthogonal to the basis vectors $\mathbf{e}_b$ on $\mathcal{M}^n$, so that $\nabla_a(\mathbf{e}_b \cdot \mathbf{n}) = 0$ we get

$$K_{ab} = \mathbf{n} \cdot \nabla_a \mathbf{e}_b = \mathbf{n} \cdot \mathbf{e}_\alpha \Gamma^\alpha{}_{ba} = n^\alpha g_{\alpha\beta} \Gamma^\beta{}_{ba} = n_\alpha \Gamma^\alpha{}_{ba}, \tag{7.75}$$

where $\mathbf{n} = n^\alpha \mathbf{e}_\alpha$. We introduce an orthonormal basis $\{\mathbf{e}_{\hat{a}}\}$ on $\mathcal{M}^n$ and a normal unit vector $\mathbf{n} = \mathbf{e}_{\hat{n}}$. By defining $\mathbf{n} \cdot \mathbf{n} = \epsilon = \pm 1$ we get

$$K_{\hat{a}\hat{b}} = \Gamma^{\hat{n}}{}_{\hat{a}\hat{b}}\,, \qquad g_{\hat{n}\hat{n}} = \epsilon. \tag{7.76}$$

Equation (7.75) shows that the extrinsic curvature is symmetric.

Let us now deduce the relation between the Riemann tensors of $\mathcal{M}^{n+1}$ and $\mathcal{M}^n$ and the extrinsic curvature of $\mathcal{M}^n$.

We will calculate the Riemann tensors using orthonormal frames. The Riemann tensor in $\mathcal{M}^{n+1}$ projected onto $\mathcal{M}^n$ is given by

$$\left(\mathbf{d}^2 \mathbf{e}_{\hat{b}}\right)_\perp = \left(\frac{1}{2} {}^{(n+1)}R^{\hat{\lambda}}{}_{\hat{b}\hat{\alpha}\hat{\beta}} \mathbf{e}_{\hat{\lambda}} \otimes \boldsymbol{\omega}^{\hat{\alpha}} \wedge \boldsymbol{\omega}^{\hat{\beta}}\right)_\perp = \frac{1}{2} {}^{(n+1)}R^{\hat{a}}{}_{\hat{b}\hat{c}\hat{d}} \mathbf{e}_{\hat{a}} \otimes \boldsymbol{\omega}^{\hat{c}} \wedge \boldsymbol{\omega}^{\hat{d}}. \tag{7.77}$$

We can also write this in another way, using instead the Riemann tensor in $\mathcal{M}^n$

$$\begin{aligned} \left(\mathbf{d}^2\mathbf{e}_{\hat b}\right)_\perp &= \left(\mathbf{d}\left[\mathbf{e}_{\hat\alpha}\otimes\mathbf{\Omega}^{\hat\alpha}{}_{\hat b}\right]\right)_\perp = \left(\mathbf{d}\mathbf{e}_{\hat\alpha}\otimes\mathbf{\Omega}^{\hat\alpha}{}_{\hat b}\right)_\perp + \left(\mathbf{e}_{\hat\alpha}\otimes\mathbf{d}\mathbf{\Omega}^{\hat\alpha}{}_{\hat b}\right)_\perp \\ &= \mathbf{e}_{\hat a}\otimes\left(\mathbf{d}\mathbf{\Omega}^{\hat a}{}_{\hat b} + \mathbf{\Omega}^{\hat a}{}_{\hat\alpha}\wedge\mathbf{\Omega}^{\hat\alpha}{}_{\hat b}\right)_\perp . \end{aligned} \tag{7.78}$$

We can now use Cartan's second structural equation in $\mathcal{M}^n$ by decomposing the wedge product

$$\begin{aligned} \left(\mathbf{d}^2\mathbf{e}_{\hat b}\right)_\perp &= \mathbf{e}_{\hat a}\otimes\left(\mathbf{d}\mathbf{\Omega}^{\hat a}{}_{\hat b} + \mathbf{\Omega}^{\hat a}{}_{\hat\lambda}\wedge\mathbf{\Omega}^{\hat\lambda}{}_{\hat b} + \mathbf{\Omega}^{\hat a}{}_{\hat n}\wedge\mathbf{\Omega}^{\hat n}{}_{\hat b}\right)_\perp \\ &= \mathbf{e}_{\hat a}\otimes\left({}^{(n)}\mathbf{R}^{\hat a}{}_{b} + \left[\mathbf{\Omega}^{\hat a}{}_{\hat n}\wedge\mathbf{\Omega}^{\hat n}{}_{\hat b}\right]_\perp\right) \\ &= \frac{1}{2}\left({}^{(n)}R^{\hat a}{}_{\hat b\hat c\hat d} + \Gamma^{\hat a}{}_{\hat n\hat c}\Gamma^{\hat n}{}_{\hat b\hat d}\right)\mathbf{e}_{\hat a}\otimes\boldsymbol{\omega}^{\hat c}\wedge\boldsymbol{\omega}^{\hat d} \\ &= \frac{1}{2}\left({}^{(n)}R^{\hat a}{}_{\hat b\hat c\hat d} \pm K^{\hat a}{}_{\hat c}K_{\hat b d}\right)\mathbf{e}_{\hat a}\otimes\boldsymbol{\omega}^{\hat c}\wedge\boldsymbol{\omega}^{\hat d}. \end{aligned} \tag{7.79}$$

From equations (7.77) and (7.79) it follows that

$${}^{(n)}R^{\hat a}{}_{\hat b\hat c\hat d} = {}^{(n+1)}R^{\hat a}{}_{\hat b\hat c\hat d} \pm 2K^{\hat a}{}_{[\hat c}K_{\hat d]\hat b}. \tag{7.80}$$

This is an expression of *Gauss' Theorema Egregium*, which says that an inhabitant of, say, a three-dimensional space, may perform measurements, within the three-dimensional space, which reveals to him the curvature of that space. It is not necessary to embed the space in a higher-dimensional one.

Let us write equation (7.80) in a covariant manner. The Riemann tensor on the right side in eq. (7.80) is the projected Riemann tensor of the ambient space $\mathcal{M}^{n+1}$. If we split the metric tensor $g_{\alpha\beta}$ into

$$g_{\alpha\beta} = h_{\alpha\beta} + \epsilon n_\alpha n_\beta, \tag{7.81}$$

where n_α are the components of the unit normal vector $\mathbf{n}$, then the tensor $h_{\alpha\beta}$ will act as a projection tensor onto the space $\mathcal{M}^n$. In addition, the tensor $h_{\alpha\beta}$ will be the metric tensor of the space $\mathcal{M}^n$ for vectors on $\mathcal{M}^n$. Since the exterior curvature and the Riemann tensor in $\mathcal{M}^n$ already are projected we have

$$h^\lambda{}_\alpha K_{\lambda\beta} = K_{\alpha\beta} \tag{7.82}$$

i.e. they are eigentensors to the projection map $h^\lambda{}_\alpha$. The equation (7.80) can now be written covariantly as

$$\boxed{{}^{(n)}R^\alpha{}_{\beta\mu\nu} = {}^{(n+1)}R^\lambda{}_{\gamma\sigma\rho}h^\alpha{}_\lambda h^\gamma{}_\beta h^\sigma{}_\mu h^\rho{}_\nu + \epsilon\left(K^\alpha{}_\mu K_{\beta\nu} - K^\alpha{}_\nu K_{\beta\mu}\right).} \tag{7.83}$$

Similarly, we can show that

$$\boxed{{}^{(n)}\nabla_\alpha K_{\beta\mu} - {}^{(n)}\nabla_\mu K_{\beta\alpha} = {}^{(n+1)}R^\lambda{}_{\sigma\rho\delta}n_\lambda h^\sigma{}_\beta h^\rho{}_\alpha h^\delta{}_\mu} \tag{7.84}$$

where ${}^{(n)}\nabla_\alpha = h^\beta{}_\alpha\nabla_\beta$ is the n-dimensional connection. The derivation of this is left as a problem (see problem 7.4). This equation is called the *Codazzi equation*.

In the special case where $\mathcal{M}^{n+1}$ is flat, eq. (7.80) reduce to

$${}^{(n)}R_{\hat a\hat b\hat c\hat d} = \pm\left(K_{\hat a\hat c}K_{\hat d\hat b} - K_{\hat a\hat d}K_{\hat c\hat b}\right). \tag{7.85}$$

For a two dimensional surface $\mathcal{M}^2$ these equations reduce to the single equation

$$R_{\hat{1}\hat{2}\hat{1}\hat{2}} = K_{\hat{1}\hat{1}} K_{\hat{1}\hat{2}} - (K_{\hat{1}\hat{2}})^2 = \det(K_{\hat{a}\hat{b}}). \tag{7.86}$$

Comparing with eq. (7.30) of a surface (with $\det(g_{\hat{a}\hat{b}}) = 1$) we obtain

$$K = R_{\hat{1}\hat{2}\hat{1}\hat{2}}. \tag{7.87}$$

Thus, the Gaussian curvature represents the *intrinsic* geometry of the surface.

Example 7.2 (The curvature of a straight circular cone) **Example**

From the figure 7.4 it is seen that the line element on the conical surface is

$$ds^2 = dl^2 + r^2 d\theta^2 = dl^2 + \left(\frac{R}{H}\right)^2 l^2 d\theta^2. \tag{7.88}$$

Here are l and θ coordinates on the surface, and r a coordinate normal to the axis of the cone.

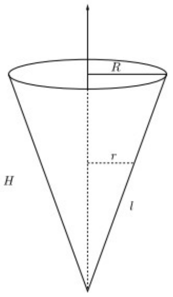

Figure 7.4: A cone is intrinsically flat

We introduce an orthonormal basis on the surface

$$\boldsymbol{\omega}^{\hat{l}} = \mathbf{dl}, \quad \boldsymbol{\omega}^{\hat{\theta}} = \left(\frac{R}{H}\right) \mathbf{d}\boldsymbol{\theta}. \tag{7.89}$$

Exterior differentiation yields

$$\mathbf{d}\boldsymbol{\omega}^{\hat{l}} = 0, \quad \mathbf{d}\boldsymbol{\omega}^{\hat{\theta}} = \frac{1}{l} \boldsymbol{\omega}^{\hat{l}} \wedge \boldsymbol{\omega}^{\hat{\theta}}. \tag{7.90}$$

Cartan's first structural equation now give the non-vanishing connection forms

$$\boldsymbol{\Omega}^{\hat{\theta}}{}_{\hat{l}} = -\boldsymbol{\Omega}^{\hat{l}}{}_{\hat{\theta}} = \frac{1}{l} \boldsymbol{\omega}^{\hat{\theta}}. \tag{7.91}$$

Thus

$$\mathbf{d}\boldsymbol{\Omega}^{\hat{\theta}}{}_{\hat{l}} = \left(\mathbf{d}\frac{1}{l}\right) \boldsymbol{\omega}^{\hat{\theta}} + \frac{1}{l} \mathbf{d}\boldsymbol{\omega}^{\hat{\theta}} = 0. \tag{7.92}$$

and Cartan's second structural equation gives

$$\mathbf{R}^{\hat{\theta}}{}_{\hat{l}} = \mathbf{R}^{\hat{l}}{}_{\hat{\theta}} = 0 \tag{7.93}$$

which shows that the intrinsic geometry of the conical surface is Euclidean.

The extrinsic curvature is given by eq. (7.75). In the present case the single non-vanishing component of this tensor is

$$K_{\hat{\theta}\hat{\theta}} = \Gamma^{\hat{n}}{}_{\hat{\theta}\hat{\theta}}. \tag{7.94}$$

In example 6.9 we found that $\Gamma^{\hat{r}}{}_{\hat{\theta}\hat{\theta}} = -\frac{1}{r}$, so

$$\mathbf{d}\mathbf{e}_{\hat{\theta}} = -\frac{1}{r}\mathbf{e}_{\hat{r}} \otimes \boldsymbol{\omega}^{\hat{\theta}} \tag{7.95}$$

From Fig.7.4 we see that

$$\mathbf{e}_{\hat{r}} = \frac{H}{L}\mathbf{e}_{\hat{n}} + \frac{R}{L}\mathbf{e}_{\hat{l}}, \quad L = (H^2 + L^2)^{\frac{1}{2}} \tag{7.96}$$

This yields

$$\mathbf{d}\mathbf{e}_{\hat{\theta}} = -\frac{H}{Lr}\mathbf{e}_{\hat{n}} \otimes \boldsymbol{\omega}^{\hat{\theta}} - \frac{R}{Lr}\mathbf{e}_{\hat{l}} \otimes \boldsymbol{\omega}^{\hat{\theta}} \tag{7.97}$$

which shows that

$$\Gamma^{\hat{n}}{}_{\hat{\theta}\hat{\theta}} = -\frac{H}{Lr} \tag{7.98}$$

Hence, the conical surface has a non-vanishing extrinsic curvature given by

$$K_{\hat{\theta}\hat{\theta}} = -\left(1 + \frac{R^2}{H^2}\right)^{-\frac{1}{2}} \cdot \frac{1}{r} \tag{7.99}$$

The limit $H \longrightarrow \infty, r \longrightarrow R$ represents a straight cylinder with $K_{\hat{\theta}\hat{\theta}} = -\frac{1}{R}$. The limit $H \longrightarrow 0$ represents a plane with $K_{\hat{\theta}\hat{\theta}} = 0$.

7.5 The equation of geodesic deviation

Consider two nearby geodesic curves, both parametrised by a parameter λ. Let s be a vector connecting points on the two curves with the same value of λ. The connecting vector s is said to measure the *geodesic deviation* of the curves.

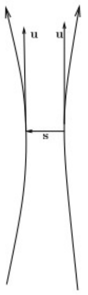

Figure 7.5: The two solid lines are neighbouring geodesics. They are connected by an infinitesimal vector s that obeys the equation of geodesic deviation

In order to deduce an equation describing how the geodesic deviation varies along the curves, we consider the covariant directional derivative of s along the curve $\nabla_{\mathbf{u}}\mathbf{s}$ where $\mathbf{u}$ is the tangent vector to the curve.

Let $\mathbf{u}$ and s be coordinate basis vectors of a coordinate system. Then $[\mathbf{s}, \mathbf{u}] = 0$, so that

$$\nabla_{\mathbf{u}}\mathbf{s} = \nabla_{\mathbf{s}}\mathbf{u} \tag{7.100}$$

giving

$$\nabla_{\mathbf{u}}\nabla_{\mathbf{u}}\mathbf{s} = \nabla_{\mathbf{u}}\nabla_{\mathbf{s}}\mathbf{u}. \tag{7.101}$$

Furthermore

$$\begin{aligned}\mathbf{R}(\mathbf{u},\mathbf{s})\mathbf{u} &= \left([\nabla_{\mathbf{u}}, \nabla_{\mathbf{s}}] - \nabla_{[\mathbf{u},\mathbf{s}]}\right)\mathbf{u} \\ &= [\nabla_{\mathbf{u}}, \nabla_{\mathbf{s}}]\,\mathbf{u}.\end{aligned} \tag{7.102}$$

Thus

$$\nabla_{\mathbf{u}}\nabla_{\mathbf{u}}\mathbf{s} = \nabla_{\mathbf{s}}\nabla_{\mathbf{u}}\mathbf{u} + \mathbf{R}(\mathbf{u},\mathbf{s})\mathbf{u}. \tag{7.103}$$

Since the curves are geodesics $\nabla_{\mathbf{u}}\mathbf{u} = 0$, and the equation reduces to

$$\boxed{\nabla_{\mathbf{u}}\nabla_{\mathbf{u}}\mathbf{s} + \mathbf{R}(\mathbf{s},\mathbf{u})\mathbf{u} = 0} \tag{7.104}$$

where we have used the antisymmetry of the Riemann tensor. Equation (7.104) is called the *equation of geodesic deviation*. The component form of the equation is

$$\left(\frac{d^2\mathbf{s}}{d\lambda^2}\right)^{\mu} + R^{\mu}{}_{\alpha\nu\beta}u^{\alpha}s^{\nu}u^{\beta} = 0. \tag{7.105}$$

This equation shows that the Riemann tensor can be determined entirely from measurements of geodesic deviation.

In comoving geodesic normal coordinates with $\mathbf{u} = (1, 0, 0, 0)$ the equation reduces to

$$\left(\frac{d^2\mathbf{s}}{d\lambda^2}\right)^{i} + R^{i}{}_{0j0}s^{j} = 0. \tag{7.106}$$

7.6 Spaces of constant curvature

We have in section 6.11 seen how important Killing vectors may be for the solvability of the equations that govern particle motion. Highly symmetric spaces are therefore important both in mathematics and in physics. We will study maximally symmetric spaces with a Riemannian metric, S^n, $\mathbb{P}^n$, $\mathbb{E}^n$ and $\mathbb{H}^n$. The first 2 of these differ only at a global scale, that is they are locally the same but their topology is different. Maybe the mathematically most interesting one is the hyperbolic space $\mathbb{H}^n$. We will start out with the most familiar one, the Euclidean space $\mathbb{E}^n$.

The Euclidean space, $\mathbb{E}^n$

We are all familiar with this space. The metric can be written

$$ds^2 = g_{ab}\mathbf{dx}^a \otimes \mathbf{dx}^b \tag{7.107}$$

where $g_{ab} = \delta_{ab}$. We can easily generalize this to the Minkowskian case by letting the components of the metric tensor be of either sign, $g_{ab} = \pm\delta_{ab}$. As claimed, this is a maximally symmetric space, thus having $\frac{1}{2}n(n+1)$ linearly independent Killing vectors. We should stress that when we say linearly independent in this context, we mean linearly independent *solutions* of Killing's equations. The Killing vectors are not linearly independent in the space itself. Killing's equations do in this case reduce to

$$\xi_{i,j} + \xi_{j,i} = 0 \tag{7.108}$$

because the connection coefficients all vanish identically. We can easily find n linearly independent solutions to this equation,

$$\boldsymbol{\xi}_{(a)} = \frac{\partial}{\partial x^b}. \tag{7.109}$$

Another set of solutions are[1]

$$\boldsymbol{\xi}_{(ab)} = x^b \frac{\partial}{\partial x^a} - x^a \frac{\partial}{\partial x^b} \tag{7.110}$$

The solutions $\boldsymbol{\xi}_{(ab)}$ are antisymmetric in the indices so they represent $\frac{1}{2}n(n-1)$ linearly independent solutions. Thus all in all we have found $n + \frac{1}{2}n(n-1) = \frac{1}{2}n(n+1)$ linearly independent solutions of Killing's equation. Hence, as claimed, the Euclidean spaces admit $\frac{1}{2}n(n+1)$ linearly independent Killing vectors and is therefore maximally symmetric.

The one-parameter group of diffeomorphisms associated to these Killing vectors can be found by solving the equations

$$\frac{d}{dt}\phi_t = \boldsymbol{\xi}. \tag{7.111}$$

Representing ϕ_t by a vector $\mathbf{V}$, the equations for $\boldsymbol{\xi}_{(a)}$ can be written

$$\frac{d}{dt}\mathbf{V}_{(a)} = \mathbf{e}_a. \tag{7.112}$$

It has solutions

$$\mathbf{V}_{(a)} = \mathbf{V}_0 + t\mathbf{e}_a \tag{7.113}$$

where $\mathbf{V}_0$ is a constant vector corresponding to the initial condition. These mappings are mere translations a distance t in the a-direction. The Euclidean spaces have translation invariance.

Defining $\mathsf{J}_{(ab)}$ as the antisymmetric matrix with indices

$$\left(\mathsf{J}_{(ab)}\right)_{ij} = \delta_{ai}\delta_{bj} - \delta_{bi}\delta_{aj} \tag{7.114}$$

---

[1] Since we use Cartesian coordinates we have $x_i \equiv g_{ij}x^j = x^i$. Hence, the position of the index does not matter.

we can write for the Killing vectors $\boldsymbol{\xi}_{(ab)}$

$$\frac{d}{dt}\mathbf{V}_{(ab)} = \mathsf{J}_{(ab)}\mathbf{V}_{(ab)}. \tag{7.115}$$

This equation have solutions

$$\mathbf{V}_{(ab)} = e^{t\mathsf{J}_{(ab)}} \cdot \mathbf{V}_0 \tag{7.116}$$

where

$$e^{t\mathsf{J}_{(ab)}} = 1 + t\mathsf{J}_{(ab)} + \frac{1}{2}t^2\mathsf{J}^2_{(ab)} + ... = \mathsf{R}_{(ab)}(t) \tag{7.117}$$

is the rotation matrix through an angle t with respect to the (ab)-plane. Showing this is left as an exercise, see the problems in the end of this chapter. Thus, the Euclidean spaces are also rotationally symmetric. The three-dimensional Euclidean space has 6 linear independent Killing vectors, representing translation and rotational invariance. There is one significant difference between these operations. While the translations move "the whole space", the rotations leave an axis fixed. For a point p, the subgroup of the isometry group that leaves p fixed, is called *the isotropy subgroup*. In the case of $\mathbb{E}^3$, the isotropy subgroup of any point is the group of rotations with respect to this point. We will come back to these concepts in a later chapter, where we will define these groups more rigorously.

The elliptic spaces, S^n and $\mathbb{P}^n$

Let us first start out by defining the spheres S^n. Consider the $(n+1)$-dimensional Euclidean space and look at the hypersurface

$$(x^1)^2 + (x^2)^2 + ... + (x^{n+1})^2 = 1. \tag{7.118}$$

This hypersurface with the induced metric is the sphere S^n. We claim now that the Killing vectors of the sphere is the Killing vectors from the Euclidean space that generate maps that map the sphere onto itself. These are the rotations with respect to the origin, with corresponding Killing vectors

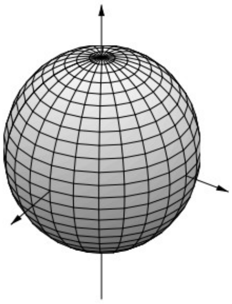

Figure 7.6: The two-dimensional sphere embedded in a Euclidean space

$$\boldsymbol{\xi}_{(\alpha\beta)} = x^\beta\frac{\partial}{\partial x^\alpha} - x^\alpha\frac{\partial}{\partial x^\beta} \tag{7.119}$$

where Latin indices run from 1 to $(n+1)$. Here we have $\frac{1}{2}n(n+1)$ of them, and when constrained to the sphere, they form the Killing vectors of the sphere. Thus this space is maximally symmetric. Let us use Gauss' Theorema Egregium to calculate its curvature properties. Given a point on the sphere, then for one of the coordinates $x^a \neq 0$. Assume that $x^{n+1} \neq 0$. Then we can define the following basis vectors

$$\mathbf{e}_a = \boldsymbol{\xi}_{(a(n+1))} = x^{n+1}\frac{\partial}{\partial x^a} - x^a \frac{\partial}{\partial x^{n+1}} \tag{7.120}$$

where Greek indices run from 1 to n. The metric in this basis is

$$\begin{aligned} g_{ab} &= \mathbf{e}_a \cdot \mathbf{e}_b = \left(x^{n+1}\frac{\partial}{\partial x^a} - x^a \frac{\partial}{\partial x^{n+1}}\right) \cdot \left(x^{n+1}\frac{\partial}{\partial x^b} - x^b \frac{\partial}{\partial x^{n+1}}\right) \\ &= x^a x^b + \left(x^{n+1}\right)^2 \delta_{ab}. \end{aligned} \tag{7.121}$$

The radial vector

$$\mathbf{e}_r = x^\alpha \frac{\partial}{\partial x^\alpha} \tag{7.122}$$

has unit length on the sphere. Using this we can calculate the components of the extrinsic curvature

$$\begin{aligned} K_{ab} &= \mathbf{e}_r \cdot (\mathbf{d}\mathbf{e}_a(\mathbf{e}_b)) = \mathbf{e}_r \cdot \left[\frac{\partial}{\partial x^a}\left(\mathbf{d}\mathbf{x}^{n+1}(\mathbf{e}_b)\right) - \frac{\partial}{\partial x^{n+1}}\left(\mathbf{d}\mathbf{x}^a(\mathbf{e}_b)\right)\right] \\ &= \mathbf{e}_r \cdot \left[x^b \frac{\partial}{\partial x^a} + \delta_{ab}(x^{n+1})\frac{\partial}{\partial x^{n+1}}\right] = x^a x^b + \left(x^{n+1}\right)^2 \delta_{ab}. \end{aligned} \tag{7.123}$$

Thus we have

$$K_{ab} = g_{ab}. \tag{7.124}$$

The Gauss' Theorema Egregium now gives us the Riemann tensor

$$R_{abcd} = g_{ac}g_{bd} - g_{ad}g_{bc}. \tag{7.125}$$

Contracting once,

$$R_{bd} = (n-1)g_{bd} \tag{7.126}$$

we see that the Ricci tensor is proportional to the metric[2]. Thus in an orthonormal frame, the Ricci tensor will be everywhere positive and constant. Contracting once more to obtain the Ricci scalar

$$R = n(n-1). \tag{7.127}$$

The projective space $\mathbb{P}^n$ can now be obtained by identifying opposite points on the sphere S^n. The projective space is therefore basically half of the sphere. There is a pathology however, for n even, the projective space is *non-orientable*. That means there is no globally defined unit normal vector field on the space. However, for n odd (including therefore dimension 3), the space is orientable, and no problem of such kind exists.

---

[2] More generally, spaces for which the Ricci tensor can be written $R_{ab} = \lambda g_{ab}$ where λ is a constant, are called *Einstein spaces*. All the constant curvature spaces are Einstein spaces.

Let us derive a useful form of the metric of the sphere. We introduce a radial coordinate r by

$$r^2 = \sum_a (x^a)^2 \tag{7.128}$$

so that

$$x^{n+1} = \pm\sqrt{1-r^2}. \tag{7.129}$$

Hence,

$$\left(dx^{n+1}\right)^2 = \frac{r^2 dr^2}{1-r^2}. \tag{7.130}$$

Assuming now that $d\Omega_{n-1}$ is the metric on the $(n-1)$-dimensional sphere, S^{n-1}, then

$$\sum_a (dx^a)^2 = dr^2 + r^2 d\Omega_{n-1}^2 \tag{7.131}$$

which is just the expression for the Euclidean metric in spherical coordinates. The metric on the sphere, S^n, is now

$$ds^2 = \left(dx^{n+1}\right)^2 + \sum_a (dx^a)^2 = \frac{dr^2}{1-r^2} + r^2 d\Omega_{n-1}^2. \tag{7.132}$$

Note that this metric only covers half of the sphere. For the case $\mathbb{P}^n$ it covers the whole space, except for the points on the equator which forms a set of measure zero.

The Hyperbolic spaces, $\mathbb{H}^n$

As for the sphere, the hyperbolic space can be viewed upon as a hypersurface in a flat $(n+1)$-dimensional space. But now we have to use the flat $(n+1)$-dimensional Minkowski space with metric

$$ds^2 = \eta_{\alpha\beta}\mathbf{dx}^\alpha \otimes \mathbf{dx}^\beta = -\mathbf{dx}^{n+1} \otimes \mathbf{dx}^{n+1} + \sum_a \mathbf{dx}^a \otimes \mathbf{dx}^a. \tag{7.133}$$

The hyperbolic space is defined as the hyperboloid

$$-(x^{n+1})^2 + (x^1)^2 + ... + (x^n)^2 = -1, \quad x^{n+1} > 0. \tag{7.134}$$

This surface is space-like and has a Riemannian metric. Its symmetries can be found by using the same argument as for the sphere. The symmetries for the Minkowski space that leave the hyperboloid invariant, are the Lorentz transformations in $(n+1)$ dimensions. The Killing vectors for the Lorentz transformations come in two classes, boosts

$$\boldsymbol{\xi}_{(a)} = x^{n+1}\frac{\partial}{\partial x^a} + x^a \frac{\partial}{\partial x^{n+1}} \tag{7.135}$$

and rotations

$$\boldsymbol{\xi}_{(ab)} = x^b\frac{\partial}{\partial x^a} - x^a \frac{\partial}{\partial x^b}. \tag{7.136}$$

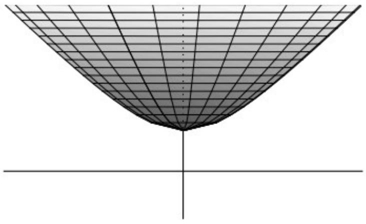

Figure 7.7: The Hyperbolic plane embedded in three-dimensional Minkowski space

As for the sphere we can now choose a set of basis vectors by

$$\mathbf{e}_a = \boldsymbol{\xi}_{(a)} \tag{7.137}$$

but these will now be globally defined since $x^{n+1} \geq 1$. The metric in this basis is

$$\begin{aligned} g_{ab} &= \mathbf{e}_a \cdot \mathbf{e}_b = \left(x^{n+1} \frac{\partial}{\partial x^a} + x^a \frac{\partial}{\partial x^{n+1}} \right) \cdot \left(x^{n+1} \frac{\partial}{\partial x^b} + x^b \frac{\partial}{\partial x^{n+1}} \right) \\ &= -x^a x^b + \left(x^{n+1} \right)^2 \delta_{ab} \end{aligned} \tag{7.138}$$

since $\frac{\partial}{\partial x^{n+1}} \cdot \frac{\partial}{\partial x^{n+1}} = -1$. The radial vector

$$\mathbf{e}_r = x^\alpha \frac{\partial}{\partial x^\alpha} \tag{7.139}$$

has on the hyperboloid a length

$$\mathbf{e}_r \cdot \mathbf{e}_r = -(x^{n+1})^2 + \sum_a (x^a)^2 = -1. \tag{7.140}$$

Following an almost identical procedure to the case of the sphere, we can calculate the extrinsic curvature

$$\begin{aligned} K_{ab} &= \mathbf{e}_r \cdot (\mathbf{d}\mathbf{e}_a(\mathbf{e}_b)) \\ &= g_{ab}. \end{aligned} \tag{7.141}$$

The Gauss's Theorema Egregium now turns into (we have to choose the negative sign due to the negative length of the normal unit vector)

$$R_{abcd} = -(g_{ac}g_{bd} - g_{ad}g_{bc}). \tag{7.142}$$

Contracting once,

$$R_{bd} = -(n-1)g_{bd}. \tag{7.143}$$

This space has negative curvature, and basically just the same curvature properties as for the sphere, just with an opposite sign of the curvature. A metric on the hyperbolic space can written by the following. Introduce spherical coordinates,

$$r^2 = \sum_a (x^a)^2 \tag{7.144}$$

and following the procedure as for the sphere, the metric can be written

$$ds^2 = \frac{dr^2}{1+r^2} + r^2 d\Omega_{n-1}^2 \tag{7.145}$$

where $d\Omega_{n-1}^2$ is the metric on the $(n-1)$-dimensional sphere. In this case the metric covers the whole of $\mathbb{H}^n$.

As we see, this space has infinite volume in contrast to the sphere. Note that there exist (and a lot of them) compact hyperbolic spaces as well, but these breaks the isometries for the $\mathbb{H}^n$ at a global scale. Locally, however, they have a hyperbolic metric and are locally isometric to $\mathbb{H}^n$.

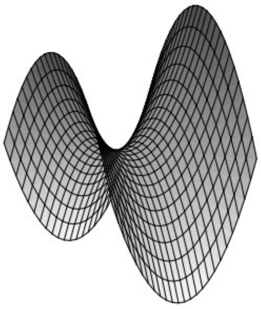

Figure 7.8: The hyperbolic plane can be seen upon as a saddle-surface

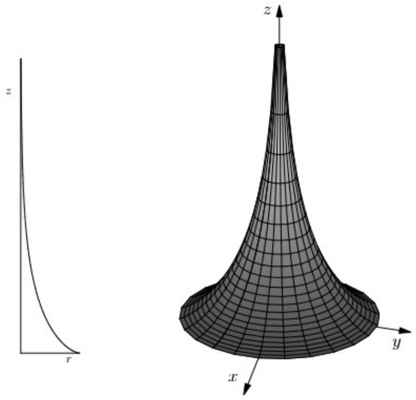
A more intuitive view of the hyperbolic plane is by considering it as the surface of a saddle, Fig. 7.8. A saddle surface in Euclidean three-space has a negative curvature and has therefore much of the same properties of the constantly curved hyperbolic plane. We should emphasize that the whole hyperbolic plane given by eq. (7.134) for $n = 2$ cannot be embedded in the three-dimensional Euclidean space. So the surface in Fig. 7.8 has not a constant curvature.

We can find a constant negatively curved space in Euclidean space. Consider the surface generated by the rotation around the z-axis of the *tractrix*

$$z = \ln\left|\frac{1 \pm \sqrt{1-r^2}}{r}\right| \mp \sqrt{1-r^2} \tag{7.146}$$

where $r^2 = x^2 + y^2$. This space will have constant negative curvature and are sometimes called a *pseudo-sphere*. The tractrix and the pseudo-sphere are depicted in Fig.7.9.

The name tractrix is due to the fact that this is the curve which is traced out by an object on the end of a rope of unit length held by a running child along the z-axis. If the object and the child start in the xz-plane at $(1,0)$ and $(0,0)$, respectively, then the curve is precisely the curve eq. (7.146) with $y = 0$. The points along the circle $r = 1$ correspond to a singular line, and hence, this cannot be the whole hyperbolic space.



(a) The tractrix (b) The pseudo-sphere

Figure 7.9: The tractrix and the pseudo-sphere. The pseudo-sphere is obtained by rotating the tractrix around the z-axis.

Problems

7.1. *Rotation matrices*
Show that

$$e^{t\mathsf{J}_{(ab)}} = 1 + t\mathsf{J}_{(ab)} + \frac{1}{2}t^2\mathsf{J}^2_{(ab)} + ... = \mathsf{R}_{(ab)}(t), \tag{7.147}$$

i.e. verify eq. (7.117).

7.2. *Inverse metric on* S^n
In this problem we will use the basis vectors $\mathbf{e}_a$ defined in eq. (7.120):

$$\mathbf{e}_a = \boldsymbol{\xi}_{(a(n+1))} = x^{n+1}\frac{\partial}{\partial x^a} - x^a\frac{\partial}{\partial x^{n+1}}. \tag{7.148}$$

(a) Assume that the basis forms on the sphere S^n has the form

$$\boldsymbol{\omega}^a = C^a_{\ \mu}\mathbf{dx}^\mu \tag{7.149}$$

Find the coefficients $C^a_{\ \mu}$.

(b) Find g^{ab}, and verify that $g^{ab}g_{bc} = \delta^a_{\ c}$.

7.3. *The curvature of a curve*
Consider a curve $y = y(x)$ in a two-dimensional plane. Utilize that the differential of the arc length is $ds = \left(1 + y'^2\right)^{1/2} dx$ and show that the tangent vector, the curvature vector and the curvature of the curve are given by

$$\begin{aligned} \mathbf{t} &= \left(1 + y'^2\right)^{-1/2}(\mathbf{e}_x + y'\mathbf{e}_y), \\ \mathbf{k} &= \left(1 + y'^2\right)^{-2} y''(y'\mathbf{e}_x + \mathbf{e}_y), \\ \kappa &= \left(1 + y'^2\right)^{-3/2} y'', \end{aligned} \tag{7.150}$$

respectively.

7.4. *The Gauss-Codazzi equations*
The Gauss-Codazzi equations are of great importance and tells us much about the geometry of hypersurfaces. We will need these equations for a later chapter, and in this problem we will show an important relation between the Ricci curvatures in the ambient space and on the hypersurface.

(a) We will first show that the projection operator $h^{\alpha}_{\ \beta}$, defined by eq. (7.81) is what it is claimed to be. We define $h_{\alpha\beta}$ with eq. (7.81):

$$g_{\alpha\beta} = h_{\alpha\beta} + \epsilon n_{\alpha} n_{\beta} \tag{7.151}$$

where $g_{\alpha\beta}$ is the metric in the ambient space, and n_{α} is the components of the unit normal vector. The operator $h^{\alpha}_{\ \beta}$ is now defined by $h^{\alpha}_{\ \beta} = g^{\alpha\lambda} h_{\lambda\beta}$. Show the following:

$$\begin{aligned} h_{\alpha\beta} &= h_{\beta\alpha} \\ h^{\alpha}_{\ \lambda} h^{\lambda}_{\ \beta} &= h^{\alpha}_{\ \beta}. \end{aligned}$$

These properties defines a projection map. We now have to show that it projects onto the space that is orthogonal to n^{α}. Hence, if v^{β} is a vector, we have to show that

$$\begin{aligned} h^{\alpha}_{\ \beta} v^{\beta} &= 0, && \text{iff } v^{\beta} \text{ is parallel to } n^{\beta}. \\ h^{\alpha}_{\ \beta} v^{\beta} &= v^{\alpha}, && \text{iff } v^{\beta} \text{ is orthogonal to } n^{\beta}. \end{aligned}$$

Prove this. Explain now we can define the projection of an arbitrary tensor by projection the tensor, index by index.

(b) Verify the Codazzi equation, eq. (7.84). (Hint: Calculate $\left(\mathbf{d}^2 \mathbf{e}_{\hat{b}}\right) \cdot \mathbf{n}$.)

(c) Show that

$${}^{(n+1)}R = {}^{(n)}R - \epsilon\left(K^2 - K^{\alpha\beta}K_{\alpha\beta}\right) + 2\epsilon^{(n+1)}R_{\alpha\beta}n^{\alpha}n^{\beta}, \tag{7.152}$$

which can be written

$$-2\epsilon^{(n+1)}E_{\alpha\beta}n^{\alpha}n^{\beta} = {}^{(n)}R - \epsilon\left(K^2 - K^{\alpha\beta}K_{\alpha\beta}\right). \tag{7.153}$$

7.5. *The Poincaré half-space*
Consider half of $\mathbb{R}^3$, $z > 0$ with metric

$$ds^2 = \frac{1}{z^2}\left(dx^2 + dy^2 + dz^2\right) \tag{7.154}$$

(a) Calculate the connection forms and the curvature forms using the structural equations of Cartan.

(b) Calculate the Riemann tensor, the Ricci tensor and the Ricci scalar.

(c) Show that

$$R_{abcd} = -(g_{ac}g_{bd} - g_{ad}g_{bc}) \tag{7.155}$$

Compare this with the three-dimensional hyperbolic space. Are there any way we can differentiate between these two cases? Are they different manifestations of the same space?

7.6. *The pseudo-sphere*
Show that the tractrix, eq. (7.146), obeys the differential equation

$$\left(\frac{dr}{dz}\right)^2 = \frac{r^2}{1-r^2}. \tag{7.156}$$

Substitute this into the line-element for flat space, do the substitution $r = \sin\theta$, and show that the metric on the pseudo-sphere can be written

$$ds^2 = d\theta^2 + \sinh^2\theta d\phi^2. \tag{7.157}$$

Show that this metric has constant negative curvature.

7.7. *A non-Cartesian coordinate system in two dimensions*
Consider the following metric on a two-dimensional surface:

$$ds^2 = v^2du^2 + u^2dv^2. \tag{7.158}$$

We will show, in two different ways, that this is only the flat Euclidean plane in disguise.

(a) Use the orthonormal frame approach and find the connection one-forms $\mathbf{\Omega}^{\hat{a}}{}_{\hat{b}}$. Find also the curvature two-forms $\mathbf{R}^{\hat{a}}{}_{\hat{b}}$ and show that they are identically zero.

(b) Show that the metric can be put onto the form

$$ds^2 = dx^2 + dy^2$$

by finding a transformation matrix $\mathsf{M} = \left(M^i{}_a\right)$ connecting the basis vectors $\mathbf{e}_u$ and $\mathbf{e}_v$, and $\mathbf{e}_x$ and $\mathbf{e}_y$. This can be done using the following relations

$$\begin{aligned} g_{ab} &= g_{ij}M^i{}_aM^j{}_b \\ \frac{\partial M^i{}_a}{\partial x^b} &= \frac{\partial M^i{}_b}{\partial x^a}. \end{aligned} \tag{7.159}$$

Where do these relations come from?

7.8. *The curvature tensor of a sphere*
Introduce an orthonormal basis on the sphere, S^2, and use Cartan's structural equations to find the physical components of the Riemann curvature tensor.

7.9. *The curvature scalar of a surface of simultaneity*
The spatial line-element of a rotating disc is

$$d\ell^2 = dr^2 + \frac{r^2}{1-\frac{\omega^2r^2}{c^2}}d\phi^2. \tag{7.160}$$

Introduce an orthonormal basis on this surface and use Cartan's structural equations to find the Ricci scalar.

7.10. *The tidal force pendulum and the curvature of space*
We will again consider the tidal force pendulum from Example 1.3. Here we shall use the equation for geodesic deviation, eq. (7.104), to find the period of the pendulum.

(a) Why can the equation for geodesic equation be used to find the period of the pendulum in spite of the fact that the particles do not move along geodesics? Explain also why the equation can be used even though the centre of the pendulum does not follow a geodesic.

(b) Assume that the centre of the pendulum is fixed at a distance R from the centre of mass of the Earth. Introduce an orthonormal basis $\{\mathbf{e}_{\hat{a}}\}$ with the origin at the centre of the pendulum (see Fig.7.10).

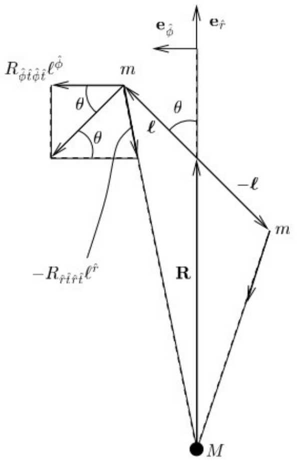


Figure 7.10: The tidal force pendulum

Show that, to first order in v/c and ϕ/c^2, where v is the three-velocity of the masses and ϕ the gravitational potential at the position of the pendulum, that the equation of geodesic equation takes the form

$$\frac{d^2\ell_{\hat i}}{dt^2} + R_{\hat i\hat 0\hat j\hat 0}\ell^{\hat j} = 0. \tag{7.161}$$

(c) Find the period of the pendulum expressed in terms of the components of Riemann's curvature tensor.

7.11. *The Weyl tensor vanishes for spaces of constant curvature*
Use the definition eq. (7.72) to show that the constant curvature spaces S^4, $\mathbb{E}^4$, and $\mathbb{H}^4$ all have zero Weyl tensor.

7.12. *Frobenius' Theorem*
In this problem we will consider integrability conditions for vector fields. In particular, we shall obtain a necessary and sufficent criterion for when a vectorfield is hypersurface orthogonal. Assume that we have a m-dimensional manifold M and a smooth collection of r-dimensional subspaces $\mathcal{D}_p \in T_pM$, one for each $p \in M$. A submanifold N of M is called an *integral submanifold* if $\mathcal{D}_p = T_pN$ for each $p \in N$. Frobenius' theorem can now be stated:

Frobenius' Theorem: Given a smooth collection of spaces $\mathcal{D}_p$ as above. Then there exists an integral submanifold N at every p if and only if $\{\mathcal{D}_p\}$ is involute; i.e., for all $p \in M$,

$$[\mathbf{X}_i, \mathbf{X}_j] \in \mathcal{D}_p, \quad \forall X_k \in \mathcal{D}_p.$$

(a) Assume that $\boldsymbol{\omega}^a$ is a set of one-forms that span the orthogonal complement of $\mathcal{D}_p$; i.e. $\boldsymbol{\omega}^a(\mathbf{X}_i) = 0$ for all $\mathbf{X}_i \in \mathcal{D}_p$. Show that $\mathbf{d}\boldsymbol{\omega}^a$ must be on the form

$$\mathbf{d}\boldsymbol{\omega}^a = \sum_b \boldsymbol{\omega}^b \wedge \boldsymbol{\rho}^b,$$

where each $\boldsymbol{\rho}^b$ is in T_pM. (Hint: Show first that $X^\mu Y^\nu \nabla_{[\mu}\omega^a_{\nu]} = 0$ for all $X^\mu, Y^\nu \in T_pN$.)

(b) In particular, this means if M is a m-dimensional manifold and ξ_μ is a covariant vector field, then ξ_μ is hypersurface orthogonal to some $(m-1)$-dimensional submanifold if and only if $\nabla_{[\mu}\xi_{\nu]} = \xi_{[\mu}\rho_{\nu]}$. Show that a sufficent condition for ξ_μ to be hypersurface orthogonal is

$$\xi_{[\mu}\nabla_\nu\xi_{\sigma]} = 0. \tag{7.162}$$

(a) Show that in this case the radial geodesic equation reduces to

$$\Gamma^r{}_{tt}dt^2 + 2\Gamma^r{}_{\phi t}d\phi dt + \Gamma^r_{\phi\phi}d\phi^2 = 0.$$

(b) Calculate the Christoffel symbols and show that the equation takes the form

$$\left(\frac{dt}{d\phi}\right)^2 - 2a\frac{dt}{d\phi} + a^2 - \frac{r^3}{M} = 0,$$

where M is the mass of the rotating body and a its angular momentum per unit mass, $a = J/M$.

(c) Use the solution of the geodesic equation and the four-velocity identity to show that the proper time interval $d\tau$ shown on a clock moving an angle $d\phi$ is

$$d\tau = \pm\sqrt{1 - \frac{3M}{r} \pm 2a\omega_0}d\phi,$$

where $\omega_0 = \left(M/r^3\right)^{1/2}$ is the angular velocity of a clock moving in the Schwarzschild spacetime in accordance with Kepler's 3rd law. The plus and minus sign apply to direct and retrograde motion, respectively.

(d) Show that to first order in a the proper time difference for one closed orbit ($\phi \to \phi + 2\pi$) in the direct and the retrograde direction is $\tau_+ - \tau_- \approx 4\pi a = 4\pi J/M$, or in S.I. units, $\tau_+ - \tau_- \approx 4\pi a = 4\pi J/mc^2$.

Estimate this time difference for clocks in satellites moving in the equatorial plane of the Earth. (The mass of the Earth is $m = 6 \cdot 10^{26}$kg and its angular momentum $J = 10^{34}$kg m^{2}s^{-1}.)

10.9. *The photon sphere radius of a Reissner-Nordström black hole*
Show that there exists a sphere of radius

$$r_{PS} = \frac{3M}{2}\left(1 + \sqrt{1 - \frac{8Q^2}{9M^2}}\right) \tag{10.276}$$

in the Reissner-Nordström black hole spacetime where photons will have circular orbits around the black hole.

10.10. *Curvature of 3-space and 2-surfaces of the internal and the external Schwarzschild spacetimes*

(a) The 3-space of the internal Schwarzschild solution has a geometry given by the line-element

$$d\ell_I^2 = \frac{dr^2}{1 - \frac{R_S}{R^2}r^2} + r^2(d\theta^2 + \sin^2\theta d\phi^2)$$

where $R_S = 2M$ is the Schwarzschild radius of the mass distribution and R its radius. The corresponding line-element for the external Schwarzschild solution is

$$d\ell_E^2 = \frac{dr^2}{1 - \frac{R_S}{r}} + r^2(d\theta^2 + \sin^2\theta d\phi^2)$$

Find the spatial curvature $k = k(r) = \frac{1}{6}R$ of the 3-spaces, where R is the Ricci scalar.

(b) We shall now consider the equatorial surfaces $\theta = \pi/2$. The line-elements of these surfaces are, for the internal solution

$$d\sigma_I^2 = \frac{dr^2}{1 - \frac{R_S}{R^2} r^2} + r^2 d\phi^2,$$

and for the external solution

$$d\sigma_E^2 = \frac{dr^2}{1 - \frac{R_S}{r}} + r^2 d\phi^2.$$

For these line-elements the Gaussian curvatures of the surfaces they describe are given by

$$K = -\frac{1}{2g} g_{\phi\phi}'' + \frac{g_{\phi\phi}}{4g^2} g_{rr}' g_{\phi\phi}' + \frac{g_{rr}}{4g^2} \left(g_{\phi\phi}' \right)^2,$$

where $g = g_{rr} g_{\phi\phi}$ and differentiation is with respect to r. Show that the Gaussian curvature of the equatorial surfaces are for
The internal solution: $K = R_S/R^3$. What sort of surface is this?
The external solution: $K = -(1/2)(R_S/r^3)$.

(c) The equatorial surfaces shall now be compared to the embedding surfaces. The Gaussian curvature of a surface of revolution given by $z = z(r)$, is

$$K = \frac{z' z''}{r(1 + z'^2)^2}.$$

Calculate the Gaussian curvatures of the embedding surfaces of the internal Schwarzschild solution, as given in problem 10.2, and of the external solution, as given in eq.(10.98). Compare the results with those of the previous point.

10.11. *Proper radial distance in the external Schwarzschild space*
Show that the proper radial distance from a coordinate position r to the horizon R_S in the external Schwarzschild space is

$$\ell_r = \sqrt{r}\sqrt{r - R_S} + R_S \ln \left(\sqrt{\frac{r}{R_S}} - \sqrt{\frac{r}{R_S} - 1} \right).$$

Find the limit of this expression for $R_S \ll r$.

10.12. *Gravitational redshift in the Schwarzschild spacetime*
Define z, describing the redshift of light, by

$$z = \frac{\Delta\lambda}{\lambda_e}, \tag{10.277}$$

where $\Delta\lambda$ is the change in the photons wavelength and λ_e the wavelength of the photon when emitted.

Show that the gravitational redshift of light emitted at r_E and received at r_R in the Schwarzschild spacetime outside a star of mass M is

$$z = \left(\frac{r_R - R_S}{r_E - R_S} \right)^{\frac{1}{2}} - 1$$

where $R_S = 2M$ is the Schwarzschild radius of the star. What is the gravitational redshift of light emitted from the surface of a neutron star as observed by a faraway observer? A neutron star has typically a mass of 1.2 solar masses and a radius of about 20km.

10.13. *The Reissner-Nordström repulsion*
Consider a radially infalling neutral particle in the Reissner-Nordström spacetime with $M > |Q|$. Show that when the particle comes inside the radius $r = Q^2/M$ it will feel a repulsion away from $r = 0$ (i.e. that $d^2r/d\tau^2 < 0$ for τ the proper time of the particle). Is this inside or outside the outer horizon r_+? Show further that the particle can never reach the singularity at $r = 0$.

10.14. *Light-like geodesics in the Reissner-Nordström spacetime*
We will in this problem consider radial photon paths in the Reissner-Nordström spacetime. The horizons of this spacetime are at $r_\pm = M \pm \sqrt{M^2 - Q^2}$, and we will assume that $M > |Q|$.

(a) Show that the radial light rays obey the differential equation

$$\frac{dr}{dt} = \pm\left(1 - \frac{2M}{r} + \frac{Q^2}{r^2}\right).$$

(b) It is convenient to introduce two *null coordinates* u and v by

$$\begin{aligned} u &= t - r^* \\ v &= t + r^*, \end{aligned} \qquad (10.278)$$

where

$$r^* = \int \frac{dr}{1 - \frac{2M}{r} + \frac{Q^2}{r^2}}.$$

Show that u is a constant of motion for outgoing photons, while v is a constant of motion for ingoing photons. Show further that

$$r^* = r + \frac{r_+^2}{r_+ - r_-}\ln\left[\frac{1}{2M}|r - r_+|\right] + \frac{r_-^2}{r_+ - r_-}\ln\left[\frac{1}{2M}|r - r_-|\right] \qquad (10.279)$$

(c) Draw the light-cones in the tr-plane for the three regions $r < r_-$, $r_- < r < r_+$ and $r_+ < r$.

10.15. *Birkhoff's theorem*
We will in this problem consider a spherically symmetric metric describing the spacetime external to some region. We will first assume that the metric is time dependent, but will show that, under some assumptions, that this cannot be possible.

A spherically symmetric metric outside a source can always be put onto the canonical form

$$ds^2 = -e^{2\alpha(r,t)}dt^2 + e^{2\beta(r,t)}dr^2 + r^2(d\theta^2 + \sin^2\theta d\phi^2). \qquad (10.280)$$

Assume also that the spacetime is asymptotically flat; i.e.

$$\lim_{r\to\infty}\alpha(r,t) = \lim_{r\to\infty}\beta(r,t) = 0.$$

(a) Outside some r_0 we have $T_{\mu\nu} = 0$. Denote the derivative $\frac{\partial}{\partial r}$ with a prime and $\frac{\partial}{\partial t}$ with a dot. Show that Einstein's field equations in vacuum (for

$r > r_0$) can be written as

$$
\begin{aligned}
e^{-2\beta}\left(\frac{2\alpha'}{r}+\frac{1}{r^2}\right)-\frac{1}{r^2} &= 0 && (10.281)\\
e^{-2\beta}\left(\frac{1}{r^2}-\frac{2\beta'}{r}\right)-\frac{1}{r^2} &= 0 && (10.282)\\
2e^{-2\beta}\frac{\dot{\beta}}{r} &= 0 && (10.283)\\
e^{-2\beta}\left(\alpha''+\alpha'^2+\frac{\alpha'-\beta'}{r}-\alpha'\beta'\right) & && \\
-e^{-2\alpha}\left(\ddot{\beta}+\dot{\alpha}^2-\dot{\alpha}\dot{\beta}\right) &= 0. && (10.284)
\end{aligned}
$$

(b) Show that for $r > r_0$ we have $\beta(r,t) = \beta(r)$. Show also that $\alpha' = -\beta'$, and by integrating, $\alpha(r,t) = -\beta(r)$ for $r > r_0$. Explain that the metric has to have the form of metric (10.4).

This is what is called Birkhoff's theorem: *If a spacetime contains a region which is spherically symmetric, asymptotically flat, and empty ($T_{\mu\nu} = 0$) for $r > r_0$, then the metric in this region is time independent and hence independent of the dynamical properties of its source.*

10.16. *Gravitational mass*

(a) Use the line-element (10.4) and show that the surface gravity of a Schwarzschild black hole can be written

$$\kappa = -e^{\alpha-\beta}\alpha'. \tag{10.285}$$

(b) Show, using Einstein's field equations, that

$$4\pi r^2 e^{\alpha+\beta}\left(T^0_{\ 0}-T^1_{\ 1}-T^2_{\ 2}-T^3_{\ 3}\right) = \left(r^2 e^{\alpha-\beta}\alpha'\right)'. \tag{10.286}$$

Hence, deduce that the surface gravity can be written

$$\kappa = -\frac{4\pi}{r^2}\int\limits_0^r \left(T^0_{\ 0}-T^1_{\ 1}-T^2_{\ 2}-T^3_{\ 3}\right)e^{\alpha+\beta}r^2 dr. \tag{10.287}$$

(c) Define the gravitational mass M_G inside a radius r of a spherical mass distribution by

$$\kappa = -\frac{M_G}{r^2}, \tag{10.288}$$

and deduce that

$$M_G = 4\pi\int\limits_0^r \left(T^0_{\ 0}-T^1_{\ 1}-T^2_{\ 2}-T^3_{\ 3}\right)e^{\alpha+\beta}r^2 dr. \tag{10.289}$$

This is the *Tolman-Whittaker* expression for the gravitational mass of a system.

What is the condition for repulsive gravitation?

('/" 7! 9 !=

and hence, there must be a coordinate transformation on Σ which relates $h^+_{\mu\nu}$ with $h^-_{\mu\nu}$. Thus we can set $h^\pm_{\mu\nu} = h_{\mu\nu}$.

From the Gauss' Theorema Egregium, eq. (7.83), and the Codazzi equation (7.84) we have

$$\begin{aligned} E_{\mu\nu}n^\mu n^\nu|^\pm &= -\frac{1}{2}\epsilon^{(3)}R + \frac{1}{2}\left(K^2 - K_{\alpha\beta}K^{\alpha\beta}\right)^\pm && (16.9) \\ E_{\mu\nu}h^\mu{}_\alpha n^\nu|^\pm &= -\left({}^{(3)}\nabla_\mu K^\mu_\alpha - {}^{(3)}\nabla{}_\alpha K\right)^\pm && (16.10) \\ E_{\mu\nu}h^\mu{}_\alpha h^\nu{}_\beta|^\pm &= {}^{(3)}E_{\alpha\beta} + \epsilon n^\mu \nabla_\mu \left(K_{\alpha\beta} - h_{\alpha\beta}K\right)^\pm - 3\epsilon K_{\alpha\beta}K|^\pm \\ &\quad + 2\epsilon K^\mu_\alpha K_{\mu\beta}|^\pm + \frac{1}{2}\epsilon h_{\alpha\beta}(K^2 + K^{\mu\nu}K_{\mu\nu})^\pm. && (16.11) \end{aligned}$$

16.2 Einstein's field equations

We will now relate the curvature tensors to the energy-momentum tensor according to Einstein's field equations. We will allow for the energy-momentum tensor to be discontinuous at Σ, but continuous elsewhere. The metric tensor is required to be continuous across the whole spacetime.

The Einstein tensor contains second derivatives of the metric tensor, but we will allow the derivative $g_{\mu\nu;\alpha}n^\alpha$ to be discontinuous. The second derivative can therefore be a delta-function since $\theta'(x) = \delta(x)$ where $\theta(x)$ is the step-function

$$\theta(x) = \begin{cases} 0, & x < 0 \\ 1, & x > 1. \end{cases} \tag{16.12}$$

Let y be an orthogonal coordinate so that $\frac{\partial}{\partial y} = \mathbf{n}$ and $y = 0$ at the surface Σ. The most general energy-momentum tensor we can have across the boundary is therefore

$$T_{\alpha\beta} = S_{\alpha\beta}\delta(y) + T^+_{\alpha\beta}\theta(y) + T^-_{\alpha\beta}\theta(-y). \tag{16.13}$$

The energy-momentum tensor of the surface $S_{\alpha\beta}$ can be defined as the integral over the thickness of the surface Σ as the thickness goes to zero

$$S_{\alpha\beta} = \lim_{\tau\to 0} \int_{-\tau/2}^{\tau/2} T_{\alpha\beta}dy. \tag{16.14}$$

For this to be well defined the tensor $S_{\alpha\beta}$ has to live on the hypersurface so that

$$h^\alpha{}_\mu h^\beta{}_\nu S_{\alpha\beta} = S_{\mu\nu}. \tag{16.15}$$

This way of defining the tensor $S_{\alpha\beta}$ is called the *thin shell approximation*.

Introduce a set of coordinates so that x^i are coordinates on the hypersurface and y is the coordinate in the orthogonal direction (as before). Using the thin shell approximation we can find an expression for S_{ij}.

From Gauss' equation (16.11), we have

$$\lim_{\tau\to 0} \int_{-\tau/2}^{\tau/2} E_{ij}dy = \lim_{\tau\to 0} \int_{-\tau/2}^{\tau/2} \left[\epsilon n^\mu \nabla_\mu \left(K_{ij} - h_{ij}K\right) + U_{ij}\right] dy \tag{16.16}$$

is $K = 2/(1+4x^2)^{3/2}$. This expression shows that the curvature of the parabola is largest, equal to 2, at $x = 0$, and decreases towards zero for large values of x. Far away from the y-axis the parabola approaches a straight line. Looking at Fig. 2.4 you see that this is in accordance with the shape of the curve. Note also that if we had tried to define the curvature as the rate of change of slope per unit distance along the x-axis, i.e. as y'', we would have found a constant curvature, equal to 2 for the parabola. A constant curvature corresponds to a circular arc, which clearly does not correspond to the shape of the parabola.

9.2 The curvature of surfaces

Let us inspect a simple surface; the *surface* of a cylinder. Suppose the cylinder you look at is of paper and that you roll it out like you would do with a rolled-up newspaper fetched by your dog. If there were drawings of triangles and other figures on the cylinder they would all retain their shapes and lengths. There would be no trace of distortions or deformations. The geometry of a cylindrical surface is the same as that of a flat paper. The right triangle drawn on a paper with lengths 3, 4, and 5 cm, retain these quantities when we roll the paper into a cylinder. The theorem of Pythagoras holds good also on the curved cylindrical surface. The sum of the angles remains 180 degrees. Two-dimensional creatures on a cylinder develop the plane Euclidean geometry. They have no concept of a cylinder as we see it. But of course a sufficiently long *straight* journey on the surface may lead back to where they started. This is an astonishing fact for the cylindrians, showing that the topology of their world is different from that of an Euclidean plane.

As three-dimensional creatures we may curl the paper cylinder more and more. The diameter of the cylinder gets smaller and smaller, the paper curves 'more and more' per cm. The 5 cm straight line of our drawn triangle is eventually changed into a spiral. But the cylindrians, as *mathematicians*, may not notice anything whatsoever. The geometrical measurements of the cylindrians show no difference. Technically we say that the *intrinsic curvature* of the cylindrical surface is zero. Embedded in a three-dimensional space, it has curvature which is greater or smaller. The curvature of a two-dimensional surface as measured when embedded in a three-dimensional space is called the *extrinsic curvature*.

In general relativity we are concerned with curved four-dimensional spacetime, without reference to any higher-dimensional flat space in which spacetime could be imagined to be embedded. Thus by 'curvature of spacetime' is always meant 'intrinsic curvature'. We might speak of the extrinsic curvature of spacetime, embedded in for example a ten-dimensional Euclidean space, but there is no need for such an exploit.

We shall deduce an expression showing how the intrinsic curvature of a two-dimensional surface can be found by measurements on the surface itself. The circumference and radius of a circle can be measured by means of a ruler. The quotient between these quantities is equal to 2π on a plane. We shall find how the intrinsic curvature of a surface is given by the deviation of this quotient from 2π.

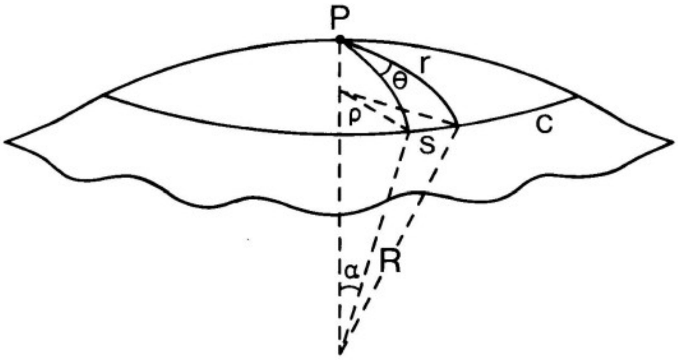

Figure 9.2: Surface of a dome

Consider a small part of any surface, for instance a part of the surface of a dome which surrounds a point P. By making the neighborhood around P small enough, the form of the considered mathematical surface will depart as little as one pleases from a spherical form. This is illustrated in Fig. 9.2.

From this figure and the definition of an angle as measured in radians (see Sect. 4.1) we see that

$$\alpha = \frac{r}{R}.$$

The flatter the dome, the larger is R, and the smaller is the angle α. Furthermore

$$\sin\alpha = \frac{\rho}{R}.$$

Thus

$$\rho = R\,\sin\alpha = R\,\sin(r/R).$$

Also, as shown more clearly in Fig. 9.3

$$\theta = \frac{s}{\rho},$$

where s is the distance along the circle C extended by the angle θ. We get

$$s = \theta\rho = \theta\,R\,\sin(r/R). \tag{9.5}$$

This expression shall be used to find the curvature at a point P of the surface depicted on Fig. 9.2. In general the curvature of a surface is a function of the position on the surface. The curvature at P is a local quantity, generally different from the curvature at other points on the surface. Therefore, we shall need to develop an expression for s, valid for very small values of r. This is performed by means of a series expansion of the expression (9.5).

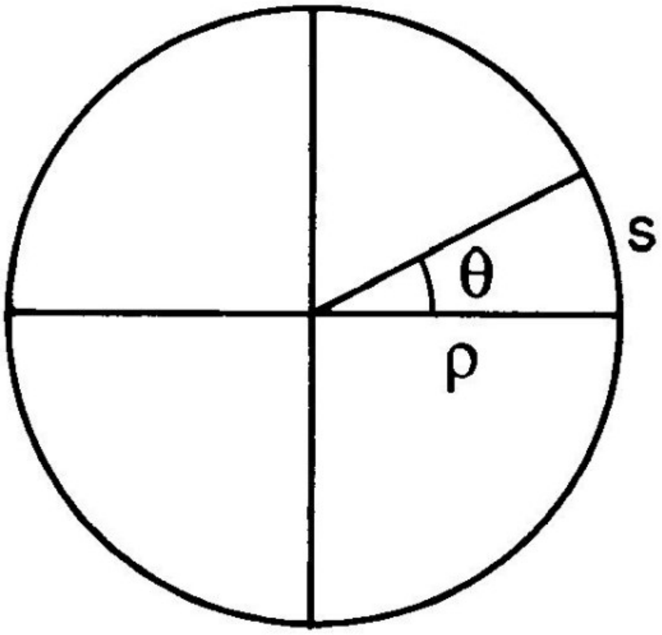

Figure 9.3: The dome seen from above

The first two terms of the MacLaurin series for $\sin x$ is (see Sect. 4.1.1)

$$\sin x = x - \frac{1}{6}x^3 + \cdots . \tag{9.6}$$

Here $x = r/R$, and we get from Eq. (9.5)

$$s = \theta\, R \left(\frac{r}{R} - \frac{1}{6}\frac{r^3}{R^3} + \cdots \right) = \theta \left(r - \frac{1}{6}\frac{1}{R^2} r^3 + \cdots \right). \tag{9.7}$$

We have obtained our desired expression for s. This will be used to find the curvature of our surface, Fig. 9.2, at P.

Here R is the radius of the sphere that the surface around P is part of. The *extrinsic curvature*—the curvature measured from the outside of the surface—is called 'K_E', and is defined as

$$K_E \equiv \frac{1}{R}.$$

It is called extrinsic because it refers to the radius of curvature R of the two-dimensional surface as embedded in the three-dimensional space external to the surface. Equation (9.7) may now be written as

$$s = \theta \left(r - \frac{1}{6}{K_E}^2\, r^3 + \cdots \right).$$

The length ℓ of the circle C around P with radius r on the surface, is

$$\ell = 2\pi\left(r - \frac{1}{6}{K_E}^2\, r^3 + \cdots\right), \tag{9.8}$$

since the angle θ around the circumference is 2π. Dividing each side of Eq. (9.8) by 2π we get

$$\frac{l}{2\pi} \approx r - \frac{1}{6}\,{K_E}^2\, r^3.$$

Thus

$$\frac{1}{6}\,{K_E}^2\, r^3 \approx r - \frac{\ell}{2\pi} = \frac{2\pi r\; - \ell}{2\pi}.$$

Multiplying by 6 and dividing by r^3 we get

$${K_E}^2 \approx \frac{3}{\pi}\,\frac{2\pi r - \ell}{r^3}.$$

Taking the limit $r \to 0$ we get

$${K_E}^2 = \frac{3}{\pi}\lim_{r\to 0}\frac{2\pi r - \ell}{r^3}. \tag{9.9}$$

We have now succeeded in expressing the extrinsic curvature of the considered surface in terms of quantities that can be measured by a two-dimensional creature on the surface.

The *intrinsic curvature* K_I of a surface at a point P is given by the expression at the right-hand side of Eq. (9.9). Thus

$$K_I = \frac{3}{\pi}\lim_{r\to 0}\frac{2\pi r - \ell}{r^3}. \tag{9.10}$$

The intrinsic curvature K_I is called the *Gaussian curvature*. From Eqs. (9.9) and (9.10) it follows that for the considered surface $K_I = {K_E}^2$. This extremely simple relation is not easily seen intuitively, and is *not* valid in general. It is due to the special property of the considered surface; that this surface was assumed to be indistinguishable from a spherical cap at a sufficiently small region around a point P. This is not a general property of surfaces. The *cylindrical surface* we mentioned above, for example, is locally similar to a plane. It has $K_E \neq 0$ and $K_I = 0$.

In general the extrinsic curvature of a surface may be characterized as follows. At every point on the surface we consider the straightest possible curves with different directions. We then find the curvature of these curves. They curve in the direction normal to the surface. Generally the curvature varies with the direction of the curve (except in the isotropic case that we considered above). The maximal and minimal curvatures are called the 'principal curvatures' of the surface, and are denoted by κ_1 and κ_2. The *extrinsic curvature* is defined by

$$K_E \equiv \frac{1}{2}\left(\kappa_1 + \kappa_2\right). \tag{9.11}$$

The *intrinsic* (Gaussian) curvature is given by

$$K_I \equiv \kappa_1\, \kappa_2. \tag{9.12}$$

For a spherical surface $\kappa_1 = \kappa_2$, which gives $K_I = {K_E}^2 =$

$1/R^2$. In the case of a cylindrical surface $\kappa_1 \neq 0$ and $\kappa_2 = 0$, which gives $K_E = \kappa_1/2 \neq 0$ and $K_I = 0$.

If $K_I \neq 0$, K_I may be either positive or negative. The case we have considered in Fig. 9.2 has $\ell < 2\pi r$, giving $K_I > 0$.

The geometry of such surfaces is called *parabolic*. In the case that $l > 2\pi r$, the spherical surface is replaced by a surface similar to a saddle. In this case $K_I < 0$. The geometry of such surfaces is called *hyperbolic*.

In elementary school the famous π is a symbol for the ratio between the circumference and diameter of a circle, and the value of π is given as $3.14159\cdots$. True or false? On a flat surface: true. But what about circles drawn on curved surfaces? Think of a circle on a spherical surface. Let the centre of the circle be at the North Pole. From the point of view of a Euclidean three-dimensional space in which the spherical surface is embedded, the radius of the circle is a curved path on the surface, from the North Pole to the circle. Assume that the radius of the circle is made larger, so that the circle approaches the Equator, and even passes the Equator. Then the circumference of the circle *decreases* while the radius increases. Obviously, the ratio of the length of the circumference and the length of the radius of the circle is not constant when the radius of the circle increases. It is due to the curvature of the surface.

What we have seen is that if one maintains the school-definition of π, then the magnitude of π will depend upon the diameter of the circle that it refers to. This may be maintained, but not the implicit assumption that the circle must be drawn on a flat surface. But both mathematical and physical flatness is an extremely special condition.

Defining the concept of π as quotient between circumference and diameter, its value may vary from zero to infinity, dependent upon the curvature of a surface! We shall in what follows mercifully retain the value of π you always find, by modifying the school definition of π, since it is admittedly not very practical that π might sometimes be equal to 2.15 and sometimes for example equal to 8.50. In order not to violate the near-sacredness of $3.14159\cdots$ we need only to add four words to the definition of π: "on a flat surface". This more precise definition has a consequence with respect to the number of radians we get for the angle around a circle (see Sect. 4.1.1). In order that a radian shall be a geometry-independent measure of an angle, we shall demand that the number of radians around a circle is the same whether it refers to circles on flat or curved surfaces. Then the definition of a radian must also refer to a flat surface. We shall illustrate all this by example 9.1.

Example 9.1 *Consider a circle on a spherical surface, as shown in Fig. 9.4.*

Here ℓ is the circumference of a circle with radius r on we must perform a difficult operation. We must 'parallel transport' to the one we want to compare it to (see Fig. 1.3). In daily life this can be done for example by means of straight threads along which we slide the ends of the arrows. Such procedures work well on a flat surface. However, difficulties will appear when we try to perform such parallel transport over great distances on the Earth, as the curvature of the Earth's spherical surface will disturb the result (see Fig. 9.2).

1.3 Vector fields

From now on vectors are no longer material arrows, but arrows in a purely abstract sense. In what follows a 'vector' is a geometric quantity with geometrically defined 'magnitude' and 'direction'. However, just as there is a correspondence between ordinary numbers and certain physical quantities, such as for example temperature (number of degrees) and length (number of centimetres), there is a correspondence between vectors and a special class of physical quantities; namely, those having a direction.

When we are outdoors in the wind, the moving air fills the region around us. There is a measurable velocity of the air everywhere in the region. In Fig. 1.4 we have shown, as an illustration, a weather map with the wind velocity field over Europe on February 3, 1988. The velocity has a magnitude and a direction. It is a vector. Thus a velocity field is linked conceptually with every point of the region. These abstract vectors are everywhere. If one can think of God as omnipresent, then one might also be able to think of vectors as omnipresent. In such a region there is said to be a vector field.

In order to be able to calculate with vectors, we must have a practical means of specifying their directions and magnitudes. Let us consider vectors on a flat surface, say on the sheet of paper you are writing on. Then we place unit vectors along the horizontal edge at the bottom and along the vertical left-hand edge of the sheet. These are reference vectors.

Drawing equidistant parallels with unit distance between each, we obtain a grid (see Fig. 1.5). Each corner is given a number containing figures; the first figure gives the distance of the point from the left edge of the sheet, and the second figure its distance from the downward edge. Imagine that each square is divided into four smaller squares. Again each corner is given a two-figured number. (The figures are not generally integer numbers.) If this division is proceeded indefinitely, we can associate a number with every point of our sheet. Note also that each point have different numbers. Such a set of numbers, by which we may specify the positions of arbitrary points in a region, is called a coordinate system. There is no reference to the grid we introduced originally, in the

definition of a coordinate system. The grid which is usually drawn on maps, or a globe, for example, is only of heuristic help, making it easier to read off the position of a point in the coordinate system.

As is well known by users of atlases, one can map a region by means of different sorts of coordinate systems. The particular coordinate system that we have described above, with vertical and horizontal straight axes, is called a Cartesian coordinate system, in honour of the great mathematician René Descartes (1596–1650). The horizontal axis is usually called the x-axis, and the vertical axis the y-axis. The position of a point is given by a number (x, y) relative to a chosen origin, which has coordinates $(0, 0)$.

By means of our coordinate-system we can specify the magnitudes of the vectors in our vector-field. In order to be able to write a vector as the sum of 'vector components' (see below) along the coordinate lines we introduce reference vectors (see above) along these lines. They are called basis vectors. The basis vectors are introduced at every point in the region of interest. Generally the basis vectors may have unequal directions and magnitudes at different positions (see for example section 4.1.1, where a system of plane polar coordinates is considered). Only in the special case of a Cartesian coordinate system (in a flat space) do they have the same magnitude and direction all over space.

At every point of an n-dimensional space there are n basis vectors. There are, for example, two basis vectors at every point of a surface. Having a coordinate system and the associated basis vector field at our disposal, we can specify the components of, for example, a velocity vector field at every point in a region. By this means we shall be able to develop the calculus of vectors.

1.4 Calculus of vectors. Two dimensions

As to notation, vectors shall be denoted by placing an arrow above the letter. Thus, 'A-vector' is denoted by $\vec{A}$. Basis vectors are denoted by a the letter 'e' with an arrow and a subscript, which tells which basis vector we are talking about, for example $\vec{e}_x$.

Consider a vector $\vec{A}$. In Fig. 1.6 this vector is placed in a two-dimensional coordinate-system. The coordinate axes are straight lines. The difference between their directions amounts to 90°. They are said to be *orthogonal* to each other. (This term will be used frequently in the present text.) We have a Cartesian coordinate system. The basis vectors along the x-axis and y-axis, are written $\vec{e}_x$ and $\vec{e}_y$, respectively. The magnitude of a vector $\vec{A}$ is designated by $|\vec{A}|$. The basis vectors $\vec{e}_x$ and $\vec{e}_y$ have per definition magnitude equal to 1, $|\vec{e}_x| = |\vec{e}_y| = 1$.

So if you cannot really test such theories, what are they useful for?

Well . . . it's not really ruled out that they can't be tested but I think that any test has to come from cosmological data in one way or another. It is hard to test it at any other scale, in particular by scattering particles. Such cumulative processes could in the end add up to something significant but it would require some very detailed calculations to show that it would be indeed the case. Such scenarios have been supported by some people in a not so far past but I think that it is still preliminary. At the moment, it seems that the best hope of constructing and testing a consistent theory is to apply the theory to our current universe. As such, I do not see such theory as providing us with multiple predictions for the future in such a way that we can live long enough to verify them (laughs).

Since it is hard to test these theories, would it be reasonable for someone to stand up and say, "This is not really science but religion" because it's a matter of belief in a specific theory of quantum gravity?

Clearly, science might come to a limit in which this will be the case because in order to construct an accurate theory of the universe you need to conduct experiments. However, you don't really have the possibility of making many experiments since you just have this one universe. From this point of view, you might have to establish different kinds of standards for what should be called *science* and *scientific predictions*. At the moment, I don't consider this to be a problem. On the other hand, I must say that you will probably always be able to wave your hands in the air and use something like the anthropic principle to explain the workings of the universe. I tend not to refer to that approach as *science*.

Can you tell me what is the story behind the approach to quantum gravity that you pursue? How did it begin?

The approach that I pursue was developed by myself and collaborators, as well as other groups, in the mid-1980s in order to provide a non-perturbative regularisation of Polyakov's string theory [4–11] and it has been extremely successful in describing two-dimensional quantum gravity and non-critical string theory. In the beginning of the 1990s, it became clear that string theory was not going anywhere and it also became unclear whether it would be able to make any predictions. At that point, one had to think whether or not there could be other descriptions of quantum gravity. The generalisation of our approach to higher dimensions, which is related to what is referred to as *asymptotic safety* [12], was possible and could potentially lead to an alternative theory. Thus, we began pursuing it.

What is asymptotic safety?

Asymptotic safety is a kind of generalisation of Wilsonian standard renormalisation group philosophy according to which a quantum theory needs not to be renormalisable in the ordinary sense [12]. By a theory being *renormalisable* one usually means that it has a Gaussian

Why is this fixed point referred to as a non-Gaussian fixed point contrary to a Gaussian fixed point?

Yes, it's a little bit of a misnomer which stems from scalar theories. According to the definition we adopted with Max Niedermaier in an early review [6], what it means to be a non-Gaussian fixed point is that the critical exponents are not the canonical ones. Basically, it is synonymous to saying that, in the language of lattice field theory, you take the continuum limit at a fixed point different from the one of perturbation theory [11].

Now going back to these flows from the fixed point, I guess you are looking at flows that go from pure classical Einstein gravity to something else in the ultraviolet?

We don't start in the infrared. I mean, logically, the first step is to find the fixed point, then to find its finite-dimensional UV-critical hypersurface, and only later look for trajectories going downward to classical Einstein gravity.

But how many fixed points are out there and how many different trajectories exist that flow to the same infrared physics?

The problem is that in the approximate calculations that we can do, we cannot yet fully explore the full size of this hypersurface, so . . .

Even in truncated theory spaces?

If I generalise the truncation then I make the full space bigger. But a priori, I don't know how many dimensions this adds to the embedded critical surface. For instance, in $f(R)$ truncations, what happens is that up to R^2 you get relevant directions [3–5, 9]. So the cosmological constant, R and R^2 give rise to parameters in the surface and so it's three-dimensional. Adding R^3 and so on, you only get irrelevant directions. In this class of truncations, you can add more and more powers of the Ricci scalar and you will not increase the number of parameters you have to determine experimentally. So, fixing three parameters experimentally, you can predict all the other coefficients of all R powers. This has been discovered by Roberto Percacci's and Frank Saueressig's groups.

What is the reason for that?

This is just the intrinsic three-dimensionality of this hypersurface. If you look at what is the unstable manifold of the fixed point, then you see that in three directions you're driven away when you lower the cutoff, while in all others you're attracted to it. But now you could ask whether, if I add something like the Riemann tensor squared, will it add a relevant direction or an irrelevant one? A priori, I do not know and I have to do the calculation. Whenever you generalise a truncation, you may add a relevant or an irrelevant direction. We have some intuition from Gaussian fixed points for which canonical dimensions are still a guide. So you can partly understand whether specific terms give rise to relevant or irrelevant dimensions. However, strictly speaking, you cannot determine the exact number of dimensions from any given truncation as it is a property of the full theory.

BOX 2.1 (*continued*)

unmanned spacecraft in 1973. Since 1969 a systematic program to determine the Moon's orbit using these devices has been carried out mainly at the McDonald Observatory at Mt. Locke, in Texas, and the Observatoire de Côte d'Azur station in Grasse, France. The lasers currently in use send pulses lasting 200 picoseconds, each containing about 10^{18} photons, about 10 times per second. Diffraction, refraction in the atmosphere, and other effects spread the beam over a 7-km radius on the Moon so that only 10^{-9} of the photons that are sent impinge on the retroreflector. On return, the reflected spot is spread over 20 km so that a 1-m telescope would detect only 10^{-9} of the returning photons. In the end, only one reflected photon is detected every few seconds. Returning photons have been detected for more than thirty years since 1970 at the time of writing.

some initial velocity, decelerates, reaches a maximum height, accelerates downward, and returns to the surface of the Earth. Any other body thrown upward from the same initial position with the same initial velocity would follow *exactly the same curve*.

This uniqueness of trajectory in space and time is a special property of gravity. The motion of a body in a magnetic field depends on what kind of charge it has. Bodies with one sign of charge will be deflected one way, bodies with the opposite charge will be deflected the other, and bodies with no charge will not be deflected at all. Only in a gravitational field do all bodies with the same initial conditions follow the same curve in space and time.

Einstein's idea was that this uniqueness of path in spacetime could be explained in terms of the geometry of the four-dimensional union of space and time called *spacetime*. Specifically, he proposed that the presence of a mass such as Earth curves the geometry of spacetime nearby, and that, in the absence of any other forces, all bodies move on the straight paths in this curved spacetime. Bodies free from forces move on straight lines of three-dimensional Euclidean space in Newtonian mechanics—that's part of Newton's first law. Einstein's idea is that the Earth moves in its orbit around the Sun, not because a force of gravity acts on it, but because it is following the straightest possible path in the slightly non-Euclidean geometry of spacetime produced by the Sun.

2.2 Experiments in Geometry

There is a story that in the late 1820s the great mathematician C. F. Gauss carried out an experiment to verify one of the standard theorems of the Euclidean geometry of space—that the interior angles of a triangle add up to 180°. Using the mountaintops of Hohenhagen, Brocken, and Inselsberg as vertices and assuming that light rays move on straight lines, he is said to have measured the angles, found the sum, and determined 180° to the accuracy with which the angles could be measured. (See Figure 2.2.)

The historical evidence is not conclusive as to whether Gauss actually carried out this experiment. However, he might have done so, and that emphasizes an important point. The sum of the angles was not guaranteed to be 180° from logic alone. Many geometries of physical space are possible that are different from

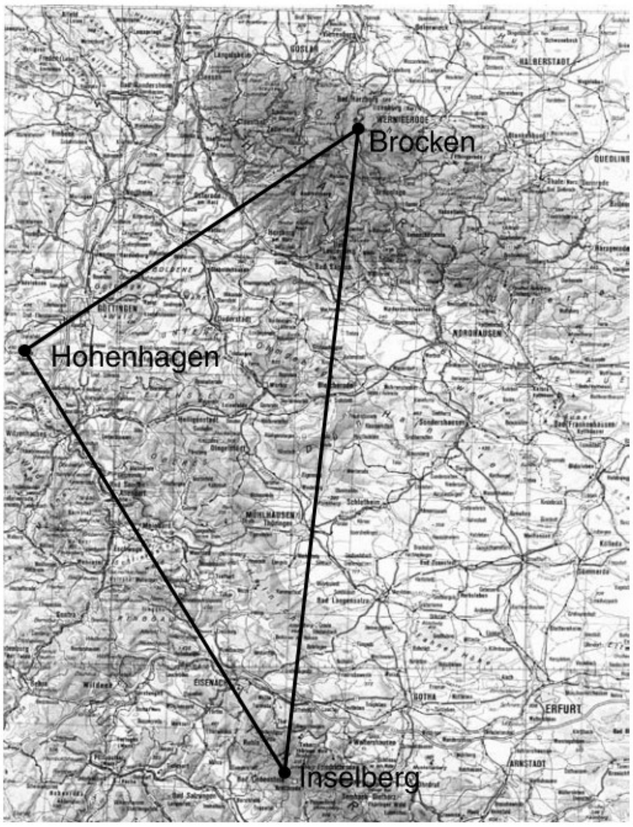

FIGURE 2.2 A modern map of Germany showing the locations of the peaks Hohenhagen, Brocken, and Inselberg, which form the vertices of a triangle that Gauss could have surveyed to check whether the interior angles add up to 180°, as predicted by Euclidean geometry.

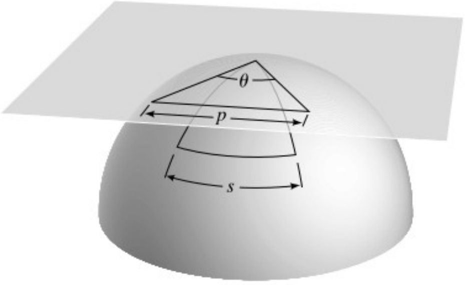
Euclid's. These predict different results for the sum of the interior angles of a triangle. The geometry of space is an empirical question. It is a question in physics, subject to measurement, hypothesis, and test. By the end of this book you will know that if Gauss had been able to carry out his experiment with sufficient accuracy, he would have found a small difference in the sum of the angles just due to the mass of the Earth, $M_\oplus$, of order

$$\left|\begin{pmatrix}\text{sum of interior angles}\\ \text{of a triangle in radians}\end{pmatrix}\right| - \pi \sim \frac{(\text{area of triangle})}{R_\oplus^2}\left(\frac{GM_\oplus}{R_\oplus c^2}\right) \tag{2.1}$$

(where $R_\oplus$ is the Earth's radius) together with contributions from the Sun and the other planets. Note the appearance of the ratio GM/Rc^2, which is characteristic of weak relativistic effects, as discussed in Chapter 1. The distances between the mountains are 69 km, 85 km, and 107 km. Using these, this works out to be a difference of order 10^{-15} radians (!). So small a discrepancy could not be detected even with present technology, but modern experiments can detect the deviations from Euclidean geometry produced by the Sun and measure the geometry of space on the very large scales of cosmology. (See Box 2.2.)

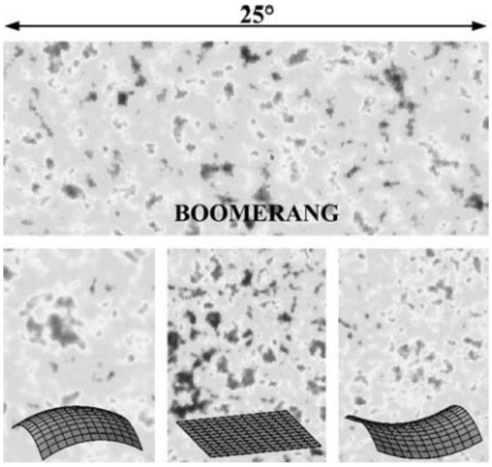
BOX 2.2 Determining the Spatial Geometry of the Universe



Modern measurements—not so different in character from that attributed to Gauss—determine the curvature of space on the distance scale of the visible universe. General relativity plus observations of the distribution of galaxies and radiation in the universe suggest only a few possibilities for the large-scale geometry of three-dimensional space at a moment of time, as we will see in detail in Chapter 18. The flat geometry of the plane, the positively curved geometry of the surface of a sphere, or the negatively curved geometry of a surface locally like some potato chips[a] are two-dimensional analogs of the possible flat, positively curved, and negatively curved large-scale geometries for three-dimensional space. How can the geometry of space in our universe be measured?

To understand a little of one method, imagine the geometry of space to be fixed in time (in contrast to the geometry of the actual universe, which is expanding). Imagine further that objects of known size p could be identified a known distance, d, away. If the geometry were flat like a plane, the angle θ subtended by these objects would be p/d. But, as illustrated in the accompanying figure, if the geometry were positively curved like the surface of a sphere, an object of smaller size s would subtend the same angle.[b] Alternatively, an object of a given size and distance away will subtend a larger angle on a positively curved surface like a sphere than it will in a flat plane (Problem 6). In a similar way, the angle subtended in a negatively curved space will be smaller. (For details, see Problem 18.12.) This discussion will be corrected to include the expansion of the universe in Chapter 19, but the qualitative result is the same: measuring the angular size of features of known size and distance is one way of determining whether the geometry of intervening space is flat, positively curved, or negatively curved. The cosmic background radiation provides such features.

The cosmic microwave background radiation (CMB) is light from the hot big bang that began the universe. The radiation started from the moment the universe had



---

[a] "Crisps" in the UK and elsewhere.

[b] If that is not clear from thinking about the figure, imagine the sphere is made of rubber and could be flattened out on a plane tangent to the North Pole. The angles between lines of longitude at the North Pole do not change, but the equator and other lines of latitude have to be stretched. Thus the angle subtended by an object spanning a range of longitude on a sphere is the same as that subtended by a larger object in a plane.

BOX 2.2 (*continued*)

expanded and cooled enough for the matter to be transparent to radiation. It has been propagating freely to us over the intervening approximately 14 billion years. Were the universe unchanging in time, it would have traveled approximately 14 billion light-years. The temperature of the radiation has cooled to 2.73°K and is very nearly the same in all directions but not quite. Tiny temperature fluctuations of only a few tens of millionths of a degree are observed. The theory of the origin of these fluctuations predicts a spectrum of sizes that is characterized by a known length scale. The fluctuations are, therefore, features with a known spectrum of sizes a known distance away. Observations of their angular size can thus measure the spatial geometry of the universe. The right hand figure on the previous page shows a map of the temperature fluctuations in a 25°-wide region of the sky that were observed by the Boomerang experiment (deBernardis et al. 2000). The three figures on the bottom show simulations of what the map would look like based on the theoretical spectrum of original sizes if the geometry were positively curved (left), flat (middle), or negatively curved (right). Quantitative comparisons of the spectrum of angular sizes show that the geometry is very close to flat. (In the near future there will be a more accurate result, but the idea will be the same.) The geometry of space is a measurable, physical question.

2.3 Different Geometries

The idea of different geometries is easily illustrated in two dimensions. In your studies of the Euclidean geometry of the plane, you met the notions of point, straight line, distance, angle, parallel, triangle, circle, chord, etc. Familiar theorems include the one just discussed for a triangle:

$$\sum_{\text{vertices}} \begin{pmatrix}\text{interior}\\ \text{angle}\end{pmatrix} = \pi. \tag{2.2}$$

Another relates the ratio of the circumference to the radius of a circle:

$$\frac{(\text{circumference})}{(\text{radius})} = \frac{C}{r} = 2\pi. \tag{2.3}$$

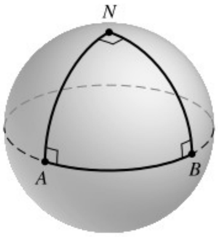


FIGURE 2.3 A spherical triangle NAB where the sum of the interior angles is 270°. The triangle consists of the parts of two lines of longitude 90° apart from the North Pole to the equator and the part of the equator between them. These are all segments of great circles and, therefore, straight lines in the geometry of the sphere.

The surface of a sphere provides an example of a *different* two-dimensional geometry in which such results of plane geometry are replaced by different theorems. Straight lines can be defined on a sphere as the shortest distance between two points, that is, as segments of great circles. Triangles are made up of three intersecting great circles. A circle is the locus of points equidistant (as measured on the surface) from a point which is its center, etc. For a spherical triangle of area A,

$$\sum_{\text{vertices}} \begin{pmatrix}\text{interior}\\ \text{angle}\end{pmatrix} = \pi + \frac{A}{a^2} \tag{2.4}$$

where a is the radius of the sphere.

Equation 2.4 shows that the sum of the interior angles of a spherical triangle is always *greater* than π. An example is shown in Figure 2.3. As the size of the triangle becomes smaller and smaller compared with the radius of curvature a, it

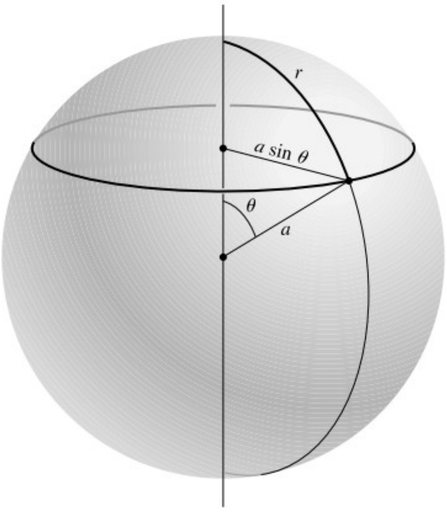

FIGURE 2.4 The relation of the circumference to the radius of a circle in the geometry of the surface of a sphere. A circle is the locus of points on the surface that are equidistant (as measured on the surface) from its center point. In this figure the North Pole has been chosen to coincide with the center of a circle that is a line of constant latitude labeled by θ. The radius r is the distance from the North Pole to this latitude measured along any line of constant longitude.

becomes increasingly difficult to tell the difference between a flat plane and the curved surface of the sphere. For triangles with very small areas ($A/a^2 \ll 1$), the result (2.4) is well approximated by the flat space result (2.2).

With the bit of geometry shown in Figure 2.4, the ratio of the circumference to the radius of a circle on a sphere can be calculated to be

$$\frac{\text{(circumference)}}{\text{(radius)}} = \frac{C}{r} = 2\pi \frac{\sin(r/a)}{(r/a)}. \tag{2.5}$$

Again, if $r \ll a$, the right-hand side reduces to the flat-space result (2.3).

It is not necessary to leave the surface of the earth to determine its geometry. Surveyors (such as Gauss) working on the surface of the earth can measure such things as the interior angles of a triangle and the circumference and radius of circles. By fitting to formulas such as (2.4) and (2.5), they could, in principle, tell if the geometry of the surface was spherical and determine the radius of curvature a. Similarly, by surveying in three dimensions we can, in principle, determine the geometry of space without needing any extra dimensions.

Visualization of three-dimensional curved geometries is not as easy as for two-dimensional curved geometries, which can often be represented as surfaces in Euclidean three-dimensional space. However some simple three-dimensional geometries can be thought of as curved surfaces in a hypothetical four-dimensional Euclidean space. For example, the three-dimensional geometry analogous to the two-dimensional sphere discussed before is the three-dimensional surface of a sphere in four dimensions—a *three-sphere*. If space had a fixed three-sphere geometry, a journey in a straight line in any direction would eventually bring one back to the starting point. However, more detailed information about the geometry of space can be determined locally. For example, it turns out[1] that the volume inside a two-dimensional sphere of radius r in such a spatial geometry is given by

$$V = 4\pi a^3 \left\{ \frac{1}{2} \sin^{-1}\left(\frac{r}{a}\right) - \frac{r}{2a}\left[1 - \left(\frac{r}{a}\right)^2\right]^{1/2} \right\} \tag{2.6a}$$

$$\approx \frac{4\pi r^3}{3}\left[1 + \begin{pmatrix} \text{corrections} \\ \text{of order } (r/a)^2 \end{pmatrix}\right], \qquad \text{for small } \frac{r}{a}, \tag{2.6b}$$

where a is the characteristic radius of curvature of the three-sphere geometry. For a two-sphere whose radius is much smaller than a, the volume-radius relation approaches the Euclidean flat-space result, as (2.6b) shows. If three-dimensional space had such a three-sphere geometry, the characteristic radius of curvature a could be determined by careful measurements of the radii and volume of two-spheres. As we will discover in Chapter 18, Einstein's theory predicts this three-sphere geometry as one possibility for the spatial geometry of a uniform universe on very large distance scales. Box 2.2 on p. 17 describes one effort to survey space on these scales.

2.4 Specifying Geometry

In addition to the geometry of the plane and the geometry of the sphere, there are an infinite number of other two-dimensional geometries. For example, there is the geometry on the surface of an egg or the geometry of the surface of a plane with a few hills on it. In three dimensions there are a similarly infinite number of geometries. How are these different geometries described and compared mathematically?

One way to describe a geometry is to embed it as a surface in a higher-dimensional space whose geometry is Euclidean. We have made use of this method in describing two-dimensional geometries as surfaces embedded in three-dimensional Euclidean geometry—planes, spheres, eggs, etc. However, it becomes almost impossible to think of any but the simplest three- and four-dimensional geometries as surfaces in four and five dimensions. Further, the extra dimension is physically superfluous. An *intrinsic* description of geometry that makes use of just the physical dimensions that can be measured is what is needed.

Another idea is to specify a geometry by giving a small number of *axioms*, or postulates, from which the other results of geometry can be derived as theorems. For the geometry of the flat plane, for example, there are Euclid's five axioms: Two points determine a unique line, parallel lines never intersect, etc. Some other simple geometries can be characterized in this way with different axioms. For example, the geometry on the surface of a sphere can be summarized by a set of axioms like Euclid's in which the parallel postulate is replaced by the axiom that two parallel lines *always* meet in two points. However, this method also is limited. What axioms describe the geometry on the surface of a potato? We need a more local and detailed description.

---

[1] This result will be derived explicitly in Example 7.6.

The key to a general description of geometry is to use differential and integral calculus to reduce all geometry to a specification of the distance between each pair of nearby points. From the distance between nearby points, the distances along curves can be built up by integration. Straight lines are the curves of the shortest distance between two points. Angles are ratios of the lengths of arcs to their radii when those radii are small. Areas, volumes, etc., can be constructed by multiple integrals over area and volume elements, themselves specified by the distances between nearby points. By specifying the distances between nearby points and using differential and integral calculus, the most general geometry may be specified. This area of mathematics is called *differential geometry*. We will explore just a few ideas of this subject in the next section.

2.5 Coordinates and Line Element

The Euclidean Geometry of a Plane

A systematic way of labeling points is a prerequisite to a specification of the distance between nearby ones. A system of coordinates assigns unique labels to each point, and there are many systems that do so. In two dimensions, for instance, there are Cartesian coordinates (x, y), polar coordinates (r, ϕ) about some origin, etc. (Figure 2.5).

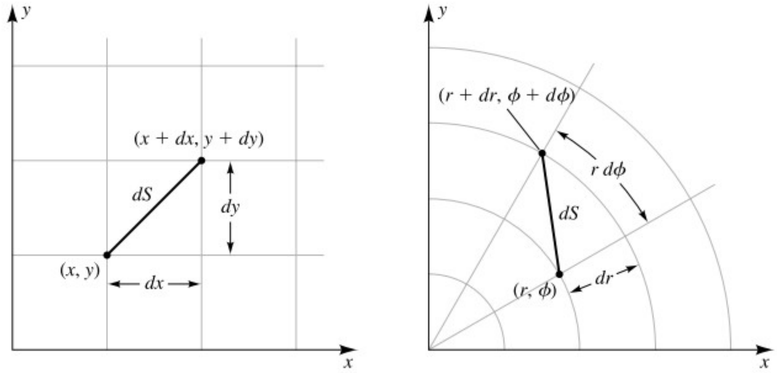

FIGURE 2.5 Cartesian and polar coordinates. Cartesian and polar coordinates are both systematic ways of labeling points in the plane, and the distance between nearby points can be expressed in terms of either.

Nearby points have nearby values of their coordinates. For example, the points (x, y) and $(x+dx, y+dy)$ are nearby when dx and dy are infinitesimal. Similarly, (r, ϕ) and $(r + dr, \phi + d\phi)$ are nearby.

In Cartesian coordinates (x, y), the distance dS between the points (x, y) and $(x + dx, y + dy)$ is (see Figure 2.5)

$$dS = \left[(dx)^2 + (dy)^2\right]^{1/2}. \tag{2.7}$$

The same rule can be expressed in polar coordinates where the distance between the nearby points (r, ϕ) and $(r + dr, \phi + d\phi)$ is (see Figure 2.5)

$$dS = \left[(dr)^2 + (r\, d\phi)^2\right]^{1/2}. \tag{2.8}$$

Expression (2.8) and others like it are valid only if dr and $d\phi$ are small. However, large distances can be built up from these infinitesimal relations by integration. Let's, for example, calculate the ratio of the circumference to the diameter of a circle of radius R. Choosing the origin at the center, the equation for such a circle in Cartesian coordinates is

$$x^2 + y^2 = R^2. \tag{2.9}$$

The circumference C is the integral of dS around the circle. Using (2.7) this is

$$C = \oint dS = \oint \left[(dx)^2 + (dy)^2\right]^{1/2} \tag{2.10a}$$

$$= 2\int_{-R}^{+R} dx \left[1 + \left(\frac{dy}{dx}\right)^2\right]^{1/2}_{x^2+y^2=R^2} \tag{2.10b}$$

$$= 2\int_{-R}^{+R} dx \sqrt{\frac{R^2}{R^2 - x^2}}. \tag{2.10c}$$

Changing variables by writing $x = R\xi$, we have

$$C = 2R\int_{-1}^{1} \frac{d\xi}{\sqrt{1-\xi^2}} = 2\pi R. \tag{2.11}$$

This is the correct answer. The integral could even be taken to define π; by doing it numerically, one could discover that $\pi = 3.1415926535\ldots$.

Deriving the relation between radius and circumference is even easier in polar coordinates, where the equation of the circle is just $r = R$. Evaluating (2.8) on the circle and integrating the resulting dS over it gives

$$C = \oint dS = \int_0^{2\pi} R\, d\phi = 2\pi R. \tag{2.12}$$

The ease of using polar coordinates to arrive at (2.12) shows that, for a given problem, some coordinates are better than others.

By proceeding in this way we could derive all the theorems of Euclidean plane geometry. The angle between two intersecting lines, for example, can be defined as the ratio of the length ΔC of the part of a circle centered on their intersection that lies between the lines to the circle's radius R.

$$\theta \equiv \frac{\Delta C}{R} \qquad \text{(radians)}. \tag{2.13}$$

With this definition we could prove that the sum of the interior angles of a triangle is π. Indeed, we could verify the *axioms* of Euclidean plane geometry from (2.7) or (2.8). All geometry can be reduced to relations between distances; all distances can be reduced to integrals of distances between nearby points; all Euclidean plane geometry is contained in (2.7) or (2.8).

Line Element

To summarize, a geometry is specified by the *line element*, such as (2.7) or (2.8), which gives the distance between nearby points in terms of the coordinate intervals between them in some coordinate system. Conventionally, a line element is written as a quadratic relation for dS^2, e.g.,

$$dS^2 = dx^2 + dy^2 \tag{2.14}$$

with no brackets around the differentials. The form of the line element for a geometry varies from coordinate system to coordinate system [e.g., (2.7) and (2.8)], but the geometry remains the same.

The Non-Euclidean Geometry of a Sphere

An example of a non-Euclidean geometry is provided by the surface of a two-dimensional sphere of radius a. We can use the angles (θ, ϕ) of three-dimensional polar coordinates to label points on the sphere. The distance between points (θ, ϕ) and $(\theta + d\theta, \phi + d\phi)$ can be seen after a little work (Figure 2.6) to be

Line Element for a Sphere

$$dS^2 = a^2\left(d\theta^2 + \sin^2\theta\, d\phi^2\right). \tag{2.15}$$

This is the line element of the surface of a sphere.

Let's use the line element (2.15) to calculate the ratio of the circumference to the radius of a circle on the sphere. By circle we mean the locus of points *on the surface* that are a constant distance (the radius) *along the surface* from a fixed point (the center) *in the surface*. Since no one point is distinguished geometrically from any other on the sphere, we may conveniently orient our polar coordinate system so that the polar axis is at the center of the circle. A circle is then a curve of constant θ. Consider the circle defined by the equation

$$\theta = \Theta \tag{2.16}$$

for constant Θ. The circumference is the distance around this curve. Nearby points along the curve are separated by $d\phi$ but have $d\theta = 0$. Thus, (2.15) gives $dS =$

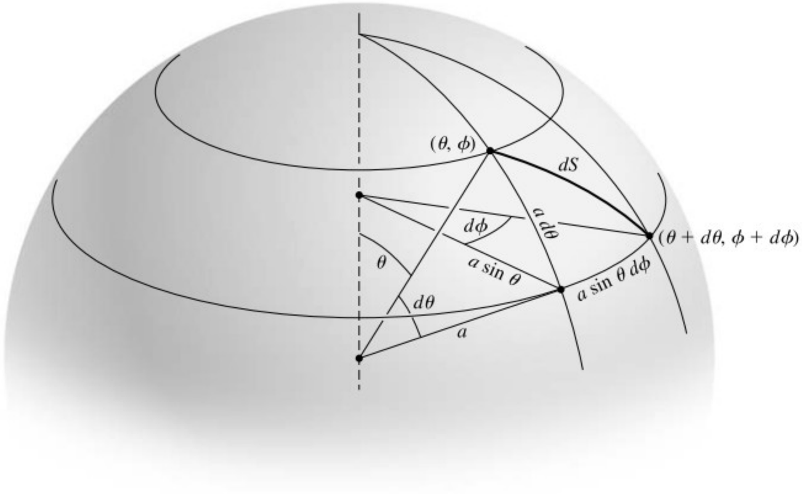

FIGURE 2.6 Deriving the line element on the sphere. The derivation makes use of the fact that the two-dimensional sphere is a surface in three-dimensional Euclidean space. Two infinitesimally separated points at locations (θ, ϕ) and $(\theta+d\theta, \phi+d\phi)$ are indicated. The construction shows that the distance between ϕ and $\phi + d\phi$ along a line of constant latitude θ is $a \sin\theta\, d\phi$. The distance between θ and $\theta+d\theta$ along a line of constant longitude is $a\, d\theta$. Because the θ and ϕ coordinate lines are orthogonal, the sum of the squares of these two differentials gives the square of the distance dS between the two points when $d\theta$ and $d\phi$ are infinitesimally small. This gives (2.15).

$a \sin\Theta\, d\phi$ along the circle, and the circumference is

$$C = \oint dS = \int_0^{2\pi} a \sin\Theta\, d\phi = 2\pi a \sin\Theta. \tag{2.17}$$

The radius is the distance from the center to the circle along a curve for which θ varies but $d\phi = 0$. Along this curve, (2.15) gives $dS = a\, d\theta$, and the radius is

$$r = \int_{\text{center}}^{\text{circle}} dS = \int_0^{\Theta} a\, d\theta = a\Theta. \tag{2.18}$$

Using (2.18) to eliminate Θ in (2.17), the relation between the circumference and radius of a circle in the non-Euclidean geometry of a sphere becomes

$$C = 2\pi a \sin\left(\frac{r}{a}\right). \tag{2.19}$$

In this expression a is a fixed number characterizing the geometry. It measures the scale on which the geometry is curved. When the radius of the circle is much smaller than the radius of the sphere, $r \ll a$, then we have approximately

$$C \approx 2\pi r, \tag{2.20}$$

which is the familiar result in Euclidean geometry. The geometry of the surface of the Earth is the same as a sphere to a good approximation.

The many different projections used to make maps of its surface are just different coordinate systems for expressing the geometry of a sphere as described in Box 2.3.

BOX 2.3 Map Projections

The various projections used to make planar maps of the Earth's surface are examples of a familiar geometry expressed in different systems of coordinates. The geometry is that of the two-dimensional surface of the sphere to an excellent approximation. In usual polar coordinates the line element is given by (2.15), with a being the radius of the Earth. On the surface of the Earth, the angle ϕ is the longitude (measured in radians rather than degrees). The latitude λ is $\pi/2 - \theta$. Expressed in terms of latitude and longitude, the line element is

$$dS^2 = a^2(d\lambda^2 + \cos^2\lambda\, d\phi^2). \tag{a}$$

To make a map we introduce new coordinates x and y on the sphere, defined by relations of the form

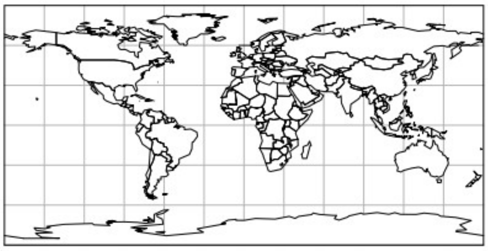
$$x = x(\lambda, \phi), \qquad y = y(\lambda, \phi), \tag{b}$$

and use these as rectangular coordinates in the plane to plot the outlines of the continents, locations of cities, etc. Different projections correspond to different choices for the functions $x(\lambda, \phi)$ and $y(\lambda, \phi)$. One can think of these functions as providing a map in the mathematical sense from the sphere into the plane.

There are as many projections as there are different functions. The simplest example is

$$x = (L\phi)/2\pi, \qquad y = (L\lambda)/\pi, \tag{c}$$

where L is the width of the map. This just plots ϕ and λ as x and y on rectangular axes. The result, shown in the accompanying figure, is called an *equirectangular* projection. However, there are more useful projections which preserve some properties of the geometry of the sphere on a plane. Not all properties can be preserved because the geometry of a sphere is different from that of the plane!



Equirectangular projection.

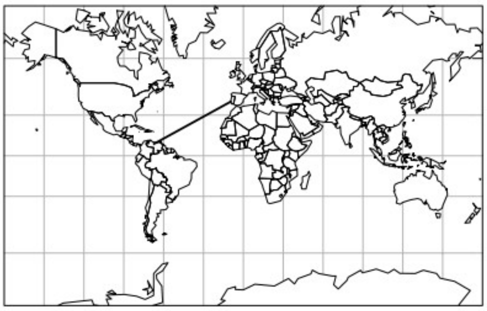
A wide class of useful projections send longitude linearly into x:

$$x = \frac{L\phi}{2\pi}, \qquad y = y(\lambda). \tag{d}$$

For projections of this kind, the true distances are given by the line element

$$dS^2 = a^2\left[\left(\frac{2\pi}{L}\cos[\lambda(y)]\right)^2 dx^2 + \left(\frac{d\lambda}{dy}\right)^2 dy^2\right]. \tag{e}$$

A simple example of a projection of this kind is the Mercator projection, invented by G. Kramer in 1569 and illustrated below. Kramer's idea was that angles on the map should equal compass bearings on the sphere. That is, the map from the sphere to the plane should preserve angles between different directions from a point. A mariner wishing to sail between Caracas and Lisbon would draw the straight line on the map connecting these two ports. The angle between that line and the y-axis would be the bearing from north that when held constant during the voyage would bring the ship from Caracas



Mercator projection.

to Lisbon. What choice of function $y(\lambda)$ or $\lambda(y)$ would make a map like this?

Angles are *ratios* of distances, as we saw in (2.13). The angle between two directions on a sphere will equal the angle between the corresponding directions on the plane if the line element on the sphere is *proportional* to the line element on the flat plane, $dS^2_{\text{flat}} = dx^2 + dy^2$. Thus, to implement Kramer's idea we seek a function $\lambda(y)$ such that (e) can be written

$$dS^2 = \Omega^2(x, y)(dx^2 + dy^2) \tag{f}$$

for some function $\Omega(x, y)$. Clearly we need

$$\frac{d\lambda}{dy} = \frac{2\pi}{L}\cos\lambda. \tag{g}$$

Choosing $y = 0$ to coincide with $\lambda = 0$ gives

$$y(\lambda) = \frac{L}{2\pi}\int_0^\lambda \frac{d\lambda'}{\cos\lambda'} = \frac{L}{2\pi}\log\left[\tan\left(\frac{\pi}{4} + \frac{\lambda}{2}\right)\right]. \tag{h}$$

Equations (h) and (d) define the Mercator projection. The equator $\lambda = 0$ is mapped to the line $y = 0$. The poles $\lambda = \pm\pi/2$ are mapped to $y = \pm\infty$, respectively.

The proportionality factor between the spherical metric and the flat metric on the plane $\Omega(x, y)$ that was defined in (f) is

$$\Omega(y) = \frac{2\pi a}{L}\cos\lambda(y) = \frac{4\pi a}{L}\frac{e^{2\pi y/L}}{1 + e^{4\pi y/L}}. \tag{i}$$

Most of the familiar properties of the Mercator projection follow from this factor. For example, consider two points at the same latitude separated by a difference in longitude, Δx. The physical distance between these points, ΔS, is

$$\Delta S = \Omega(y)\Delta x \tag{j}$$

and depends on latitude. As $y \to \infty$, the North Pole, this distance shrinks to zero, as it should. True distances in x at higher latitudes are smaller than coordinate distances because of the factor $\Omega(y)$.

The same holds true for areas. A small rectangle on the map of coordinate dimensions Δx and Δy has area

$$\Delta A = [\Omega(y)\Delta x][\Omega(y)\Delta y] = \Omega^2(y)\Delta x\Delta y. \tag{k}$$

Thus, although Greenland looms large on the Mercator projection in coordinate area when compared with South Americal, for example, its actual area is much smaller.

The Geometry of Some More General Surfaces

The line element of the plane and the sphere were worked out before, starting from a clear picture of these geometries as surfaces in Euclidean space. However, in general relativity it is more usual to be confronted with a line element and have to figure out the properties of the geometry it represents.

Consider as an example the line element

$$dS^2 = a^2(d\theta^2 + f^2(\theta)\,d\phi^2) \tag{2.21}$$

for various possible choices of the function $f(\theta)$. The choice $f(\theta) = \sin\theta$ gives the geometry of the surface of a sphere (2.15). But what surfaces in three-

where

$$\nabla^2 := \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \tag{1.9}$$

is the familiar Laplacian operator; Poisson's equation (known after its originator Siméon Denis Poisson, who unfortunately is not related to either author of this book), is the generalization of Eq. (1.4b) to continuous matter.

As was stated previously, these equations will be properly introduced in the following two sections. To complete the formulation of the theory we must impose a relationship between the pressure and the density of the fluid. This relationship, known as the *equation of state*, takes the general form of

$$p = p(\rho, T, \cdots), \tag{1.10}$$

in which the pressure is expressed as a function of the density, temperature, and possibly other relevant variables such as chemical composition. The equation of state encodes information about the microphysics that governs the fluid, and this information must be provided as an input in most applications of the theory.

A complete description of a physical situation involving gravity and a distribution of matter can be obtained by integrating Eqs. (1.5), (1.6), and (1.8) simultaneously and self-consistently. The solutions must be subjected to suitable boundary conditions, which will be part of the specification of the problem. All of Newtonian gravity is contained in these equations, and all associated phenomena follow as consequences of these equations.

1.3 Newtonian field equation

In this section we examine the equations that govern the behavior of the gravitational field, and show how Eq. (1.8) is an appropriate generalization of the more primitive form of Eq. (1.4b).

We recall that the relation $U = GM/r$ applies to a point body of active gravitational mass M situated at the origin of the coordinate system. Suppose that we are given an arbitrary number N of point bodies, and that we assign to each one a label $A = 1, 2, \cdots, N$. The mass and position of each body are then denoted M_A and $\boldsymbol{r}_A(t)$, respectively. If we *assume* that the total Newtonian potential U is a linear superposition of the individual potentials U_A created by each body, we have that the potential at position $\boldsymbol{x}$ is given by

$$U = \sum_A U_A = G \sum_A \frac{M_A}{|\boldsymbol{x} - \boldsymbol{r}_A|}. \tag{1.11}$$

The generalization of this relation to a continuous distribution of matter is straightforward. We convert the discrete sum $\sum_A M_A$ to a continuous integral $\int d^3x' \rho(t, \boldsymbol{x}')$, and we replace the discrete positions $\boldsymbol{r}_A$ with the continuous integration variable $\boldsymbol{x}'$. The result is

$$U(t, \boldsymbol{x}) = G \int \frac{\rho(t, \boldsymbol{x}')}{|\boldsymbol{x} - \boldsymbol{x}'|} d^3x', \tag{1.12}$$

one of the key defining equations for the Newtonian potential. The integral can be evaluated as soon as the density field $\rho(t, \boldsymbol{x}')$ is specified, regardless of whether ρ is a proper solution to the remaining fluid equations. As such, Eq. (1.12) gives U as a *functional* of an arbitrary function ρ. The potential, however, will be physically meaningful only when ρ itself is physically meaningful, which means that it must be a proper solution to the continuity and Euler equations.

The integral equation (1.12) can easily be transformed into a differential equation for the Newtonian potential U. The transformation relies on the identity

$$\nabla^2 \frac{1}{|\boldsymbol{x} - \boldsymbol{x}'|} = -4\pi \delta(\boldsymbol{x} - \boldsymbol{x}') , \tag{1.13}$$

in which $\delta(\boldsymbol{x} - \boldsymbol{x}') := \delta(x - x')\delta(y - y')\delta(z - z')$ is a three-dimensional delta function defined by the properties

$$\delta(\boldsymbol{x} - \boldsymbol{x}') = 0 \qquad \text{when } \boldsymbol{x} \neq \boldsymbol{x}', \tag{1.14a}$$

$$f(\boldsymbol{x})\delta(\boldsymbol{x} - \boldsymbol{x}') = f(\boldsymbol{x}')\delta(\boldsymbol{x} - \boldsymbol{x}') \qquad \text{for any smooth function } f(\boldsymbol{x}), \tag{1.14b}$$

$$\int \delta(\boldsymbol{x} - \boldsymbol{x}')\, d^3x' = 1 \qquad \text{for any domain of integration that encloses } \boldsymbol{x}. \tag{1.14c}$$

These properties further imply that $\delta(\boldsymbol{x}' - \boldsymbol{x}) = \delta(\boldsymbol{x} - \boldsymbol{x}')$. The identity of Eq. (1.13) is derived in Box 1.2. If we apply the Laplacian operator on both sides of Eq. (1.12) and exchange the operations of integration and differentiation on the right-hand side, we obtain

$$\begin{aligned} \nabla^2 U &= G \int \rho(t, \boldsymbol{x}') \nabla^2 \frac{1}{|\boldsymbol{x} - \boldsymbol{x}'|}\, d^3x' \\ &= -4\pi G \int \rho(t, \boldsymbol{x}')\delta(\boldsymbol{x} - \boldsymbol{x}')\, d^3x' \\ &= -4\pi G\rho(t, \boldsymbol{x}) ; \end{aligned}$$

the identity was used in the second step, and the properties of the delta function displayed in Eq. (1.14) allowed us to evaluate the integral. The end result is Poisson's equation,

$$\nabla^2 U = -4\pi G\rho , \tag{1.15}$$

whose formulation was anticipated in Eq. (1.8).

It is possible to proceed in the opposite direction, and show that Eq. (1.12) provides a solution to Poisson's equation (1.15). A powerful tool in the integration of differential equations is the *Green's function* $G(\boldsymbol{x}, \boldsymbol{x}')$, a function of a field point $\boldsymbol{x}$ and a source point $\boldsymbol{x}'$. In the specific context of Poisson's equation, the Green's function is required to be a solution to

$$\nabla^2 G(\boldsymbol{x}, \boldsymbol{x}') = -4\pi \delta(\boldsymbol{x} - \boldsymbol{x}') , \tag{1.16}$$

which is recognized as a specific case of the general differential equation, corresponding to a point mass situated at $\boldsymbol{x}'$. Armed with such an object, a formal solution to Eq. (1.15) can be expressed as

$$U(t, \boldsymbol{x}) = G \int G(\boldsymbol{x}, \boldsymbol{x}')\rho(t, \boldsymbol{x}')\, d^3x' ; \tag{1.17}$$

Box 1.2

Proof that $\nabla^2|\boldsymbol{x}-\boldsymbol{x}'|^{-1} = -4\pi\,\delta(\boldsymbol{x}-\boldsymbol{x}')$

To simplify the proof of Eq. (1.13) we set $\boldsymbol{x}' = \boldsymbol{0}$ without loss of generality; this can always be achieved by a translation of the coordinate system. This gives rise to the simpler equation

$$\nabla^2 r^{-1} = -4\pi\,\delta(\boldsymbol{x})\,, \tag{1}$$

with $r := |\boldsymbol{x}|$.

We first show that $\nabla^2 r^{-1} = 0$ whenever $\boldsymbol{x} \neq \boldsymbol{0}$. Derivatives of r^{-1} can be evaluated with the help of the identities

$$\frac{\partial r}{\partial x^j} = n_j\,, \qquad \frac{\partial n_j}{\partial x^k} = \frac{\partial n_k}{\partial x^j} = \frac{1}{r}\big(\delta_{jk} - n_j n_k\big)\,,$$

where $x^j := (x, y, z)$ is a component notation for the vector $\boldsymbol{x}$, $n^j := x^j/r$, and δ_{jk} is the Kronecker delta, equal to one when $j = k$ and zero otherwise. These equations hold provided that $r \neq 0$. According to this we have that

$$\frac{\partial}{\partial x^j} r^{-1} = -\frac{1}{r^2} n_j$$

and

$$\frac{\partial^2}{\partial x^j \partial x^k} r^{-1} = \frac{1}{r^3}\big(3n_j n_k - \delta_{jk}\big)\,.$$

Because $\boldsymbol{n}$ is a unit vector, it follows that $\nabla^2 r^{-1} = 0$ whenever $r \neq 0$.

To handle the special case $r = 0$ we introduce the vector $\boldsymbol{j} := \boldsymbol{\nabla} r^{-1}$ and write the left-hand side of Eq. (1) as $\boldsymbol{\nabla} \cdot \boldsymbol{j}$. Integrating this over a volume V bounded by a spherical surface S of radius η, we obtain

$$\int_V \boldsymbol{\nabla} \cdot \boldsymbol{j}\, d^3x = \oint_S \boldsymbol{j} \cdot d\boldsymbol{S}$$

by virtue of Gauss's theorem. Here $d\boldsymbol{S}$ is an outward-directed surface element on S, which can be expressed as $d\boldsymbol{S} = \boldsymbol{n}\eta^2\, d\Omega$, with $d\Omega$ denoting an element of solid angle centered at $\boldsymbol{n}$. The vector $\boldsymbol{j}$ is equal to $-\eta^{-2}\boldsymbol{n}$ on S, and evaluating the surface integral returns -4π.

Because $\nabla^2 r^{-1}$ vanishes when $\boldsymbol{x} \neq 0$ and integrates to -4π whenever the integration domain encloses $\boldsymbol{x} = \boldsymbol{0}$, we conclude that it is distributionally equal to $-4\pi\,\delta(\boldsymbol{x})$. The proof is complete.

the steps involved in establishing that this U is indeed a solution to Poisson's equation are identical to those that previously led us to Eq. (1.15) from Eq. (1.12). The difference is that in the earlier derivation the identity of the Green's function was already known. In the approach described here, the result follows simply by virtue of Eq. (1.16). It is not difficult, of course, to identify the Green's function: comparison with Eq. (1.13) allows us to write

$$G(\boldsymbol{x}, \boldsymbol{x}') = \frac{1}{|\boldsymbol{x} - \boldsymbol{x}'|}\,. \tag{1.18}$$

Not surprisingly, the Green's function represents the potential of a point mass situated at $\boldsymbol{x}'$.

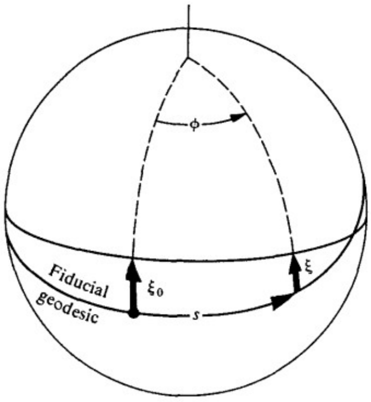
Figure 1.10.
Curvature as manifested in the "acceleration of the separation" of two nearby geodesics. Two geodesics, originally parallel, and separated by the distance ("geodesic deviation") ξ_0, are no longer parallel when followed a distance s. The separation is $\xi = \xi_0 \cos\phi = \xi_0 \cos(s/a)$, where a is the radius of the sphere. The separation follows the equation of simple harmonic motion, $d^2\xi/ds^2 + (1/a^2)\,\xi = 0$ ("equation of geodesic deviation").

The direction of the separation vector, $\boldsymbol{\xi}$, is fixed fully by its orthogonality to the fiducial geodesic. Hence, no reference to the direction of $\boldsymbol{\xi}$ is needed or used in the equation of geodesic deviation: only the magnitude ξ of $\boldsymbol{\xi}$ appears there, and only the magnitude, not direction, of the relative acceleration appears.



In a space of more than two dimensions, an equation of the same general form applies, with several differences. In two dimensions the *direction* of acceleration of one geodesic relative to a nearby, fiducial geodesic is fixed uniquely by the demand that their separation vector, $\boldsymbol{\xi}$, be perpendicular to the fiducial geodesic (see Figure 1.10). Not so in three dimensions or higher. There $\boldsymbol{\xi}$ can remain perpendicular to the fiducial geodesic but rotate about it (Figure 1.11). Thus, to specify the relative acceleration uniquely, one must give not only its magnitude, but also its direction.

The relative acceleration in three dimensions and higher, then, is a vector. Call it "$D^2\boldsymbol{\xi}/ds^2$," and call its four components "$D^2\xi^\alpha/ds^2$." Why the capital D? Why not "$d^2\xi^\alpha/ds^2$"? Because our coordinate system is completely arbitrary (cf. §1.2). The twisting and turning of the coordinate lines can induce changes from point to point in the components ξ^α of $\boldsymbol{\xi}$, even if the vector $\boldsymbol{\xi}$ is not changing at all. Consequently, the accelerations of the components $d^2\xi^\alpha/ds^2$ are generally not equal to the components $D^2\xi^\alpha/ds^2$ of the acceleration!

How, then, in curved spacetime can one determine the components $D^2\xi^\alpha/ds^2$ of the relative acceleration? By a more complicated version of the equation of geodesic deviation (1.6). Differential geometry (Part III of this book) provides us with a geometrical object called the *Riemann curvature tensor*, "***Riemann***." ***Riemann*** is

Curvature is characterized by Riemann tensor

(*continued on page 34*)

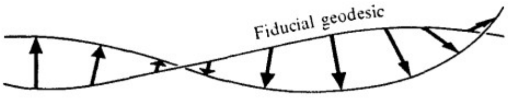


Figure 1.11.
The separation vector $\boldsymbol{\xi}$ between two geodesics in a curved three-dimensional manifold. Here $\boldsymbol{\xi}$ can not only change its length from point to point, but also rotate at a varying rate about the fiducial geodesic. Consequently, the relative acceleration of the geodesics must be characterized by a direction as well as a magnitude: it must be a vector, $D^2\boldsymbol{\xi}/ds^2$.

Box 1.6 CURVATURE OF WHAT?

Nothing seems more attractive at first glance than the idea that gravitation is a manifestation of the curvature of space (A), and nothing more ridiculous at a second glance (B). How can the tracks of a ball and of a bullet be curved so differently if that curvature arises from the geometry of space? No wonder that great Riemann did not give the world a geometric theory of gravity. Yes, at the age of 28 (June 10, 1854) he gave the world the mathematical machinery to define and calculate curvature (metric and Riemannian geometry). Yes, he spent his dying days at 40 working to find a unified account of electricity and gravitation. But if there was one reason more than any other why he failed to make the decisive connection between gravitation and curvature, it was this, that he thought of space and the curvature of space, not of spacetime and the curvature of spacetime. To make that forward step took the forty years to special relativity (1905: time on the same footing as space) and then another ten years (1915: general relativity). Depicted in spacetime (C), the tracks of ball and bullet appear to have comparable curvature. In fact, however, neither track has any curvature at all. They both look curved in (C) only because one has forgotten that the spacetime they reside in is itself curved—curved precisely enough to make these tracks the straightest lines in existence ("geodesics").

If it is at first satisfying to see curvature, and curvature of spacetime at that, coming to the fore in so direct a way, then a little more reflection produces a renewed sense of concern. Curvature with respect to what? Not with respect to the labo-

Photograph of stars when sun swims elsewhere

A. Bending of light by the sun depicted as a consequence of the curvature of space near the sun. Ray of light pursues geodesic, but geometry in which it travels is curved (actual travel takes place in spacetime rather than space; correct deflection is twice that given by above elementary picture). Deflection inversely proportional to angular separation between star and center of sun. See Box 40.1 for actual deflections observed at time of an eclipse.

ratory. The earth-bound laboratory has no simple status whatsoever in a proper discussion. First, it is no Lorentz frame. Second, even to mention the earth makes one think of an action-at-a-distance version of gravity (distance from center of earth to ball or bullet). In contrast, it was the whole point of Einstein that physics looks simple only when analyzed locally. To look at local physics, however, means to compare one geodesic of one test particle with geodesics of other test particles traveling (1) nearby with (2) nearly the same directions and (3) nearly the same speeds. Then one can "look at the separations between these nearby test particles and from the second time-rate of change of these separations and the 'equation of geodesic deviation' (equation 1.8) read out the curvature of spacetime."

the higher-dimensional analog of the Gaussian curvature R of our apple's surface. ***Riemann*** is the mathematical embodiment of the bends and warps in spacetime. And ***Riemann*** is the agent by which those bends and warps (curvature of spacetime) produce the relative acceleration of geodesics.

Riemann, like the metric tensor $\boldsymbol{g}$ of Box 1.3, can be thought of as a family of machines, one machine residing at each event in spacetime. Each machine has three slots for the insertion of three vectors:

$$\boldsymbol{Riemann}\;(\overset{\text{slot 1}}{\downarrow}\quad,\quad\overset{\text{slot 2}}{\downarrow}\quad,\quad\overset{\text{slot 3}}{\downarrow}).$$

Choose a fiducial geodesic (free-particle world line) passing through an event $\mathscr{Q}$, and denote its unit tangent vector (particle 4-velocity) there by

$$\boldsymbol{u} = \boldsymbol{dx}/d\tau;\ \text{components},\ u^\alpha = dx^\alpha/d\tau. \tag{1.7}$$

Choose another, neighboring geodesic, and denote by $\boldsymbol{\xi}$ its perpendicular separation from the fiducial geodesic. Then insert $\boldsymbol{u}$ into the first slot of ***Riemann*** at $\mathscr{Q}$, $\boldsymbol{\xi}$ into the second slot, and $\boldsymbol{u}$ into the third. ***Riemann*** will grind for awhile; then out will pop a new vector,

$$\boldsymbol{Riemann}\;(\boldsymbol{u}, \boldsymbol{\xi}, \boldsymbol{u}).$$

Riemann tensor, through equation of geodesic deviation, produces relative accelerations

The equation of geodesic deviation states that this new vector is the negative of the relative acceleration of the two geodesics:

$$D^2\boldsymbol{\xi}/d\tau^2 + \boldsymbol{Riemann}\;(\boldsymbol{u}, \boldsymbol{\xi}, \boldsymbol{u}) = 0. \tag{1.8}$$

The Riemann tensor, like the metric tensor (Box 1.3), and like all other tensors, is a linear machine. The vector it puts out is a linear function of each vector inserted into a slot:

$$\begin{aligned}&\boldsymbol{Riemann}\;(2\boldsymbol{u}, a\boldsymbol{w} + b\boldsymbol{v}, 3\boldsymbol{r})\\ &= 2 \times a \times 3\;\boldsymbol{Riemann}\;(\boldsymbol{u}, \boldsymbol{w}, \boldsymbol{r}) + 2 \times b \times 3\;\boldsymbol{Riemann}\;(\boldsymbol{u}, \boldsymbol{v}, \boldsymbol{r}).\end{aligned} \tag{1.9}$$

Consequently, in any coordinate system the components of the vector put out can be written as a "trilinear function" of the components of the vectors put in:

$$\boldsymbol{r} = \boldsymbol{Riemann}\;(\boldsymbol{u}, \boldsymbol{v}, \boldsymbol{w}) \Longleftrightarrow r^\alpha = R^\alpha{}_{\beta\gamma\delta}\, u^\beta\, v^\gamma\, w^\delta. \tag{1.10}$$

(Here there is an implied summation on the indices β, γ, δ; cf. Box 1.1.) The $4 \times 4 \times 4 \times 4 = 256$ numbers $R^\alpha{}_{\beta\gamma\delta}$ are called the "components of the Riemann tensor in the given coordinate system." In terms of components, the equation of geodesic deviation states

$$\frac{D^2\xi^\alpha}{d\tau^2} + R^\alpha{}_{\beta\gamma\delta}\frac{dx^\beta}{d\tau}\xi^\gamma\frac{dx^\delta}{d\tau} = 0. \tag{1.8$'$}$$

In Einstein's geometric theory of gravity, this equation of geodesic deviation summarizes the entire effect of geometry on matter. It does for gravitation physics what the Lorentz force equation,

Equation of geodesic deviation is analog of Lorentz force law

$$\frac{D^2x^\alpha}{d\tau^2} - \frac{e}{m}F^\alpha{}_\beta\frac{dx^\alpha}{d\tau} = 0, \tag{1.11}$$

does for electromagnetism. See Box 1.7.

The units of measurement of the curvature are cm^{-2} just as well in spacetime as on the surface of the apple. Nothing does so much to make these units stand out clearly as to express mass in "geometrized units":

Geometrized units

$$\begin{aligned} m(\mathrm{cm}) &= (G/c^2)m_{\mathrm{conv}}(\mathrm{g}) \\ &= (0.742 \times 10^{-28}\ \mathrm{cm/g})m_{\mathrm{conv}}(\mathrm{g}). \end{aligned} \tag{1.12}$$

This conversion from grams to centimeters by means of the ratio

$$G/c^2 = 0.742 \times 10^{-28}\ \mathrm{cm/g}$$

is completely analogous to converting from seconds to centimeters by means of the ratio

$$c = \frac{9.4605460000 \times 10^{17}\ \mathrm{cm}}{31{,}556{,}925.974\ \mathrm{sec}}$$

(see end of §1.5). The sun, which in conventional units has $m_{\mathrm{conv}} = 1.989 \times 10^{33}$ g, has in geometrized units a mass $m = 1.477$ km. Box 1.8 gives further discussion.

Components of Riemann tensor evaluated from relative accelerations of slowly moving particles

Using geometrized units, and using the Newtonian theory of gravity, one can readily evaluate nine of the most interesting components of the Riemann curvature tensor near the Earth or the sun. The method is the gravitational analog of determining the electric field strength by measuring the acceleration of a slowly moving test particle. Consider the separation between the geodesics of two nearby and slowly moving ($v \ll c$) particles at a distance r from the Earth or sun. In the standard, nearly inertial coordinates of celestial mechanics, all components of the 4-velocity of the

Box 1.8 GEOMETRIZED UNITS

Throughout this book, we use "geometrized units," in which the speed of light c, Newton's gravitational constant G, and Boltzman's constant k are all equal to unity. The following alternative ways to express the number 1.0 are of great value:

$$1.0 = c = 2.997930 \cdots \times 10^{10}\ \mathrm{cm/sec}$$

$$1.0 = G/c^2 = 0.7425 \times 10^{-28}\ \mathrm{cm/g};$$

$$1.0 = G/c^4 = 0.826 \times 10^{-49}\ \mathrm{cm/erg};$$

$$1.0 = Gk/c^4 = 1.140 \times 10^{-65}\ \mathrm{cm/K};$$

$$1.0 = c^2/G^{1/2} = 3.48 \times 10^{24}\ \mathrm{cm/gauss^{-1}}.$$

One can multiply a factor of unity, expressed in any one of these ways, into any term in any equation without affecting the validity of the equation. Thereby one can convert one's units of measure from grams to centimeters to seconds to ergs to . . . . For example:

$$\begin{aligned}\text{Mass of sun} = M_\odot &= 1.989 \times 10^{33}\ \mathrm{g}\\ &= (1.989 \times 10^{33}\, g) \times (G/c^2)\\ &= 1.477 \times 10^{5}\ \mathrm{cm}\\ &= (1.989 \times 10^{33}\, g) \times (c^2)\\ &= 1.788 \times 10^{54}\ \mathrm{ergs}.\end{aligned}$$

The standard unit, in terms of which everything is measured in this book, is centimeters. However, occasionally conventional units are used; in such cases a subscript "conv" is sometimes, but not always, appended to the quantity measured:

$$M_{\odot\mathrm{conv}} = 1.989 \times 10^{33}\ \mathrm{g}.$$

fiducial test particle can be neglected except $dx^0/d\tau = 1$. The space components of the equation of geodesic deviation read

$$d^2\xi^k/d\tau^2 + R^k{}_{0j0}\xi^j = 0. \tag{1.13}$$

Comparing with the conclusions of Newtonian theory, equations (1.5), we arrive at the following information about the curvature of spacetime near a center of mass:

$$\begin{Vmatrix} R^{\hat{x}}{}_{\hat{0}\hat{x}\hat{0}} & R^{\hat{y}}{}_{\hat{0}\hat{x}\hat{0}} & R^{\hat{z}}{}_{\hat{0}\hat{x}\hat{0}} \\ R^{\hat{x}}{}_{\hat{0}\hat{y}\hat{0}} & R^{\hat{y}}{}_{\hat{0}\hat{y}\hat{0}} & R^{\hat{z}}{}_{\hat{0}\hat{y}\hat{0}} \\ R^{\hat{x}}{}_{\hat{0}\hat{z}\hat{0}} & R^{\hat{y}}{}_{\hat{0}\hat{z}\hat{0}} & R^{\hat{z}}{}_{\hat{0}\hat{z}\hat{0}} \end{Vmatrix} \begin{matrix} = \\ = \\ = \end{matrix} \begin{Vmatrix} m/r^3 & 0 & 0 \\ 0 & m/r^3 & 0 \\ 0 & 0 & -2m/r^3 \end{Vmatrix} \tag{1.14}$$

(units cm^{-2}). Here and henceforth the caret or "hat" is used to indicate the components of a vector or tensor in a local Lorentz frame of reference ("physical components," as distinguished from components in a general coordinate system). Einstein's theory will determine the values of the other components of curvature (e.g., $R^{\hat{x}}{}_{\hat{z}\hat{x}\hat{z}} = -m/r^3$); but these nine terms are the ones of principal relevance for many applications of gravitation theory. They are analogous to the components of the electric field in the Lorentz equation of motion. Many of the terms not evaluated are analogous to magnetic field components—ordinarily weak unless the source is in rapid motion.

This ends the survey of the effect of geometry on matter ("effect of curvature of apple in causing geodesics to cross"—especially great near the dimple at the top, just as the curvature of spacetime is especially large near a center of gravitational attraction). Now for the effect of matter on geometry ("effect of stem of apple in causing dimple")!

§1.7. EFFECT OF MATTER ON GEOMETRY

> *The weight of any heavy body of known weight at a particular distance from the center of the world varies according to the variation of its distance therefrom; so that as often as it is removed from the center, it becomes heavier, and when brought near to it, is lighter. On this account, the relation of gravity to gravity is as the relation of distance to distance from the center.*
>
> AL KHĀZINĪ (*Merv, A.D. 1115*), *Book of the Balance of Wisdom*

Figure 1.12 shows a sphere of the same density, $\rho = 5.52$ g/cm^3, as the average density of the Earth. A hole is bored through this sphere. Two test particles, A and B, execute simple harmonic motion in this hole, with an 84-minute period. Therefore their geodesic separation $\boldsymbol{\xi}$, however it may be oriented, undergoes a simple periodic motion with the same 84-minute period:

$$d^2\xi^j/d\tau^2 = -\left(\frac{4\pi}{3}\rho\right)\xi^j, \qquad j = x \text{ or } y \text{ or } z. \tag{1.15}$$

Thereby conclude that the general relativistic line element, accurate to linearized order, is

$$ds^2 = -(1 - 2M/r)\,dt^2 + (1 + 2M/r)(dr^2 + r^2\,d\theta^2 + r^2\sin^2\theta\,d\phi^2).$$

(c) Derive this general, static, spherically symmetric, Lorentz-gauge, vacuum solution to the linearized field equations from scratch, working entirely in spherical coordinates. [*Hint:* As discussed at the end of Box 18.2, $\eta_{\mu\nu}$ in equation (18.8c) must be replaced by $g_{\mu\nu\,\text{flat}}$; and in the field equations and gauge conditions (18.8a, b), all commas (partial derivatives) must be replaced by covariant derivatives, whose connection coefficients come from $g_{\mu\nu\,\text{flat}}$.]
(d) Calculate the Riemann curvature tensor for this gravitational field. The answer should agree with equation (1.14).

---

§18.2. GRAVITATIONAL WAVES

Linearized theory and electromagnetic theory compared

The gauge conditions and field equations (18.8a, b) of linearized theory bear a close resemblance to the equations of electromagnetic theory in Lorentz gauge and flat spacetime,

$$A^{\alpha}{}_{,\alpha} = 0, \tag{18.10a}$$

$$-A^{\mu}{}_{,\alpha}{}^{\alpha} = 4\pi J^{\mu}. \tag{18.10b}$$

They differ only in the added index ($h^{\mu\nu}$ versus A^{μ}, $T^{\mu\nu}$ versus J^{μ}). Consequently, from past experience with electromagnetic theory, one can infer much about linearized gravitation theory.

For example, the field equations (18.8b) must have gravitational-wave solutions. The analog of the electromagnetic plane wave

$$A^x = A^x(t-z), \qquad A^y = A^y(t-z), \qquad A^z = 0, \qquad A^0 = 0,$$

Plane gravitational waves

will be the gravitational plane wave

$$\begin{gathered} \bar{h}^{xx} = \bar{h}^{xx}(t-z), \qquad \bar{h}^{xy} = \bar{h}^{xy}(t-z), \qquad \bar{h}^{yy} = \bar{h}^{yy}(t-z), \\ \bar{h}^{\mu 0} = \bar{h}^{\mu z} = 0 \text{ for all } \mu. \end{gathered} \tag{18.11}$$

Although a detailed study of such waves will be delayed until Chapters 35–37, some properties of these waves are explored in the exercises at the end of the next section.

§18.3. EFFECT OF GRAVITY ON MATTER

How to analyze effects of weak gravity on matter

The effects of weak gravitational fields on matter can be computed by using the linearized metric (18.1) and Christoffel symbols (18.2) in the appropriate equations of motion—i.e., in the geodesic equation (for the motion of particles or light rays), in the hydrodynamic equations (for fluid matter), in Maxwell's equations (for electromagnetic waves), or in the equation $\boldsymbol{\nabla} \cdot \boldsymbol{T} = 0$ for the total stress-energy tensor of whatever fields and matter may be present. Exercises 18.5, 18.6 and 18.7 provide examples, as do the Newtonian-limit calculations in exercises 16.1 and 16.4, and in §17.4. If, however, the lowest-order (linearized) gravitational "forces" (Christoffel-symbol terms) have a significant influence on the motion of the sources of the gravitational field, one finds that the linearized field equation (18.7) is inadequate, and better approximations to Einstein's equations must be considered. [Thus emission of gravitational waves by a mechanically or electrically driven oscillator falls within the scope of linearized theory, but emission by a double-star system, or by stellar oscillations that gravitational forces maintain, will require discussion of nonlinear terms (gravitational "stress-energy") in the Einstein equations; see §§36.9 to 36.11.]

The above conclusions follow from a consideration of conservation laws associated with the linearized field equation. Just as the electromagnetic equations (18.10a, b) guarantee charge conservation

$$J^{\mu}{}_{,\mu} = 0, \qquad \int_{\text{all space}} J^0(t, \boldsymbol{x})\, dx\, dy\, dz \equiv Q = \text{const},$$

Conservation of 4-momentum and angular momentum in linearized theory

so the gravitational equations (18.8a, b) guarantee conservation of the total 4-momentum and angular momentum of any body bounded by vacuum:

$$T^{\mu\nu}{}_{,\nu} = 0, \tag{18.12a}$$

$$\int_{\text{body}} T^{\mu 0}(t, \boldsymbol{x})\, dx\, dy\, dz \equiv P^{\mu} = \text{const}; \tag{18.12b}$$

$$(x^{\alpha} T^{\beta\mu} - x^{\beta} T^{\alpha\mu})_{,\mu} = 0, \tag{18.13a}$$

$$\int_{\text{body}} (x^{\alpha} T^{\beta 0} - x^{\beta} T^{\alpha 0})\, dx\, dy\, dz \equiv J^{\alpha\beta} = \text{const}. \tag{18.13b}$$

(See §5.11 for the basic properties of angular momentum in special relativity. The angular momentum here is calculated relative to the origin of the coordinate system.) Now it is important that the stress-energy components $T^{\mu\nu}$, which appear in the linearized field equations (18.7) and in these conservation laws, are precisely the components one would calculate using special relativity (with $g_{\mu\nu} = \eta_{\mu\nu}$). As a result, the energy-momentum conservation formulated here contains no contributions or effects of gravity! From this one sees that linearized theory assumes that gravitational forces do no significant work. For example, energy losses due to gravitational radiation-damping forces are neglected by linearized theory. Similarly, conservation of 4-momentum P^{μ} for each of the bodies acting as sources of $h_{\mu\nu}$ means that each body moves along a geodesic of $\eta_{\mu\nu}$ (straight lines in the nearly Lorentz coordinate system) rather than along a geodesic of $g_{\mu\nu} = \eta_{\mu\nu} + h_{\mu\nu}$. Thus, linearized theory can be used to calculate the motion of test particles and fields, using $g_{\mu\nu} = \eta_{\mu\nu} + h_{\mu\nu}$; but to include gravitational corrections to the motion of the sources themselves—to allow them to satisfy $T^{\mu\nu}{}_{;\nu} = 0$ rather than $T^{\mu\nu}{}_{,\nu} = 0$—one must reinsert into the field equations the nonlinear terms that linearized theory discards. (See, e.g., Chapter 20 on conservation laws; §§36.9–36.11 on the generation of gravitational waves and radiation reaction; and Chapter 39 on the post-Newtonian approximation.)

Limit on validity of linearized theory: gravity must not affect motions of sources significantly

The energy, momentum, and angular momentum radiated by gravitational waves in linearized theory can be calculated by special-relativistic methods analogous to those used in electromagnetic theory for electromagnetic waves [Fiertz and Pauli (1939)], but it will be more informative and powerful to use a fully gravitational approach (Chapters 35 and 36).

EXERCISES

Exercise 18.4. SPACETIME CURVATURE FOR A PLANE GRAVITATIONAL WAVE

Calculate the components of the Riemann curvature tensor [equations (18.9)] for the gravitational plane wave (18.11). [*Answer:*

$$R_{x0x0} = -R_{y0y0} = -R_{x0xz} = +R_{y0yz} = +R_{xzxz} = -R_{yzyz} = -\frac{1}{4}(\bar{h}_{xx} - \bar{h}_{yy})_{,tt};$$

$$R_{x0y0} = -R_{x0yz} = +R_{xzyz} = -R_{xzy0} = -\frac{1}{2}\bar{h}_{xy,tt};$$

all other components vanish except those obtainable from the above by the symmetries $R_{\alpha\beta\gamma\delta} = R_{[\alpha\beta][\gamma\delta]} = R_{\gamma\delta\alpha\beta}$.

Exercise 18.5. A PRIMITIVE GRAVITATIONAL-WAVE DETECTOR (see Figure 18.1)

Two beads slide almost freely on a smooth stick; only slight friction impedes their sliding. The stick falls freely through spacetime, with its center moving along a geodesic and its ends attached to gyroscopes, so they do not rotate. The beads are positioned equidistant (distance $\frac{1}{2}\ell$) from the stick's center. Plane gravitational waves [equation (18.11) and exercise 18.4], impinging on the stick, push the beads back and forth ("geodesic deviation"; "tidal gravitational forces"). The resultant friction of beads on stick heats the stick; and the passage of the waves is detected by measuring the rise in stick temperature.* (Of course, this is not the best of all conceivable designs!) Neglecting the effect of friction on the beads' motion, calculate the proper distance separating them as a function of time. [*Hints:* Let $\boldsymbol{\xi}$ be the separation between the beads; and let $\boldsymbol{n} = \boldsymbol{\xi}/|\boldsymbol{\xi}|$ be a unit vector that points along the stick in the stick's own rest frame. Then their separation has magnitude $\ell = \boldsymbol{\xi} \cdot \boldsymbol{n}$. The fact that the stick is nonrotating is embodied in a parallel-transport law for $\boldsymbol{n}$, $\nabla_{\boldsymbol{u}}\boldsymbol{n} = 0$. ("Fermi-Walker transport" of §§6.5, 6.6, and 13.6 reduces to parallel transport, because the stick moves along a geodesic with $\boldsymbol{a} = \nabla_{\boldsymbol{u}}\boldsymbol{u} = 0$.) Thus,

$$d\ell/d\tau = \nabla_{\boldsymbol{u}}(\boldsymbol{\xi} \cdot \boldsymbol{n}) = (\nabla_{\boldsymbol{u}}\boldsymbol{\xi}) \cdot \boldsymbol{n},$$

$$d^2\ell/d\tau^2 = \nabla_{\boldsymbol{u}}\nabla_{\boldsymbol{u}}(\boldsymbol{\xi} \cdot \boldsymbol{n}) = (\nabla_{\boldsymbol{u}}\nabla_{\boldsymbol{u}}\boldsymbol{\xi}) \cdot \boldsymbol{n},$$

where τ is the stick's proper time. But $\nabla_{\boldsymbol{u}}\nabla_{\boldsymbol{u}}\boldsymbol{\xi}$ is produced by the Riemann curvature of the wave (geodesic deviation):

$$\nabla_{\boldsymbol{u}}\nabla_{\boldsymbol{u}}\boldsymbol{\xi} = \text{projection along } \boldsymbol{n} \text{ of } [-\textbf{Riemann}(\ldots, \boldsymbol{u}, \boldsymbol{\xi}, \boldsymbol{u})].$$

(The geodesic-deviation forces perpendicular to the stick, i.e., perpendicular to $\boldsymbol{n}$, are coun-

---

*This thought experiment was devised by Bondi [1957, 1965; Bondi and McCrea (1960)] as a means for convincing skeptics of the reality of gravitational waves.

EXERCISE

Exercise 19.3. GRAVITATIONAL FIELD FAR FROM A STATIONARY, FULLY RELATIVISTIC SOURCE

Derive the line element (19.13) for the special case of a source that is time-independent ($g_{\mu\nu,t} = 0$). This can be a difficult problem, if one does not proceed carefully along the following outlined route. (1) Initially ignore all nonlinearities in the Einstein field equations. The field is weak far from the source. These nonlinearities will be absent from the dominant terms. (2) Calculate the dominant terms using linearized theory in the Lorentz gauge [equations (18.8)]. (3) In particular, write the general solution to the vacuum, time-independent wave equation (18.8b) in the following form involving $n^j \equiv x^j/r \equiv$ (unit vector in radial direction):

$$\begin{aligned}
\bar{h}_{00} &= \frac{A^0}{r} + \frac{B^j n^j}{r^2} + 0\left(\frac{1}{r^3}\right),\\
\bar{h}_{0j} &= \frac{A^j}{r} + \frac{B^{jk} n^k}{r^2} + 0\left(\frac{1}{r^3}\right),\\
\bar{h}_{jk} &= \frac{A^{jk}}{r} + \frac{B^{jkl} n^l}{r^2} + 0\left(\frac{1}{r^3}\right),\\
A^{jk} &= A^{(jk)}, \qquad B^{jkl} = B^{(jk)l}.
\end{aligned} \tag{19.17}$$

(Round brackets denote symmetrization.) (4) Then impose the Lorentz gauge conditions $\bar{h}_{\alpha}{}^{\beta}{}_{,\beta} = 0$ on this general solution, thereby learning

$$\begin{aligned}
&A^j = 0, \qquad A^{jk} = 0,\\
&B^{jk}(\delta^{jk} - 3n^j n^k) = 0,\\
&B^{jkl}(\delta^{kl} - 3n^k n^l) = 0.
\end{aligned} \tag{19.18}$$

(5) Write B^{jk} as the sum of its trace $3B$, its traceless symmetric part S^{jk}, and its traceless antisymmetric part (these are its "irreducible parts"):

$$B^{jk} = B\delta^{jk} + S^{jk} + \epsilon^{jkl}F^l, \qquad S^{jj} = 0. \tag{19.19}$$

Show that any tensor B^{jk} can be put into such a form. Then show that the gauge conditions (19.18) imply $S^{jk} = 0$. (6) Similarly show that any tensor B^{jkl} that is symmetric on its first two indices can be put into the form

$$\begin{aligned}
&B^{jkl} = \delta^{jk}A^l + C^{(j}\delta^{k)l} + \epsilon^{ml(j}E^{k)m} + S^{jkl},\\
&E^{km} \text{ symmetric and traceless, i.e.,} \quad E^{km} = E^{(km)}, \qquad E^{kk} = 0,\\
&S^{jkl} \text{ symmetric and traceless, i.e.,} \quad S^{jkl} = S^{(jkl)},\\
&\qquad S^{jjl} = S^{jkk} = S^{jkj} = 0.
\end{aligned} \tag{19.20}$$

Then show that the gauge conditions (19.18) imply $C^j = -2A^j$ and $E^{km} = S^{jkl} = 0$. (7) Combining all these results, conclude that

$$\begin{aligned}
\bar{h}_{00} &= \frac{A^0}{r} + \frac{B^j n^j}{r^2} + 0\left(\frac{1}{r^3}\right),\\
\bar{h}_{0j} &= \frac{\epsilon^{jkl} n^k F^l}{r^2} + \frac{B n^j}{r^2} + 0\left(\frac{1}{r^3}\right),\\
\bar{h}_{jk} &= \frac{\delta^{jk} A^l n^l - A^j n^k - A^k n^j}{r^2} + 0\left(\frac{1}{r^3}\right).
\end{aligned} \tag{19.21}$$

Then use gauge transformations, which stay within Lorentz gauge, to eliminate B and A^j from $\bar{h}_{0j}$ and $\bar{h}_{jk}$; so

$$\begin{aligned}\bar{h}_{00} &= \frac{A^0}{r} + \frac{(B^j + A^j)n^j}{r^2} + 0\left(\frac{1}{r^3}\right),\\ \bar{h}_{0j} &= \frac{\epsilon^{jkl}n^k F^l}{r^2} + 0\left(\frac{1}{r^3}\right),\\ \bar{h}_{jk} &= 0\left(\frac{1}{r^3}\right).\end{aligned} \tag{19.22}$$

(8) Translate the origin of coordinates so ${x^j}_{\text{new}} = {x^j}_{\text{old}} - (B^j + A^j)/A^0$; in the new coordinate system $\bar{h}_{\alpha\beta}$ has the same form as (19.22), but with $B^j + A^j$ removed. From the resultant $\bar{h}_{\alpha\beta}$, construct the metric and redefine the constants A^0 and F^l to agree with equation (19.13). (9) All linear terms in the metric are now accounted for. The dominant nonlinear terms must be proportional to the square, $(M/r)^2$, of the dominant linear term. The easiest way to get the proportionality constant is to take the Schwarzschild geometry for a fully relativistic, static, spherical source [equation (31.1)], by a change of coordinates put it in the form

$$ds^2 = -\left(\frac{1 - M/2r}{1 + M/2r}\right)^2 dt^2 + \left(1 + \frac{M}{2r}\right)^4 (dx^2 + dy^2 + dz^2) \tag{19.23}$$

(exercise 25.8), and expand it in powers of M/r.

§19.4. MASS AND ANGULAR MOMENTUM OF A CLOSED UNIVERSE

> *"There are no snakes in Ireland."*
>
> Statement of St. Patrick after driving the snakes out of Ireland (legend*)

For a closed universe the total mass-energy M and angular momentum S are undefined and undefinable

There is no such thing as "the energy (or angular momentum, or charge) of a closed universe," according to general relativity, and this for a simple reason. To weigh something one needs a platform on which to stand to do the weighing.

To weigh the sun, one measures the periods and semimajor axes of planetary orbits, and applies Kepler's "1-2-3" law, $M = \omega^2 a^3$. To measure the angular momentum, S, of the sun (a task for space technology in the 1970's or 1980's!), one measures the precession of a gyroscope in a near orbit about the sun, or one examines some other aspect of the "dragging of inertial frames." To determine the electric charge

---

[*] Stokes (1887) and other standard references deny this legend. In part I of Stokes the basic manuscript references are listed, including especially codex manuscript Rawlinson B.512 in 154 folios, in double columns, written by various hands in the fourteenth and fifteenth centuries (*cf. Catalogi codicum manuscriptorum Bibliothecae Bodleianae Partis Quintae Fasciculus Primus*, Oxford, 1862, col. 728–732). In this manuscript, folio 97b.1, line 14, reads in the translation of Stokes, Part I, p. xxx: "as Paradise is without beasts, without a snake, without a lion, without a dragon, without a scorpion, without a mouse, without a frog, so is Ireland in the same manner without any harmful animal, save only the wolf. . ."

with

$$S[q,p]=\int p\,\mathrm{d}q-H(q,p)\,\mathrm{d}t \tag{1.4}$$

the covariance of the relevant Gaussian is a Green's function of the Jacobi operator with boundary conditions determined by the domain of integration. We recall that the Jacobi operator (alias the small disturbance operator, alias the operator of geodetic deviation) is obtained from the second variation of the action. For instance, on the space of paths with values in the configuration space, $q: T\to\mathbb{R}^n$, $T=[t_a,t_b]$, the expansion of the action around the classical path Q is

$$S[Q+q]=S[Q]+(\text{boundary terms})+\tfrac{1}{2}S''[Q]qq+\ldots \tag{1.5}$$

and the Jacobi operator $\mathscr{J}[Q(t)]\equiv\mathscr{J}_t$ is the differential operator (of second-order for Lagrangians that depend quadratically on velocities) defined by

$$S''[Q]qq=\int_{t_a}^{t_b} q(t)(\mathscr{J}_t q(t))\,\mathrm{d}t\equiv\langle q,\mathscr{J}q\rangle. \tag{1.6}$$

On the space of paths (q,p) with values in phase space, $\mathbb{R}^{2n}$, the expansion of the action around the classical path (Q,P) is

$$S[Q+q,P+p]=S[Q,P]+(\text{boundary terms})+\tfrac{1}{2}(q,p)S''[Q,P]\begin{pmatrix}q\\p\end{pmatrix}+\ldots \tag{1.7}$$

and the phase space Jacobi operator is defined by the equation

$$(q,p)S''[Q,P]\begin{pmatrix}q\\p\end{pmatrix}=\int_{t_a}^{t_b}(q(t),p(t))\mathscr{J}_t^{(\text{p.s.})}\begin{pmatrix}q(t)\\p(t)\end{pmatrix}\mathrm{d}t \tag{1.8}$$

where $\mathscr{J}_t^{(\text{p.s.})}$ is a $2n\times 2n$ matrix built up with first-order differential operators.

Although one might expect the configuration space version and the phase space version of the path integrals for simple systems, say systems without constraints, to be totally equivalent, we shall find it not to be so. Even for a free particle in $\mathbb{R}^n$ there is an important difference: given equivalent boundary conditions, the configuration space Jacobi operator may have only positive eigenvalues whereas the corresponding phase space Jacobi operator has both positive and negative eigenvalues. It follows that the Green's function of the configuration space Jacobi operator can be used as a covariance, whereas the Green's function of the corresponding phase space Jacobi operator cannot.†

In the following, we consider the Lagrangian‡

$$L=\tfrac{1}{2}\dot{q}^2-V(q) \tag{1.9}$$

---

† Path integration using Green's functions of the phase space Jacobi operator has been developed in DeWitt-Morette *et al* (1979) and in DeWitt-Morette *et al* (1982). The path integrals in these papers are defined in terms of prodistributions and the non-positivity of the Green's function is not an issue.

‡ See for instance DeWitt-Morette *et al* (1979) for the configuration and phase space Jacobi operators for arbitrary systems.

The Riemann tensor can be defined via

$$R^{\mu}{}_{\nu\rho\sigma}\; e^I_\mu = R^I{}_{J\;\rho\sigma}\; e^J_\nu, \tag{2.90}$$

The Ricci tensor is

$$R_{\mu\nu} \quad = \quad R^I_\mu\; e_{I\nu} \tag{2.91}$$

(R^I_μ is defined in (2.11)), and the energy momentum tensor (see footnote after (2.37))

$$T_{\mu\nu} \quad = \quad T^I_\mu\; e_{I\nu}. \tag{2.92}$$

Using this, the Einstein equations (2.37) read

$$R_{\mu\nu} - \frac{1}{2} g_{\mu\nu}(R+\lambda) = 8\pi G T_{\mu\nu}. \tag{2.93}$$

The Minkowski solution is

$$g_{\mu\nu}(x) = \eta_{\mu\nu}, \tag{2.94}$$

where we see clearly that the spacetime Minkowski metric is nothing but a particular value of the gravitational field. With a straightforward calculation, the action (2.10) reads

$$S[g] = \frac{1}{16\pi G}\int (R+\lambda)\; \sqrt{-\det g}\; d^4x. \tag{2.95}$$

The matter action cannot be written in metric variables.

Riemann geometry. The tensor g equips the spacetime manifold M with a metric structure: it defines a distance between any two points, and this distance is a smooth function on M. (More precisely, it defines a pseudo-metric structure, as distance can be imaginary.) Riemann studied the structure defined by (M, g), called today a riemannian manifold, and defined the Riemann curvature tensor, as a generalization of Gauss theory of curved surfaces to an arbitrary number of dimensions. Riemann presented this mathematical theory as a general theory of "geometry" that generalizes Euclidean geometry. Einstein utilized this mathematical theory for describing the physical dynamics of the gravitational field. In retrospect, the reason this was possible is because –as understood by Einstein– the Euclidean structure of the physical space in which we live is determined by the local gravitational field. Therefore elementary physical geometry is simply a description of the local properties of the gravitational field, as revealed by matter (rigid bodies) interacting with it. This point is discussed in more detail below in section 2.2.3.

The basic equations of GR presented in this section do not look too different from the equations of a prerelativistic[9] field theory, such as QED or the standard model. But the similarity can be very misleading. The physical interpretation of a general relativistic theory is very different from the interpretation of a prerelativistic one. In particular, the meaning of the coordinates x^μ is different than in prerelativistic physics, and the gauge invariant observables are not related to the fields as they are in prerelativistic physics.

Understanding the physical meaning of the GR formalism has been a long process. This process has taken decades and perhaps it is not entirely concluded yet. For several decades after Einstein's discovery of the theory, for instance, it was not clear whether or not the theory predicted gravitational waves. The prevailing opinion was that wave solutions were only a coordinate artifact and did not represent physical waves capable of carrying energy and momentum, or, as Bondi put it, capable of "boiling a glass of water". This opinion was wrong of course. Einstein himself got badly wrong on the meaning of the Schwarzshild singularity. Wrong high precision measurements of the Earth-Moon distance have been in the literature for a while, because of a mistake due to a conceptual confusion between physical and coordinate distance. . .

I do not want to give the impression that GR is foggy. On the very contrary, the fact that in all these and similar instances consensus has eventually emerged indicates that the conceptual

---

[9] Recall that in this book "relativistic" means *general* relativistic.

This opinion was wrong of course. Einstein himself got badly wrong on the meaning of the Schwarzshild singularity. Wrong high precision measurements of the Earth-Moon distance have been in the literature for a while, because of a mistake due to a conceptual confusion between physical and coordinate distance...

I do not want to give the impression that GR is foggy. On the very contrary, the fact that in all these and similar instances consensus has eventually emerged indicates that the conceptual structure of GR is secure. But to understand this conceptual structure, to understand how to use the equations of GR correctly and how to relate the quantities appearing in these equations to the numbers measured in the laboratory or observed by the astronomers, is definitely a non-trivial problem. More generally, the problem is to understand what precisely GR says about the world. On the other hand, clarity is this respect is essential if we want to understand the quantum physics of the theory.

---

[9] Recall that in this book "relativistic" means *general* relativistic.

In order to shed light on this problem, it is illuminating to retrace the conceptual path and the problems that led to the discovery of the theory. This is done in the following section 2.2. The impatient reader may skip section 2.2 and jump to section 2.3, where the interpretation of GR is compactly presented (but impatience slows understanding. . .)

and defined the Riemann curvature tensor as a generalization of Gauss' theory of curved surfaces to an arbitrary number of dimensions.

Riemann presented this mathematical theory as a general theory of "geometry" that generalized Euclidean geometry.

Einstein utilized this mathematical theory for describing the physical dynamics of the gravitational field.

Case (d)

Here the contribution to the integral comes entirely from two arbitrary spacelike hypersurfaces, $\mathcal{S}_A$ and $\mathcal{S}_B$, cutting all the way across spacetime. As in cases (a) and (b), the integral form of the conservation law says

Total 4-momentum independent of hypersurface where measured

$$\boldsymbol{p}_{\text{on } \mathcal{S}_A} = \boldsymbol{p}_{\text{on } \mathcal{S}_B}; \tag{5.33}$$

i.e., *the total 4-momentum on a spacelike slice through spacetime is independent of the specific slice chosen*—so long as the energy-momentum flux across the "hypersurface at infinity" connecting $\mathcal{S}_A$ and $\mathcal{S}_B$ is zero.

Case (e)

This case concerns a box whose walls oscillate and accelerate as time passes. The three-dimensional boundary $\partial\mathcal{V}$ is made up of (1) the interior $\mathcal{S}$ of the box, at an initial moment of time $t =$ constant in the box's initial Lorentz frame, taken with nonstandard orientation; (2) the interior $\bar{\mathcal{S}}$ of the box, at $\bar{t} =$ constant in its final Lorentz frame, with standard orientation; (3) the 3-volume $\mathcal{T}$ swept out by the box's two-dimensional faces between the initial and final states, with positive sense oriented outward. The integral conservation law $\int_{\partial\mathcal{V}} \boldsymbol{T} \cdot d^3\boldsymbol{\Sigma} = 0$ says

Change with time of 4-momentum in a box equals flux of 4-momentum across its faces

$$\begin{aligned}\begin{pmatrix}\text{total 4-momentum}\\ \text{in box at } \bar{\mathcal{S}}\end{pmatrix} - \begin{pmatrix}\text{total 4-momentum}\\ \text{in box at } \mathcal{S}\end{pmatrix}&\\ = \begin{pmatrix}\text{total 4-momentum that enters box through}\\ \text{its faces between states } \mathcal{S} \text{ and } \bar{\mathcal{S}}\end{pmatrix}&.\end{aligned} \tag{5.34}$$

§5.9. CONSERVATION OF 4-MOMENTUM: DIFFERENTIAL FORMULATION

Complementary to any "integral conservation law in flat spacetime" is a "differential conservation law" with identical information content. To pass back and forth between them, one can use Gauss's theorem.

Gauss's theorem in four dimensions, applied to the law of 4-momentum conservation, converts the surface integral of $T^{\mu\alpha}$ into a volume integral of $T^{\mu\alpha}{}_{,\alpha}$:

$$0 = \oint_{\partial\mathcal{V}} T^{\mu\alpha}\, d^3\Sigma_\alpha = \int_{\mathcal{V}} T^{\mu\alpha}{}_{,\alpha}\, dt\, dx\, dy\, dz. \tag{5.35}$$

(See Box 5.3 for elementary discussion; Box 5.4 for sophisticated discussion.) If the integral of $T^{\mu\alpha}{}_{,\alpha}$ is to vanish, as demanded, for any and every 4-volume $\mathcal{V}$, then $T^{\mu\alpha}{}_{,\alpha}$ must itself vanish everywhere in spacetime:

Differential conservation law for 4-momentum: $\boldsymbol{\nabla} \cdot \boldsymbol{T} = 0$

$$T^{\mu\alpha}{}_{,\alpha} = 0;\ \text{i.e., } \boldsymbol{\nabla} \cdot \boldsymbol{T} = 0 \text{ everywhere.} \tag{5.36}$$

(*continued on page 152*)

Box 5.3 VOLUME INTEGRALS, SURFACE INTEGRALS, AND GAUSS'S THEOREM IN COMPONENT NOTATION

A. Volume Integrals in Spacetime

1. By analogy with three-dimensional space, the volume of a "hyperparallelepiped" with vector edges $\boldsymbol{A}$, $\boldsymbol{B}$, $\boldsymbol{C}$, $\boldsymbol{D}$ is

$$\text{4-volume} \equiv \Omega \equiv \epsilon_{\alpha\beta\gamma\delta} A^\alpha B^\beta C^\gamma D^\delta = \det \begin{Vmatrix} A^0 & A^1 & A^2 & A^3 \\ B^0 & B^1 & B^2 & B^3 \\ C^0 & C^1 & C^2 & C^3 \\ D^0 & D^1 & D^2 & D^3 \end{Vmatrix}$$

$$= {}^*(\boldsymbol{A} \wedge \boldsymbol{B} \wedge \boldsymbol{C} \wedge \boldsymbol{D}).$$

Here, as for 3-volumes, orientation matters; interchange of any two edges reverses the sign of Ω. The *standard orientation* for any 4-volume is the one which makes Ω positive; thus, $\boldsymbol{e}_0 \wedge \boldsymbol{e}_1 \wedge \boldsymbol{e}_2 \wedge \boldsymbol{e}_3$ has standard orientation if $\boldsymbol{e}_0$ points toward the future and $\boldsymbol{e}_1$, $\boldsymbol{e}_2$, $\boldsymbol{e}_3$ are a righthanded triad.

2. The "volume element" whose edges in a specific, standard-oriented Lorentz frame are

$$A^\alpha = (\Delta t, 0, 0, 0),\ B^\alpha = (0, \Delta x, 0, 0),\ C^\alpha = (0, 0, \Delta y, 0),\ D^\alpha = (0, 0, 0, \Delta z)$$

has a 4-volume, according to the above definition, given by

$$\Delta^4\Omega = \epsilon_{0123}\, \Delta t\, \Delta x\, \Delta y\, \Delta z = \Delta t\, \Delta x\, \Delta y\, \Delta z.$$

3. Thus, the volume integral of a tensor $\boldsymbol{S}$ over a four-dimensional region $\mathcal{V}$ of spacetime, defined as

$$\boldsymbol{M} \equiv \lim_{\left(\substack{\text{number of} \\ \text{elementary} \\ \text{volumes} \\ \to\infty}\right)} \sum_{\left(\substack{\text{elementary} \\ \text{volumes } \mathcal{A} \\ \text{in } \mathcal{V}}\right)} \boldsymbol{S}_{\text{at center of } \mathcal{A}}\, (\text{volume of } \mathcal{A}),$$

can be calculated in a Lorentz frame by

$$M^\alpha{}_{\beta\gamma} = \int_{\mathcal{V}} S^\alpha{}_{\beta\gamma}\, d^4\Omega = \int_{\mathcal{V}} S^\alpha{}_{\beta\gamma}\, dt\, dx\, dy\, dz.$$

Box 5.3 *(continued)*

B. Integrals over 3-Surfaces in Spacetime

1. Introduce arbitrary coordinates a, b, c on the three-dimensional surface. The elementary volume bounded by coordinate surfaces

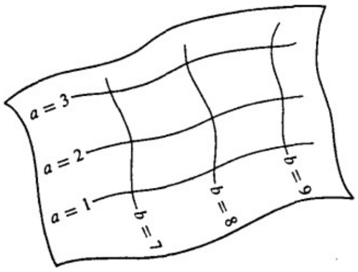
   $$a_0 < a < a_0 + \Delta a, \qquad b_0 < b < b_0 + \Delta b,$$
   $$c_0 < c < c_0 + \Delta c$$

   has edges

   $$A^\alpha = \frac{\partial x^\alpha}{\partial a}\Delta a,\ B^\beta = \frac{\partial x^\beta}{\partial b}\Delta b,\ C^\gamma = \frac{\partial x^\gamma}{\partial c}\Delta c;$$

   so its volume 1-form is

   $$\Delta^3\Sigma_\mu = \epsilon_{\mu\alpha\beta\gamma}\frac{\partial x^\alpha}{\partial a}\frac{\partial x^\beta}{\partial b}\frac{\partial x^\gamma}{\partial c}\Delta a\,\Delta b\,\Delta c.$$



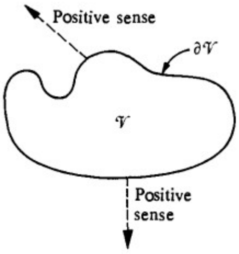
2. The integral of a tensor $\boldsymbol{S}$ over the 3-surface $\mathcal{S}$ thus has components

   $$N^\alpha{}_\beta = \int_{\mathcal{S}} S^\alpha{}_\beta{}^\gamma\, d^3\Sigma_\gamma = \int_{\mathcal{S}} S^\alpha{}_\beta{}^\gamma \epsilon_{\gamma\mu\nu\lambda}\frac{\partial x^\mu}{\partial a}\frac{\partial x^\nu}{\partial b}\frac{\partial x^\lambda}{\partial c}\, da\, db\, dc.$$

   An equivalent formula involving a Jacobian is often used (see exercise 5.5):

   $$N^\alpha{}_\beta = \int_{\mathcal{S}} S^\alpha{}_\beta{}^\gamma \frac{1}{3!}\epsilon_{\gamma\mu\nu\lambda}\frac{\partial(x^\mu, x^\nu, x^\lambda)}{\partial(a, b, c)}\, da\, db\, dc.$$

C. Gauss's Theorem Stated



1. Consider a bounded four-dimensional region of spacetime $\mathcal{V}$ with closed boundary $\partial\mathcal{V}$. Orient the volume 1-forms on $\partial\mathcal{V}$ so that the "positive sense" is away from $\mathcal{V}$.
2. Choose a tensor field $\boldsymbol{S}$. Integrate its divergence over $\mathcal{V}$, and integrate it itself over $\partial\mathcal{V}$. The results must be the same (*Gauss's theorem*):

   $$\int_{\mathcal{V}} S^\alpha{}_\beta{}^\gamma{}_{,\gamma}\, d^4\Omega = \oint_{\partial\mathcal{V}} S^\alpha{}_\beta{}^\gamma\, d^3\Sigma_\gamma.$$

D. Proof of Gauss's Theorem

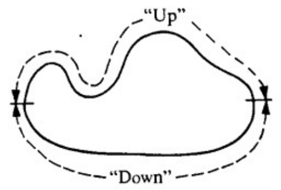
1. The indices α and β of $S^{\alpha}{}_{\beta}{}^{\gamma}$ "go along for a free ride," so one can suppress them from the proof. Then the equation to be derived is

$$\int_{\mathcal{V}} S^{\gamma}{}_{,\gamma}\, dt\, dx\, dy\, dz = \oint_{\partial\mathcal{V}} S^{\gamma}\, d^3\Sigma_{\gamma}.$$

2. Since the integral of a derivative is just the original function, the volume integral of $S^0{}_{,0}$ is

$$\int_{\mathcal{V}} S^0{}_{,0}\, dt\, dx\, dy\, dz$$

$$= \int_{\text{“up”}} S^0\, dx\, dy\, dz - \int_{\text{“down”}} S^0\, dx\, dy\, dz.$$



3. The surface integral $\int_{\partial\mathcal{V}} S^0\, d^3\Sigma_0$ can be reduced to the same set of terms:
   a. Use x, y, z as coordinates on $\partial\mathcal{V}$. On the "up" side, $d^3\Sigma_0$ must be positive to achieve a "positive" sense pointing away from $\mathcal{V}$, so (see part B above)

$$d^3\Sigma_0 = \epsilon_{0\alpha\beta\gamma} \frac{\partial x^{\alpha}}{\partial x} \frac{\partial x^{\beta}}{\partial y} \frac{\partial x^{\gamma}}{\partial z}\, dx\, dy\, dz = \epsilon_{0123}\, dx\, dy\, dz = dx\, dy\, dz.$$

   b. On the "down" side, $d^3\Sigma_0$ must be negative, so

$$d^3\Sigma_0 = -dx\, dy\, dz.$$

   c. Hence,

$$\int_{\partial\mathcal{V}} S^0\, d^3\Sigma_0 = \int_{\text{“up”}} S^0\, dx\, dy\, dz - \int_{\text{“down”}} S^0\, dx\, dy\, dz.$$

4. Equality is proved for the other components in the same manner. Adding components produces the result desired:

$$\int_{\mathcal{V}} S^{\gamma}{}_{,\gamma}\, d^4\Omega = \oint_{\partial\mathcal{V}} S^{\gamma}\, d^3\Sigma_{\gamma}.$$

FOR THE READER WHO HAS STUDIED CHAPTER 4

Box 5.4 I. EVERY INTEGRAL IS THE INTEGRAL OF A FORM.
II. THE THEOREM OF GAUSS IN THE LANGUAGE OF FORMS.

I. *Every integral encountered* in Chapter 5 can be interpreted as *the integral of an exterior differential form.* This circumstance shows up in fourfold and threefold integrals, for example, in the fact that

$$d^4\Omega = \boldsymbol{\varepsilon} = {}^*1 = \varepsilon_{0123}\, \boldsymbol{d}t \wedge \boldsymbol{d}x \wedge \boldsymbol{d}y \wedge \boldsymbol{d}z$$

and

$$d^3\Sigma_\mu = \varepsilon_{\mu|\alpha\beta\gamma|}\, \boldsymbol{d}x^\alpha \wedge \boldsymbol{d}x^\beta \wedge \boldsymbol{d}x^\gamma$$

are basis 4- and 3-forms. (Recall: the indices $\alpha\beta\gamma$ between vertical bars are to be summed only over $0 \leq \alpha < \beta < \gamma \leq 3$.) A more extensive glossary of notations is found in C below.

II. *Gauss's Theorem for a tensor integral* in flat space reads

$$\int_{\mathscr{V}} (\boldsymbol{\nabla} \cdot \boldsymbol{S})\, d^4\Omega = \oint_{\partial\mathscr{V}} \boldsymbol{S} \cdot d\boldsymbol{\Sigma}$$

for any tensor, such as $\boldsymbol{S} = S^\alpha{}_\beta{}^\gamma \boldsymbol{e}_\alpha \otimes \boldsymbol{\omega}^\beta \otimes \boldsymbol{e}_\gamma$ (see Box 5.3 for component form). It is an application of the generalized Stokes Theorem (Box 4.1), and *depends on the fact that the basis vectors* $\boldsymbol{e}_\alpha$ *and* $\boldsymbol{\omega}^\beta$ *of a global Lorentz frame are constants,* i.e., are independent of x. The definitions follow in A; the proof is in B.

A. *Tensor-valued integrals* can be defined in flat spaces because one uses constant basis vectors. Thus one defines

$$\int \boldsymbol{S} \cdot d^3\boldsymbol{\Sigma} = \boldsymbol{e}_\alpha \otimes \boldsymbol{\omega}^\beta \int S^\alpha{}_\beta{}^\gamma\, d^3\Sigma_\gamma$$

for a tensor of the indicated rank. One justifies pulling basis vectors and forms outside the integral sign because they are constants, independent of location in spacetime. Each of the numbers $\int S^\alpha{}_\beta{}^\gamma\, d^3\Sigma_\gamma$ (for $\alpha, \beta = 0, 1, 2, 3$) is then evaluated by substituting *any* properly oriented parametrization of the hypersurface into the 3-form $S^\alpha{}_\beta{}^\gamma\, d^3\Sigma_\gamma$ as described in Box 4.1 (arbitrary curvilinear parametrization in the part of the calculation not involving the "free indices" α and β). In other words, $\boldsymbol{S} \cdot d^3\boldsymbol{\Sigma} = \boldsymbol{e}_\alpha \otimes \boldsymbol{\omega}^\beta \otimes S^\alpha{}_\beta{}^\gamma\, d^3\Sigma_\gamma$ is considered a "tensor-valued 3-form." Under an integral sign, it is contracted with the hyperplane element tangent to the 3-surface $\mathscr{P}(\lambda^1, \lambda^2, \lambda^3)$ of integration to form the integral

$$\begin{aligned}\int \boldsymbol{S} \cdot d^3\boldsymbol{\Sigma} &= \int \left\langle \boldsymbol{S} \cdot d^3\boldsymbol{\Sigma}, \frac{\partial\mathscr{P}}{\partial\lambda^1} \wedge \frac{\partial\mathscr{P}}{\partial\lambda^2} \wedge \frac{\partial\mathscr{P}}{\partial\lambda^3} \right\rangle d\lambda^1\, d\lambda^2\, d\lambda^3 \\ &= \boldsymbol{e}_\alpha \otimes \boldsymbol{\omega}^\beta \int S^\alpha{}_\beta{}^\gamma \varepsilon_{\gamma|\lambda\mu\nu|} \underbrace{\frac{\partial(x^\lambda, x^\mu, x^\nu)}{\partial(\lambda^1, \lambda^2, \lambda^3)}}_{\substack{\text{Jacobian}\\ \text{determinant}}} d\lambda^1\, d\lambda^2\, d\lambda^3.\end{aligned}$$

Although constant basis vectors $\boldsymbol{e}_\alpha$, $\boldsymbol{\omega}^\beta$ derived from rectangular coordinates are essential here, *a completely general parametrization of the hypersurface may be used.*

B. *The proof of Gauss's Theorem* is a computation:

$$\oint_{\partial\mathcal{V}} \boldsymbol{S}\cdot d^3\boldsymbol{\Sigma} = \boldsymbol{e}_\alpha \otimes \boldsymbol{\omega}^\beta \oint_{\partial\mathcal{V}} S^\alpha{}_\beta{}^\gamma\, d^3\Sigma_\gamma \qquad (\boldsymbol{e}_\alpha, \boldsymbol{\omega}^\beta \text{ are constant})$$

$$= \boldsymbol{e}_\alpha \otimes \boldsymbol{\omega}^\beta \int_{\mathcal{V}} \boldsymbol{d}(S^\alpha{}_\beta{}^\gamma\, d^3\Sigma_\gamma) \qquad \text{(Stokes Theorem)}$$

$$= \boldsymbol{e}_\alpha \otimes \boldsymbol{\omega}^\beta \int_{\mathcal{V}} S^\alpha{}_\beta{}^\gamma{}_{,\gamma}\, {}^*1 \qquad \text{(see below)}$$

$$= \int_{\mathcal{V}} (\boldsymbol{\nabla}\cdot\boldsymbol{S})\, d^4\Omega. \qquad \text{(merely notation)}$$

The missing computational step above is

$$\begin{aligned} \boldsymbol{d}(S^\alpha{}_\beta{}^\gamma\, d^3\Sigma_\gamma) &= (\partial S^\alpha{}_\beta{}^\gamma/\partial x^\rho)\, \boldsymbol{d}x^\rho \wedge d^3\Sigma_\gamma \\ &= (\partial S^\alpha{}_\beta{}^\gamma/\partial x^\gamma)\, {}^*1. \end{aligned}$$

Here the first step uses $\boldsymbol{d}(d^3\Sigma_\gamma) = 0$ (which follows from $\varepsilon_{\mu\alpha\beta\gamma} = \text{const}$ in flat spacetime). The second step uses

$$\boldsymbol{d}x^\rho \wedge d^3\Sigma_\gamma = \delta^\rho_\gamma\, {}^*1.$$

[Write the lefthand side of this identity as $\varepsilon_{\gamma|\mu\nu\lambda|}\, \boldsymbol{d}x^\rho \wedge \boldsymbol{d}x^\mu \wedge \boldsymbol{d}x^\nu \wedge \boldsymbol{d}x^\lambda$. The only possible non-zero term in the sum over $\mu\nu\lambda$ is the one with $\mu < \nu < \lambda$ all different from ρ. The righthand side is the value of this term.]

C. *Glossary of notations.*

Charge density 3-form:

$$\begin{aligned} {}^*\boldsymbol{J} &= J^\mu\, d^3\Sigma_\mu = \boldsymbol{J}\cdot d^3\boldsymbol{\Sigma} \\ &= \rlap{$\underbrace{\phantom{J^\mu\varepsilon_{\mu\alpha\beta\gamma}}}_{({}^*J)_{\alpha\beta\gamma}}$}J^\mu \underbrace{\varepsilon_{\mu\alpha\beta\gamma}\, \boldsymbol{d}x^\alpha \wedge \boldsymbol{d}x^\beta \wedge \boldsymbol{d}x^\gamma/3!}_{d^3\Sigma_\mu}. \end{aligned}$$

Maxwell and Faraday 2-forms:

$${}^*\boldsymbol{F} = \frac{1}{2} F^{\mu\nu}\, d^2S_{\mu\nu};$$

$$\boldsymbol{F} = \frac{1}{2} F_{\mu\nu}\, \boldsymbol{d}x^\mu \wedge \boldsymbol{d}x^\nu.$$

Basis 2-forms:

$$\boldsymbol{d}x^\alpha \wedge \boldsymbol{d}x^\beta; \qquad \text{(one way to label)}$$

$$d^2S_{\mu\nu} = \varepsilon_{\mu\nu|\alpha\beta|}\, \boldsymbol{d}x^\alpha \wedge \boldsymbol{d}x^\beta. \qquad \text{(dual way to label)}$$

Energy-momentum density 3-form:

$$\boldsymbol{T}\cdot d^3\boldsymbol{\Sigma} \equiv \boldsymbol{e}_\mu T^{\mu\nu}\, d^3\Sigma_\nu \equiv \overbrace{{}^*\boldsymbol{T};}^{}$$

$$\text{dual on last index, } ({}^*T)^\mu{}_{\alpha\beta\gamma} = T^{\mu\nu}\varepsilon_{\nu\alpha\beta\gamma}.$$

Angular momentum density 3-form:

$$\boldsymbol{\mathcal{J}}\cdot d^3\boldsymbol{\Sigma} \equiv \frac{1}{2}\boldsymbol{e}_\mu \wedge \boldsymbol{e}_\nu\, \mathcal{J}^{\mu\nu\alpha}\, d^3\Sigma_\alpha \equiv {}^*\boldsymbol{\mathcal{J}};$$

$$({}^*\mathcal{J})^{\mu\nu}{}_{\alpha\beta\gamma} = \mathcal{J}^{\mu\nu\lambda}\varepsilon_{\lambda\alpha\beta\gamma}.$$

(In the frame-independent equation $\boldsymbol{\nabla} \cdot \boldsymbol{T} = 0$, one need not worry about which slot of $\boldsymbol{T}$ to take the divergence on; the slots are symmetric, so either can be used.)

The equation $\boldsymbol{\nabla} \cdot \boldsymbol{T} = 0$ is *the differential formulation of the law of 4-momentum conservation*. It is also called the *equation of motion for stress-energy*, because it places constraints on the dynamic evolution of the stress-energy tensor. To examine these constraints for simple systems is to realize the beauty and power of the equation $\boldsymbol{\nabla} \cdot \boldsymbol{T} = 0$.

§5.10. SAMPLE APPLICATIONS OF $\boldsymbol{\nabla} \cdot \boldsymbol{T} = 0$

Newtonian fluid characterized by $|v^j| \ll 1$, $p \ll \rho$

The equation of motion $\boldsymbol{\nabla} \cdot \boldsymbol{T} = 0$ makes contact with the classical (Newtonian) equations of hydrodynamics, when applied to a nearly Newtonian fluid. Such a fluid has low velocities relative to the Lorentz frame used, $|v^j| \ll 1$; and in its rest frame its pressure is small compared to its density of mass-energy, $p/\rho = p/\rho c^2 \ll 1$. For example, the air in a hurricane has

$$|v^j| \sim 100 \text{ km/hour} \sim 3{,}000 \text{ cm/sec} \sim 10^{-7}\, c = 10^{-7} \ll 1,$$

$$\frac{p}{\rho} \sim \frac{1 \text{ atmosphere}}{10^{-3} \text{ g/cm}^3} \sim \frac{10^6 \text{ dynes/cm}^2}{10^{-3} \text{ g/cm}^3} = 10^9 \,\frac{\text{cm}^2}{\text{sec}^2} \sim 10^{-12}\, c^2 = 10^{-12} \ll 1.$$

Stress-energy tensor and equation of motion for a Newtonian fluid

The stress-energy tensor for such a fluid has components

$$T^{00} = (\rho + p)u^0u^0 - p \approx \rho, \tag{5.37a}$$

$$T^{0j} = T^{j0} = (\rho + p)u^0u^j \approx \rho v^j, \tag{5.37b}$$

$$T^{jk} = (\rho + p)u^ju^k + p\,\delta^{jk} \approx \rho v^jv^k + p\,\delta^{jk}; \tag{5.37c}$$

and the equation of motion $\boldsymbol{\nabla} \cdot \boldsymbol{T} = 0$ has components

$$T^{00}{}_{,0} + T^{0j}{}_{,j} = \partial\rho/\partial t + \boldsymbol{\nabla} \cdot (\rho \boldsymbol{v}) = 0 \quad \text{("equation of continuity");} \tag{5.38a}$$

and

$$T^{j0}{}_{,0} + T^{jk}{}_{,k} = \partial(\rho v^j)/\partial t + \partial(\rho v^j v^k)/\partial x^k + \partial p/\partial x^j = 0,$$

or, equivalently (by combining with the equation of continuity),

$$\frac{\partial \boldsymbol{v}}{\partial t} + (\boldsymbol{v} \cdot \boldsymbol{\nabla})\boldsymbol{v} = -\frac{1}{\rho}\boldsymbol{\nabla} p \qquad \text{("Euler's equation").} \tag{5.38b}$$

Box 5.5 derives and discusses these results from the Newtonian viewpoint.

Application of $\boldsymbol{\nabla} \cdot \boldsymbol{T} = 0$ to an electrically charged, vibrating rubber block

As a second application of $\boldsymbol{\nabla} \cdot \boldsymbol{T} = 0$, consider a composite system: a block of rubber with electrically charged beads imbedded in it, interacting with an electromagnetic field. The block of rubber vibrates, and its accelerating beads radiate electromagnetic waves; at the same time, incoming electromagnetic waves push on the beads, altering the pattern of vibration of the block of rubber. The interactions shove 4-momentum back and forth between beaded block and electromagnetic field.

Remarks: (i) There is an alternative proof of the limit in 3.21 which is short and transparent but a bit less elementary, and affords no estimate of the speed of convergence. Let L be the function L_1 of 3.19. For integers $n > N > 0$, $z \in \overline{D}(0, N) \setminus \{0\}$ implies $1 + z/n \in D(1, 1)$. Consequently, by 3.19

$$nL(1 + z/n) = z \cdot \frac{L(1 + z/n) - L(1)}{z/n} \to zL'(1) = z \quad \text{as} \quad n \to \infty,$$

uniformly in such z, whence $(1+z/n)^n = [\exp L(1+z/n)]^n = \exp(nL(1+z/n)) \to \exp(z)$. [Similarly, $(1 + z_n/n)^n \to e^z$ whenever $z_n \to z$.]

(ii) According to 3.21 the numbers $a_n := n!\, n^{-n}$ satisfy $a_{n+1}/a_n = (1 + 1/n)^{-n} \to 1/e$, in view of which 3.9 tells us that $a_n^{1/n} = n^{-1}(n!)^{1/n} \to 1/e$. After a little algebra, involving $n^{-1} \sum_{j=1}^{n} j = \frac{1}{2}(n + 1)$, another interesting feature of e comes to light:

$$\frac{1}{2}e = \lim_{n\to\infty} \frac{\text{Arithmetic Mean of } \{1, 2, \ldots, n\}}{\text{Geometric Mean of } \{1, 2, \ldots, n\}}.$$

(A generalization to means of $\{1^s, 2^s, \ldots, n^s\}$ $(s > -1)$ was proved by different [elementary] means by Xu [2010].)

Although the constant π is ubiquitous in this subject (see Castellanos [1988]), one seldom needs estimates of it finer than (8) and (8)′ in the proof of 3.14. Nevertheless, we will look at a few of the myriad series and integrals by which it can be explicitly calculated.

Theorem 3.22 (Gregory-Leibniz series) $\dfrac{\pi}{4} = \displaystyle\int_0^1 \frac{dx}{1 + x^2} = \sum_{n=0}^{\infty} \frac{(-1)^n}{2n + 1}$.

Proof: The quadratic polynomial $X^2 - i$ has exactly two zeros in $\mathbb{C}$, $\pm(1 + i)/\sqrt{2}$. Since, in the notation of the proof of 3.14,

$$\left[C\left(\frac{\pi}{4}\right) + iS\left(\frac{\pi}{4}\right)\right]^2 = E\left(i\frac{\pi}{4}\right)^2 = E\left(i\frac{\pi}{2}\right) = i$$

and C, S are non-negative in $\left[0, \frac{\pi}{2}\right]$, it must be that

$$C\left(\frac{\pi}{4}\right) = S\left(\frac{\pi}{4}\right) = \frac{1}{\sqrt{2}}. \tag{1}$$

Since C is an even function and is never zero in $[0, \pi/2)$, by definition of π, we may form the function $T := S/C$ on $(-\pi/2, \pi/2)$ and have from equations (5) of the proof of 3.14 that

$$T' = \frac{S'C - SC'}{C^2} = \frac{C^2 + S^2}{C^2} = 1 + (S/C)^2 = 1 + T^2 > 0. \tag{2}$$

Therefore T is strictly increasing. Since $T(0) = 0$ and $T(t) \to +\infty$ as $t \uparrow \frac{\pi}{2}$, the range of the odd function T is $\mathbb{R}$. Now $T^{-1} \colon \mathbb{R} \mapsto (-\pi/2, \pi/2)$ exists and by (2)

$$(3) \qquad \int_0^x \frac{1}{1+t^2}\,dt = \int_{T^{-1}(0)}^{T^{-1}(x)} \frac{T'}{1+T^2} = \int_{T^{-1}(0)}^{T^{-1}(x)} 1 = T^{-1}(x) \qquad \forall x \in \mathbb{R}$$

and in particular, because of (1),

$$(3)' \qquad \int_0^1 \frac{1}{1+t^2}\,dt = T^{-1}(1) = \frac{\pi}{4}.$$

For every $N \in \mathbb{N}$, $t \in \mathbb{R}$

$$\sum_{n=0}^{N-1} \left(-t^2\right)^n = \frac{1-\left(-t^2\right)^N}{1-\left(-t^2\right)} = \frac{1}{1+t^2} - \frac{\left(-1\right)^N t^{2N}}{1+t^2}$$

and therefore

$$\begin{aligned} \left|\sum_{n=0}^{N-1} \frac{\left(-1\right)^n x^{2n+1}}{2n+1} - \int_0^x \frac{1}{1+t^2} dt\right| &= \left|\int_0^x \left[\sum_{n=0}^{N-1} \left(-t^2\right)^n - \frac{1}{1+t^2}\right] dt\right| \\ (4) \qquad &= \left|\int_0^x \frac{\left(-1\right)^{N-1} t^{2N}}{1+t^2} dt\right| \qquad \forall x \in \mathbb{R}. \end{aligned}$$

The trivial inequalities $\frac{1}{2}t^{2N} \leq t^{2N}(1+t^2)^{-1} \leq t^{2N}$ for $t \in [-1,1]$ let us estimate the last integral in (4), below and above, yielding for $x \in [-1,1]\,, N \in \mathbb{N}$.

$$(5) \qquad \frac{|x|^{2N+1}}{4N+2} \leq \left|\sum_{n=0}^{N-1} \frac{\left(-1\right)^n x^{2n+1}}{2n+1} - \int_0^x \frac{1}{1+t^2} dt\right| \leq \frac{|x|^{2N+1}}{2N+1}.$$

In particular, using (3)

$$(6) \qquad T^{-1}(x) = \sum_{n=0}^{\infty} \frac{\left(-1\right)^n x^{2n+1}}{2n+1} \qquad \forall x \in [-1,1]\,.$$

Now equations $(3)'$ and (6) prove the theorem, but $(3)'$ and (5) also furnish the estimate

$$(7) \qquad \frac{1}{4N+2} \leq \left|\sum_{n=0}^{N-1} \frac{\left(-1\right)^n}{2n+1} - \frac{\pi}{4}\right| \leq \frac{1}{2N+1} \qquad \forall N \in \mathbb{N}.$$

Remarks: (i) See 3.37(vii), 3.38(viii) and 11.37(viii) [with $z := 1/2$] for different proofs. This series converges excruciatingly slowly, as (7) shows; for one converging to π with geometric rapidity, see 5.82(ii). After checking (see 3.30(ii) Hints) that $T(\pi/6) = 1/\sqrt{3}$, one can also take $x := 1/\sqrt{3}$ in (6) and get the even more rapidly converging representation

$$\frac{\pi}{6} = \frac{1}{\sqrt{3}} \sum_{n=0}^{\infty} \frac{(-1)^n}{2n+1} \cdot \frac{1}{3^n}. \tag{8}$$

In 3.45(v) we will see that for each $x \in \overline{\mathbb{D}} \setminus \{-i, i\}$ the series (6) converges to a solution w of the equation $\tan w = x$. (See def. 3.27.)

(ii) Besides using the partial sums of the series or Riemann-sum approximations to the integral, there is a third (more efficient?) way to exploit 3.22 for rational approximations to π. Each $n \in \mathbb{N}$ determines a polynomial p_n with integer coefficients such that $x^{4n}(1-x)^{4n} = p_n(x)(1+x^2) + (-4)^n$. (One checks that $p_1(x) := x^6 - 4x^5 + 5x^4 - 4x^2 + 4$ works and the rest is induction.) Therefore $\int_0^1 x^{4n}(1-x)^{4n}(1+x^2)^{-1}dx$ is a rational number minus $(-4)^{n-1}\pi$. This integral is positive and less than $[\max\{x(1-x) : 0 \le x \le 1\}]^{4n} = 4^{-4n}$. A rational approximation to π closer than $4^{-4n-(n-1)} = 4^{-5n+1}$ emerges. In case $n = 1$, $\int_0^1 x^4(1-x)^4(1+x^2)^{-1}dx = 22/7 - \pi$. Since

$$\frac{1}{630} = \int_0^1 x^4(1-x)^4 dx > \int_0^1 x^4(1-x)^4(1+x^2)^{-1}dx > \int_0^1 x^4(1-x)^4 2^{-1} dx = \frac{1}{1260},$$

we get $1/630 > 22/7 - \pi > 1/1260$, and so

$$3 + \frac{10}{71} < \frac{22}{7} - \frac{1}{630} < \pi < \frac{22}{7} - \frac{1}{1260} < 3 + \frac{1}{7}.$$

This is from Dalzell [1944], with more in Lucas [2009]. The extreme inequalities are Archimedes' famous estimate; his geometric construction can be found on pp. 31–34 of C. H. Edwards [1979].

(iii) Yet a fourth way to utilize 3.22 is to express $\pi/4 = \arctan(1)$ as a rational linear combination of $\arctan(\varepsilon_j)$ for small ε_j (for which the series is more rapidly convergent). One of these goes back to Euler: $\pi/4 = 4\arctan(1/5) - \arctan(1/70) + \arctan(1/99)$. There are numerous such relations; see pp. 274–275 of Berggren, Borwein and Borwein [2004], pp. 59–65 of Eymard and Lafon [2004] and pp. 90–98 of Castellanos [1988].

(iv) In 1755, Euler found a series which, in contrast to (6), converges to $T^{-1}(x)$ throughout $\mathbb{R}$:

$$T^{-1}(x) = \frac{x}{1+x^2} \sum_{k=0}^{\infty} \frac{2^{2k}(k!)^2}{(2k)!} \, \frac{1}{2k+1} \left(\frac{x^2}{1+x^2}\right)^k \qquad \forall x \in \mathbb{R}. \tag{9}$$

To confirm it, change the variable of integration in (3) via $t =: xC(\theta)$, $x \neq 0$, $\theta \in [0, \pi/2]$, to get

$$(1+x^2)/(1+t^2) = 1/[1 - \frac{x^2}{1+x^2} S^2(\theta)] = \sum_{k=0}^{\infty} \left(\frac{x^2}{1+x^2}\right)^k S^{2k}(\theta).$$

After commuting the uniformly converging series in $S(\theta)$ with the integration, the k^{th} coefficient is $\int_0^{\pi/2} S^{2k+1}(\theta) d\theta$; that it equals $2^{2k}(k!)^2/(2k+1)!$ is confirmed by induction, reduction of k being accomplished by an integration by parts. [The Yin & Yang relation between (9) and 5.82(iv) is noteworthy.]

(v) Since $(T^{-1})'(t) = 1/(1+t^2)$, we have

$$\frac{1}{2}(T^{-1}(x))^2 = \int_0^x T^{-1}(t)/(1+t^2)\ dt.$$

Use (9) on the integrand, permute integration and summation, and make the change of integration variable $u := t^2/(1+t^2)$. You get a combinatorially remarkable companion to (9):

$$(9)^2 \qquad (T^{-1}(x))^2 = \sum_{k=0}^{\infty} \frac{2^{2k+1}(k!)^2}{(2k+2)!} \left(\frac{x^2}{1+x^2}\right)^{k+1} \qquad \forall x \in \mathbb{R}.$$

Exercise 3.23 *With the convention* $0^0 := 1$, *the function* x^{-x} *is continuous on* $[0, 1]$. *(Cf.* 3.18(4) *and recall the customary definition* $x^{-x} := e^{-x \log x}$ *for* $x > 0$.*) Prove the satisfyingly symmetric formula*

$$\int_0^1 x^{-x}\, dx = \sum_{n=1}^{\infty} n^{-n}.$$

Hints: $x^{-x} = \sum_0^\infty (-1)^n (x \log x)^n / n!$. Interchange summation and integration and evaluate $\int_0^1 x^n \log^n(x)\, dx$ by repeated integration-by-parts.

Exercise 3.24 *Consider* $f(x) := \int_0^1 (1+t^2)^{-1} e^{-x^2(1+t^2)} dt$ *and* $g(x) := \int_0^x e^{-t^2}\, dt$, $x \in [0, \infty)$.

(i) *Show that* $0 < f(x) < e^{-x^2} f(0)$ *for all* $x > 0$.

(ii) *Use* 2.19(i) *to show that* $f'(x) = -2e^{-x^2} g(x)$ *for all* $x \geq 0$*; that is,* $f' = \left(-g^2\right)'$.

(iii) *Prove that* $\int_0^\infty e^{-t^2}\, dt = \sqrt{\pi}/2$.

Hints: Integrate in (ii) from 0 to x, let $x \to \infty$ and use (i); evaluate $f(0)$ via 3.22.

(iv) *Show that* $\int_0^\infty t^k e^{-\pi t^2} \cos(2\pi xt)\,dt$ *and* $\int_0^\infty t^k e^{-\pi t^2} \sin(2\pi xt)\,dt$ *exist for each* $x \in \mathbb{R}$, $k \in \mathbb{N} \cup \{0\}$, *and they define functions* $C_k(x)$, $S_k(x)$ *which satisfy* $C_k' = -2\pi S_{k+1}$. (Cf. 2.19(i) and glance ahead to definition 3.27)

Hints: The power series shows that $e^x \geq x^{k+1}/(k+1)!$ for all $x \geq 0$, $k \in \mathbb{N} \cup \{0\}$. Hence $t^k e^{-\pi t^2} \leq (k+1)!/\pi^{k+1} t^{k+2}$, an inequality whose validity for all $t \geq 1$ clearly insures the existence of the relevant improper integrals. For real $\alpha < \beta$

$$\left|\frac{\cos\beta - \cos\alpha}{\beta - \alpha} + \sin\alpha\right| = \frac{1}{\beta - \alpha}\left|\int_\alpha^\beta (\sin\alpha - \sin t)dt\right| \leq \sup_{t \in [\alpha,\beta]} |\sin\alpha - \sin t|$$
$$= \sup_{t \in [\alpha,\beta]} \left|\int_\alpha^t \cos\right| \leq \beta - \alpha.$$

If we apply this inequality in the relevant integrand, we see that for all real $x \neq x_0$

$$\left|\frac{C_k(x) - C_k(x_0)}{x - x_0} + 2\pi S_{k+1}(x_0)\right| \leq \int_0^\infty 2\pi t^{k+1} e^{-\pi t^2} |2\pi xt - 2\pi x_0 t|\,dt$$
$$= 4\pi^2 C_{k+2}(0)|x - x_0|.$$

(v) *Identify the function* C_0 *of* (iv) *as being* $C_0(x) = \frac{1}{2} e^{-\pi x^2}$ *for all* $x \in \mathbb{R}$.

Hints: Using (iv) and integration by parts deduce that $e^{\pi x^2} C_0(x)$ has derivative $\mathbf{0}$. The constant value $C_0(0)$ of the function $e^{\pi x^2} C_0(x)$ is found via (iii).

(vi) *Show that* $\int_{-\infty}^\infty e^{-\pi t^2} e^{-2\pi ixt}\,dt = e^{-\pi x^2}$ *for all* $x \in \mathbb{R}$.

(vii) *In the integral defining* f *replace* $-x^2$ *by* ix^2 *and in the integral defining* g *replace* $-t^2$ *by* it^2. *Call the new functions* f_i, g_i, *respectively, and carry through for them the program in* (ii) *to get*

$$g_i^2(x) = \frac{\pi i}{4} - ie^{ix^2} \int_0^1 \frac{e^{ix^2 t^2}}{1 + t^2}\,dt \qquad \forall x \in \mathbb{R}. \tag{1}$$

Infer from this and 3.22 *that*

$$|g_i^2(x)| \leq \pi/2 \qquad \forall x \in \mathbb{R}. \tag{2}$$

(viii) *Use integration by parts to show that*

$$\int_0^1 \frac{e^{ix^2 t^2}}{1 + t^2}\,dt = \frac{1}{2x}\,g_i(x) + \frac{1}{x}\int_0^1 \frac{2t}{(1 + t^2)^2}\,g_i(xt)dt \qquad \forall x > 0.$$

Infer from this and (2) *that* $\int_0^1 (1+t^2)^{-1} e^{ix^2t^2}\,dt \to 0$ *as* $x \to \infty$; *then from the latter and* (1) *infer that*

$$\lim_{x\to\infty} g_i^2(x) = \frac{\pi i}{4}. \tag{3}$$

(ix) *From* (3) *and continuity of* g_i *infer that*

$$\int_0^\infty e^{it^2}\,dt := \lim_{x\to\infty} g_i(x) \text{ exists and equals } \sqrt{\frac{\pi}{2}}\left(\frac{1+i}{2}\right).$$

Hints: From (3) we know that $\operatorname{Im} g_i^2(x) > \pi/8$ for all large x. Consequently $\operatorname{Im} g_i(x)$ is of constant sign for large x. Since $\sin \ge 0$ in $[2k\pi, (2k+1)\pi]$ for all $k \in \mathbb{Z}$ (see definition 3.27 and the proof of 3.14),

$$\begin{aligned}
0 &\le \sum_{k=0}^{n-1} \int_{2k\pi}^{(2k+1)\pi} \sin t\left(\frac{1}{\sqrt{t}} - \frac{1}{\sqrt{t+\pi}}\right)dt \\
&= \sum_{k=0}^{n-1} \left(\int_{2k\pi}^{(2k+1)\pi} \frac{\sin t}{\sqrt{t}}\,dt + \int_{(2k+1)\pi}^{2(k+1)\pi} \frac{\sin t}{\sqrt{t}}\,dt\right) \\
&= \int_0^{2n\pi} \frac{\sin t}{\sqrt{t}}\,dt = \int_0^{\sqrt{2n\pi}} 2\sin(t^2)\,dt = 2\operatorname{Im} g_i(\sqrt{2n\pi}) \qquad \forall n \in \mathbb{N}.
\end{aligned}$$

Therefore the eventual constant sign of $\operatorname{Im} g_i(x)$ is $+$. Setting $A := \sqrt{\frac{\pi}{2}}(\frac{1+i}{2})$, we have $A^2 = \frac{\pi i}{4}$ and (3) reads

$$\lim_{x\to\infty} [g_i(x) - A][g_i(x) + A] = 0.$$

As $\operatorname{Im}[g_i(x)+A] \ge \operatorname{Im} A = \sqrt{\pi/8}$ for all large x, this product can only converge to 0 if its first factor does.

Remarks: The results (iii) and (ix) will be derived by complex-analysis and Fourier analysis methods in 11.32 and its Remark (iii). The real-variables techniques here are adapted from Anonyme [1889], Bloch [1922], R. M. Young [1991], and especially Výborný [1991], where $\int_0^\infty e^{-ct^2}\,dt$ is treated for arbitrary non-zero $c \in \overline{\mathbb{H}}$, thereby getting (iii) and (ix) in one stroke. For history see footnotes 1433–1436 in Burkhardt [1914].

Exercise 3.25 (i) *Show that if* f *is differentiable in an open, connected subset* Ω *of* $\mathbb{C}$ *or* $\mathbb{R}$ *and* $f' = cf$ *for some constant* c, *then*

$$f(z) = f(a)e^{-ca}e^{cz} \qquad \forall a, z \in \Omega.$$

Hint: Let $g(z) := e^{-cz}$ and note that $(f \cdot g)' = 0$ throughout Ω.

(ii) *Find all continuous homomorphisms f of the additive group $\mathbb{R}$ into the multiplicative groups $\mathbb{T}$, $\mathbb{C} \setminus \{0\}$ and $\mathbb{R} \setminus \{0\}$.* Cf. 4.23(iii).

Hints: Since f is a homomorphism, $f(0) = 1$. By continuity then there exists $a > 0$ such that $\int_0^a f = b \neq 0$. The homomorphic property $f(x + t) = f(x)f(t)$ (all $x, t \in \mathbb{R}$) then implies that

$$bf(x) = f(x) \int_0^a f(t)\,dt = \int_0^a f(x+t)\,dt = \int_x^{x+a} f = \int_0^{x+a} f - \int_0^x f.$$

From this and the fundamental theorem of calculus we learn that the function f is not only continuous but is differentiable, and

$$bf'(x) = f(x+a) - f(x) = f(x)[f(a) - 1] \qquad \forall x \in \mathbb{R},$$

so $f' = cf$, with $c := [f(a) - 1]/b$. This leads via (i) to $f(x) = f(0)e^{cx} = e^{cx}$. It is thus obvious that f maps into $\mathbb{T}$ if and only if $\operatorname{Re} c = 0$, and maps into $\mathbb{R}$ if and only if c is real.

(iii) *Show that every continuous homomorphism h of the multiplicative group $\mathbb{R}\setminus\{0\}$ into the additive group $\mathbb{R}$ has the form $c \log \circ |\ \ |$ for some $c \in \mathbb{R}$.*

Hints: According to (ii) there is a $c \in \mathbb{R}$ such that $e^{h(e^x)} = e^{cx}$ for all $x \in \mathbb{R}$. For $x = \log y$ this gives $h(y) = cx = c \log y$, for all $y > 0$. But $0 = h(1) = h((-1)(-1)) = 2h(-1)$, so $h(-y) = h(-1) + h(y) = h(y)$ for all $y \in \mathbb{R} \setminus \{0\}$.

(iv) *Show that* (iii) *remains valid if at every occurrence $\mathbb{R}$ is replaced by $\mathbb{C}$.*

Hint: Apply (iii) to $\operatorname{Re} h$ and $\operatorname{Im} h$ restricted to $\mathbb{R} \setminus \{0\}$ to come up with $c \in \mathbb{C}$ such that $h(x) = c \log x$ for all $x > 0$. Since continuous homomorphism h maps $\mathbb{T}$ onto a compact additive subgroup of $\mathbb{C}$, $h(\mathbb{T}) = \{0\}$. Thus $h(z) = h(|z|) + h(z/|z|) = h(|z|)$, for all $z \in \mathbb{C} \setminus \{0\}$.

Exercise 3.26 *Let $\phi\colon [0,1] \mapsto \mathbb{C}$ be continuous and satisfy $\phi(1) = \phi(0)$. Show that there exists a continuous $\Phi\colon \mathbb{T} \mapsto \mathbb{C}$ satisfying*

$$(*) \qquad \Phi\big(e^{2\pi i t}\big) = \phi(t) \qquad \forall t \in [0,1].$$

Hints: By 3.14(v) and the $2\pi i$-periodicity of the exponential function, the map $t \mapsto e^{2\pi i t}$ sends $[0, 1)$ one-to-one onto the circle $\mathbb{T}$. Hence we can define Φ on $\mathbb{T}$ by the decree

$$(1) \qquad \Phi\big(e^{2\pi i t}\big) = \phi(t) \qquad \forall t \in [0,1)\,.$$

The condition $\phi(1) = \phi(0)$ ensures that in fact $(*)$ holds. Suppose now that Φ is not continuous at some $z_0 \in \mathbb{T}$. This means that there exists an $\varepsilon > 0$ and a sequence $\{z_n\} \subset \mathbb{T}$ such that $z_n \to z_0$ and

$$(2) \qquad |\Phi(z_n) - \Phi(z_0)| \geq \varepsilon, \quad n \in \mathbb{N}.$$

For each $n \in \mathbb{N}$ there is a unique $t_n \in [0, 1)$ such that $z_n = e^{2\pi i t_n}$ and there is a subsequence of $\{t_n\}$ which converges to some $t_0 \in [0, 1]$. Passing to that subsequence, we can simply suppose that $\{t_n\}$ itself converges to t_0. Then $z_n = e^{2\pi i t_n} \to e^{2\pi i t_0}$, and so $z_0 = e^{2\pi i t_0}$. But then

$$\Phi(z_n) = \phi(t_n) \to \phi(t_0) \overset{(*)}{=} \Phi\big(e^{2\pi i t_0}\big) = \Phi(z_0),$$

in violation of (2).

It is customary to introduce functions cos, sin, tan and cot by

Definition 3.27 The functions cos and sin are defined for all $z \in \mathbb{C}$ by

$$\cos(z) := \frac{e^{iz} + e^{-iz}}{2} = \sum_{n=0}^{\infty} \frac{(-1)^n z^{2n}}{(2n)!}$$
$$\sin(z) := \frac{e^{iz} - e^{-iz}}{2i} = \sum_{n=0}^{\infty} \frac{(-1)^n z^{2n+1}}{(2n+1)!}.$$

The function tan is defined as sin/cos. Since the zeros of cos are evidently the odd integer multiples of $\pi/2$, the domain of tan is $\mathbb{C} \setminus \pi(\mathbb{Z} + 1/2)$. The function cot is defined as cos/sin, with the appropriate domain, viz., $\mathbb{C} \setminus \pi\mathbb{Z}$ (cf. 3.30(iii)). The closely related entire functions $z \mapsto \cos(iz) = \frac{1}{2}(e^z + e^{-z})$ and $z \mapsto -i\sin(iz) = \frac{1}{2}(e^z - e^{-z})$, the even and odd parts of the exponential function, are designated $\cosh(z)$ and $\sinh(z)$ [in French literature, $ch(z)$ and $sh(z)$].

Remarks: The functions C and S in the proof of 3.14 were just cos and sin restricted to $\mathbb{R}$ and are known collectively as the *circular* or *cyclometric* or *trigonometric* functions. The functions cos and sin are infinitely differentiable throughout $\mathbb{C}$ and $\cos' = -\sin$, $\sin' = \cos$. For each $x \in \mathbb{R} \setminus \mathbb{Z}$, $y \in \mathbb{R} \setminus \{0\}$ they map the lines $\frac{1}{2}\pi x + i\mathbb{R}$, $\mathbb{R} + iy$ onto semi-hyperbolas and ellipses with foci ± 1, as the reader can easily confirm. The (only occasionally encountered) name cis for the function $z \mapsto e^{iz}$ is suggested by the identity $e^{iz} = \cos(z) + i\sin(z)$. The functions cos, sin, and tan map $[0, \pi]$, $[-\pi/2, \pi/2]$, and $(-\pi/2, \pi/2)$ bijectively onto $[-1, 1]$, $[-1, 1]$, and $\mathbb{R}$, respectively. The inverses of these restrictions are sometimes denoted by $\cos^{-1}$, $\sin^{-1}$, and $\tan^{-1}$ (a slight abuse of language), but preferably by arccos, arcsin, and arctan. The rationale for the latter notation is the fact (see the Remarks following 3.16) that every $x+iy \in \mathbb{T}_+$ is $\cos\theta + i\sin\theta$ for a unique $\theta \in (0, \pi)$, and this θ is the length of the counterclockwise *arc* of $\mathbb{T}$ with initial point 1 and terminal point $x+iy$; so $\theta = \cos^{-1}(x)$ is an arclength.

Cosh and sinh are known as *hyperbolic trigonometric* functions. Notice that cosh is an even function which effects a strictly increasing mapping of $[0, \infty)$ onto $[1, \infty)$, and sinh is an odd function which effects a strictly increasing mapping of $\mathbb{R}$ onto $\mathbb{R}$. The inverses of these restrictions are denoted arcosh and arsinh, respectively. Just as $t \mapsto (\cos t, \sin t)$, $t \in [-\pi/2, \pi/2]$, parameterizes the right half of the circle $x^2 + y^2 = 1$, the function $t \mapsto (\cosh t, \sinh t)$, $t \in \mathbb{R}$, parameterizes the right half of the "equilateral" hyperbola $x^2 - y^2 = 1$. But the parameter t appears to lose its arclength significance in the latter case. Rather it is now an area: The sector bounded by the circle and its two radii $[0, x \pm iy]$ $(x > 0, y > 0)$ has area $\arccos(x) = \arcsin(y)$, while the analogous region bounded by the hyperbola and its "radii" $[0, x \pm iy]$ has area $\operatorname{arcosh}(x) = \operatorname{arsinh}(y)$, as the reader can routinely compute. These facts elucidate the use of the adjective "hyperbolic" and the fact that the prefix "ar" is intended to suggest "area".

In the spirit of *ars gratia artis* I want to briefly divert from business to offer the reader a glimpse into "the BOOK," Paul Erdös' famous fantasy repository of proofs that the Almighty itself judges to be *ne plus ultra*. The idea of this proof goes back to Charles Hermite, in 1873, but the exposition here follows AIGNER and ZIEGLER [2010]. T. W. JONES [2010], ZHOU and MARKOV [2010] and ZHOU [2011] analyze the mechanism of the π-proof and its evolution. They also show how these ideas can prove the irrationality of $\cos(r)$ and $\tan(r)$ for every non-zero rational r. Other elementary proofs will be found in HANČL [1986], DESBROW[1990] (via complex analysis), LACZKOVICH [1997], and HUYLEBROUCK [2001].

Theorem 3.28 *π^2 is irrational, and e^m is irrational for every $m \in \mathbb{N}$.*

Proof: A central role in both proofs is played by the $2n$-degree polynomial

$$p(x) := x^n(1-x)^n/n!, \tag{1}$$

$n \in \mathbb{N}$ to be specified later. The properties needed are

$$0 < p(x) < 1/n! \qquad \forall x \in (0,1), \tag{2}$$

$$p^{(k)}(0), p^{(k)}(1) \in \mathbb{Z} \qquad \forall k \in \mathbb{Z}_+. \tag{3}$$

Since $0 < x(1-x) < 1$ for $x \in (0,1)$, (2) is clear. Evidently the polynomial $q(x) := x^n(1-x)^n$ has the form $\sum_{j=n}^{2n} c_j x^j$ with coefficients $c_j \in \mathbb{Z}$ (use, say, induction on n), and so $q^{(k)}(0) = 0$ if $k < n$ or $k > 2n$. If, on the other

*D ! !

hand, $n \le k \le 2n$, then $q^{(k)}(x) = \sum_{j=k}^{2n} j(j-1)\dots(j-k+1)c_j x^{j-k}$, so $q^{(k)}(0) = k!c_k$, an integer multiple of $n!c_k$. Hence $p^{(k)}(0) = q^{(k)}(0)/n! \in \mathbb{Z}$. And since $p(x) = p(1-x)$, $p^{(k)}(1) = (-1)^k p^{(k)}(0) \in \mathbb{Z}$.

Now suppose first that for some $m, a, b \in \mathbb{N}$

$$e^m = a/b. \tag{4}$$

Since the power series for e^{m^2} converges, we may pick $n \in \mathbb{N}$ so that

$$(m^2)^n/n! < 1/am. \tag{5}$$

With the p in (1) form

$$P := \sum_{k=0}^{2n} (-1)^k m^{2n-k} p^{(k)}.$$

Since $p^{(2n+1)} = \mathbf{0}$, we see that

$$\begin{aligned} P' = \sum_{k=0}^{2n-1} (-1)^k m^{2n-k} p^{(k+1)} &= \sum_{j=1}^{2n} (-1)^{j-1} m^{2n-(j-1)} p^{(j)} \\ &= -m \sum_{j=1}^{2n} (-1)^j m^{2n-j} p^{(j)} = -m[P - m^{2n}p]. \end{aligned}$$

Hence

$$\frac{d}{dx}[e^{mx}P(x)] = me^{mx}P(x) + e^{mx}P'(x) = m^{2n+1}e^{mx}p(x).$$

Consequently, the mean-value theorem supplies $x \in (0,1)$ such that $e^m P(1) - e^0 P(0) = m^{2n+1} e^{mx} p(x)$. That is, in view of (4),

$$N := aP(1) - bP(0) = bm^{2n+1}e^{mx}p(x), \tag{6}$$

which is an integer, due to (3) and the definition of P. From (2) and (6)

$$0 < N \le bm^{2n+1}e^m/n! \overset{(4)}{=} m^{2n+1}a/n! \overset{(5)}{<} 1,$$

inequalities which contradict the fact $N \in \mathbb{Z}$ and thus prove that (4) is untenable.

Turning to the π^2-claim, its proof being similar, a few computations can be left to the reader. Suppose then that for some $a, b \in \mathbb{N}$

$$\pi^2 = a/b, \tag{7}$$

and select $n \in \mathbb{N}$ such that

$$a^n/n! < 1/\pi. \tag{8}$$

With the p in (1) form

$$P := b^n \sum_{k=0}^{n} (-1)^k \pi^{2(n-k)} p^{(2k)}$$

and calculate that

$$P'' = -\pi^2 P + b^n \pi^{2n+2} p.$$

Use this to further calculate

$$\begin{aligned}\frac{d}{dx}\Big[\pi^{-1}P'(x)\sin\pi x - P(x)\cos\pi x\Big] &= \Big[\pi^{-1}P''(x) + \pi P(x)\Big]\sin\pi x\\ &= b^n\pi^{2n+1}p(x)\sin\pi x\end{aligned}$$

and from this and the mean-value theorem get an $x \in (0,1)$ such that

$$N := P(1) + P(0) = b^n \pi^{2n+1} p(x) \sin \pi x. \tag{9}$$

Because of (7), $b^n\pi^{2(n-k)} \in \mathbb{N}$ for each $k = 0, 1, \ldots, n$ and therefore (3) and the definition of P tell us that $P(0)$, $P(1) \in \mathbb{Z}$. Hence $N \in \mathbb{Z}$. But from (9) and (2)

$$0 < N \le b^n\pi^{2n+1}/n! \overset{(7)}{=} a^n\pi/n! \overset{(8)}{<} 1,$$

inequalities which contradict $N \in \mathbb{Z}$ and thus prove that (7) is untenable.

I think readers will agree: a proof “from the BOOK.”

Exercise 3.29 (i) $|\sin x| \le |x|$ *for all real* x.

Hint: For each $x \neq 0$ the Mean-Value Theorem provides an x' such that

$$\left|\frac{\sin x}{x}\right| = \left|\frac{\sin(x) - \sin(0)}{x - 0}\right| = \left|\sin'(x')\right| = |\cos(x')| \le 1.$$

(ii) $\cos x \ge 1 - 2x/\pi$ *for all* x *in* $[0, \pi/2]$.

Hints: The function $g(x) := \cos x + 2x/\pi$ satisfies $g(0) = g(\pi/2) = 1$. Also $g' = 2/\pi - \sin$. From equation (10) in the proof of 3.14, sin increases on $[0, \pi/2]$ from $\sin(0) = 0$ to $\sin(\pi/2) = 1 > 2/\pi$. Therefore g' has a unique zero $x_0 \in [0, \pi/2]$, $g' > 0$ on $[0, x_0)$ and $g' < 0$ on $(x_0, \pi/2]$. It follows that g is increasing on $[0, x_0]$, decreasing on $[x_0, \pi/2]$ and so $\min g[0, \pi/2] = g(0) = g(\pi/2) = 1$.

Exercise 3.30 (i) *$\sin x \geq 2x/\pi$ for all $x \in [0, \pi/2]$.*

Hints: The function $h(x) := \sin x - 2x/\pi$ satisfies $h(0) = h(\pi/2) = 0$ and $h' = -2/\pi + \cos$. Now $\cos' = -\sin$ is negative on $(0, \pi/2]$, so h' decreases from $h'(0) = -2/\pi + 1 > 0$ to $h'(\pi/2) = -2/\pi < 0$. As in the hints of 3.29(ii), it follows that $\min h[0, \pi/2] = h(0) = h(\pi/2) = 0$. (For refinements of (i), see **MR** 2006m:26027.)

(ii) *$|\sin(\pi z)| > 1/2$ for all $z \in \mathbb{C} \setminus \bigcup_{n\in\mathbb{Z}} D(n, 1/4)$.*

Hints: Consider the hyperbolic sine function

$$h(t) := \frac{1}{2}\left(e^t - e^{-t}\right) = \sum_{k=0}^{\infty} \frac{t^{2k+1}}{(2k+1)!}, \quad t \in \mathbb{R}.$$

Evidently $h(|t|) \geq |t|$. By elementary algebra, if $x, y \in \mathbb{R}$ and $z := x + iy$, then $|\sin(\pi z)|^2 = \sin^2(\pi x) + h^2(\pi y)$. Suppose $|\sin(\pi z)|^2 \leq 1/4$. Then

$$\sin^2(\pi x) \leq 1/4 \quad \text{and} \quad h^2(\pi y) \leq 1/4. \tag{1}$$

Since $(\sqrt{3} + i)/2$ and $e^{\pi i/6}$ each lie in $\mathbb{U} \cap \mathbb{H}$ and each is a cube root of i, they must be equal. So $\sin(\pi/6) = 1/2$. Since sin is an odd function, strictly increasing on $[-\pi/2, \pi/2]$, it follows that $t \in [-\pi/2, \pi/2]$ & $|\sin t| \leq 1/2 \Rightarrow |t| \leq \pi/6$. For the x in (1) choose $n \in \mathbb{Z}$ such that $|x - n| \leq 1/2$. Then $\pi x - n\pi \in [-\pi/2, \pi/2]$ and $|\sin(\pi x - n\pi)| = |\sin(\pi x)| \leq 1/2$, so $|\pi x - n\pi| \leq \pi/6$. Furthermore, since

$$(\pi y)^2 = |\pi y|^2 \leq h^2(|\pi y|) = h^2(\pi y),$$

inequality (1) yields $(\pi y)^2 \leq 1/4$ and so

$$|z - n|^2 = (x - n)^2 + y^2 \leq \left(\frac{1}{6}\right)^2 + \frac{1}{4\pi^2}. \tag{2}$$

But by $(8)'$ in the proof of 3.14, $\pi > 3$, so (2) gives

$$|z - n|^2 < \left(\frac{1}{6}\right)^2 + \left(\frac{1}{6}\right)^2 < \left(\frac{1}{4}\right)^2.$$

(iii) *Show that the only zeros in* $\mathbb{C}$ *of* sin *are those in* $\pi\mathbb{Z}$ *and the only periods in* $\mathbb{C}$ *of* sin *are those in* $2\pi\mathbb{Z}$.

Hints: $\sin z = 0 \Leftrightarrow e^{2iz} - 1 = 0 \Leftrightarrow 2iz \in 2\pi i\mathbb{Z}$. From the (routinely confirmed) identity

$$\sin(z+2p) - \sin(z) = 2\cos(z+p)\sin(p) \qquad \forall z, p \in \mathbb{C}$$

it follows that $2p$ is a period of sin if and only if $\sin(p) = 0$.

Exercise 3.31 $\int_0^{\pi/4} e^{-R\cos 2x}\,dx \leq \pi/4R$ *for all* $R > 0$.

Hint: By 3.29(ii), $e^{-R\cos 2x} \leq e^{-R(1-4x/\pi)} = e^{-R}e^{(4R/\pi)x}$, so

$$\int_0^{\pi/4} e^{-R\cos 2x}\,dx \leq \left[e^{-R}\frac{\pi}{4R}e^{(4R/\pi)x}\right]_{x=0}^{x=\pi/4} < e^{-R}\cdot\frac{\pi}{4R}\cdot e^{4(R/\pi)(\pi/4)}.$$

Exercise 3.32 *Suppose* $\lim_{N\to\infty}\sum_{n=-N}^{N} c_n z^n$ *exists uniformly on* $C(0,r)$, *for some* $r > 0$. *Denote this limit by* $f(z)$.

(i) *Prove* Parseval's Formula

$$\frac{1}{2\pi}\int_0^{2\pi} \left|f\left(re^{it}\right)\right|^2 dt = \sum_{n=-\infty}^{\infty} |c_n|^2 r^{2n} := \lim_{N\to\infty}\sum_{n=-N}^{N} |c_n|^2 r^{2n}.$$

Hints: The functions $S_N(z) := \sum_{n=-N}^{N} c_n z^n$ satisfy

$$\begin{aligned}\left|S_N\left(re^{it}\right)\right|^2 &= \left[\sum_{n=-N}^{N} c_n r^n e^{int}\right]\left[\sum_{k=-N}^{N} \bar{c}_k r^k e^{-ikt}\right]\\ &= \sum_{n=-N}^{N}\sum_{k=-N}^{N} c_n\bar{c}_k r^{n+k} e^{i(n-k)t},\end{aligned}$$

and so

$$\int_0^{2\pi} \left|S_N\left(re^{it}\right)\right|^2 dt = \sum_{n=-N}^{N}\sum_{k=-N}^{N} c_n\bar{c}_k r^{n+k}\int_0^{2\pi} e^{i(n-k)t}\,dt = \sum_{n=-N}^{N} 2\pi|c_n|^2 r^{2n}.$$

By hypothesis, $S_N\left(re^{it}\right) \to f(re^{it})$ uniformly in $t \in \mathbb{R}$ for $N \to \infty$.

(ii) *Show that if* $c_n = 0$ *for all* $n < 0$, *then*

$$\frac{1}{2\pi}\int_0^{2\pi} \left[\operatorname{Re} f\left(re^{it}\right)\right]^2 dt = (\operatorname{Re} c_0)^2 + \frac{1}{2}\sum_{n=1}^{\infty} |c_n|^2 r^{2n}$$

and infer that if additionally $|\operatorname{Re} f| \leq A$, *then*

$$2(\operatorname{Re} c_0)^2 + \sum_{n=1}^{\infty} |c_n|^2 r^{2n} \leq 2A^2.$$

Hints: Define

$$c_n^* := \begin{cases} c_n & \text{if } n > 0 \\ c_0 + \bar{c}_0 & \text{if } n = 0 \\ \bar{c}_{-n} & \text{if } n < 0 \end{cases}$$

and note that $c_k^* c_{-k}^* = |c_k^*|^2$ for all k. Hence

$$\begin{aligned} 2 \operatorname{Re} S_N\bigl(re^{it}\bigr) &= \sum_{n=0}^{N} c_n \bigl(re^{it}\bigr)^n + \sum_{n=0}^{N} \bar{c}_n \bigl(\overline{re^{it}}\bigr)^n = \sum_{k=-N}^{N} c_k^* r^{|k|} e^{ikt} \\ \bigl[2 \operatorname{Re} S_N\bigl(re^{it}\bigr)\bigr]^2 &= \sum_{j=-N}^{N} \sum_{k=-N}^{N} c_k^* c_j^* r^{|k|+|j|} e^{i(k+j)t}, \quad \text{whence} \\ \int_0^{2\pi} \bigl[2 \operatorname{Re} S_N\bigl(re^{it}\bigr)\bigr]^2 \, dt &= \sum_{k=-N}^{N} c_k^* c_{-k}^* r^{2|k|} \cdot 2\pi = 2\pi \sum_{k=-N}^{N} |c_k^*|^2 r^{2|k|} \\ &= 2\pi \left[(2 \operatorname{Re} c_0)^2 + 2 \sum_{n=1}^{N} |c_n|^2 r^{2n} \right]. \end{aligned}$$

Now let $N \to \infty$

(iii) *For every* $j \in \mathbb{N}$ *the coefficient* c_j *in* (ii) *can be expressed as an integral of* $\operatorname{Re} f$ *over* $C(0, r)$. *Find explicit formulae.*

Hint: Multiply the above sum for $2 \operatorname{Re} S_N(re^{it})$ by e^{-ijt}, integrate and let $N \to \infty$ to learn that $\pi r^j c_j = \int_0^{2\pi} e^{-ijt} \operatorname{Re} f(re^{it}) \, dt$.

(iv) *Consider* $R(z) := \sum_{j=-n}^{n} c_j z^j$ $(n \in \mathbb{N}, c_j \in \mathbb{C})$, $M(r) := \max\{|R(z)| : |z| = r\}$ *and* $m(r) := \min\{|R(z)| : |z| = r\}$ *for* $r > 0$. *The useful inequalities*

$$m^2(r) \leq \sum_{j=-n}^{n} |c_j|^2 r^{2j} \leq M^2(r) \qquad \forall r > 0$$

are a simple consequence of (i). *But they can be proved without recourse to either integrals or the exponential function, by a clever averaging technique that has broader applicability.*

Hints: (suggested by Oswaldo Rio Branco de Oliveira) Fix $u \in \mathbb{T}$ such that $1 \notin \{u^m : 1 \leq m \leq 2n\}$. Then define $K := \max\{|1 - u^m|^{-1} : 1 \leq m \leq 2n\}$ zand note that

$$(*) \qquad \left|\sum_{k=0}^{N-1} u^{km}\right| = \left|\frac{1 - u^{Nm}}{1 - u^m}\right| \leq 2K \quad \text{for} \quad 1 \leq m \leq 2n, N \in \mathbb{N}.$$

Direct calculation delivers, for $z \neq 0$ and $k \in \mathbb{Z}$

$$|R(u^k z)|^2 = \sum_{-n \leq j \leq n} |c_j|^2 |z|^{2j} + 2 \sum_{-n \leq j < l \leq n} \operatorname{Re}[\bar{c}_j \bar{z}^j c_l z^l u^{k(l-j)}].$$

Summing over k gives

$$\begin{aligned} N \sum_{-n \leq j \leq n} |c_j|^2 |z|^{2j} &\leq \sum_{k=0}^{N-1} |R(u^k z)|^2 + 2 \sum_{-n \leq j < l \leq n} |c_j c_l| |z|^{j+l} \left|\sum_{k=0}^{N-1} u^{k(l-j)}\right| \\ &\overset{(*)}{\leq} \sum_{k=0}^{N-1} |R(u^k z)|^2 + 4K \sum_{-n \leq j < l \leq n} |c_j c_l| |z|^{j+l}. \end{aligned}$$

Taking $z \in C(0, r)$, this yields

$$N \sum_{-n \leq j \leq n} |c_j|^2 r^{2j} \leq N M^2(r) + 4K \sum_{-n \leq j < l \leq n} |c_j c_l| r^{j+l} \qquad \forall r > 0, N \in \mathbb{N}.$$

Divide by N and let $N \to \infty$. ("O frabjous day! Callooh! Callay!") Obvious sign changes in this argument lead to the $m^2(r)$ inequality.

(v) *Prove* Gutzmer's Inequalities:

$$m^2(r) \leq \sum_{n=-\infty}^{\infty} |c_n|^2 r^{2n} \leq M^2(r).$$

Hints: This too follows trivially from (i), but in Weierstrass' approach to function theory a proof without integration theory was desirable, and follows routinely from (iv): Given $\varepsilon > 0$, there is an $N(\varepsilon) \in \mathbb{N}$ such that the partial sums $S_N(z) := \sum_{n=-N}^{N} c_n z^n$ satisfy

$$|S_N(z) - f(z)| \leq \varepsilon \qquad \forall z \in C(0, r), N \geq N(\varepsilon).$$

The numbers $M_N := \max\{|S_N(z)| : |z| = r\}$ consequently satisfy

$$M_N \leq \varepsilon + \sup\{|f(z)| : |z| = r\} = \varepsilon + M(r),$$

and (iv) delivers

$$\sum_{n=-N}^{N} |c_j|^2 r^{2n} \le M_N^2 \le (\varepsilon + M(r))^2 \qquad \forall N \ge N(\varepsilon).$$

Let $N \to \infty$ and then let $\varepsilon \downarrow 0$.

Exercise 3.33 *The series $\sum_{n=0}^{\infty} c_n z^n$ converges to $f(z)$ for all $z \in D(0,R)$ and some $0 < R \le \infty$.*

(i) (Liouville) *Deduce from either* 3.32(i) *or* (v) *that if f is bounded and $R = \infty$, then f is constant.*

(ii) *Deduce from either* 3.32(i) *or* (v) *that if $|f(z)| \le |f(0)|$ for all $z \in C(0,r)$ and some $0 < r < R$, then f is constant.*

Hint: Parseval gives

$$\sum_{n=0}^{\infty} |c_n|^2 r^{2n} \le \frac{1}{2\pi} \int_0^{2\pi} |f(0)|^2 \, dt = |c_0|^2,$$

whence $\sum_{n=1}^{\infty} |c_n|^2 r^{2n} \le 0$.

(iii) (Maximum-Modulus Principle for functions of power series type). $F : \Omega \mapsto \mathbb{C}$ *is bounded in the region Ω, each point of which is the center of a disk in which F is represented by a power series. Show that if there is some $a \in \Omega$ such that $|F(a)| = M := \sup |F(\Omega)|$, then F is constant.*

Hints: Rotating F lets us assume $F(a) = M$. Consider the set $S := F^{-1}(M)$. By continuity of F it is relatively closed in Ω. If $c \in S$, we can apply (ii) to infer that $F = M$ throughout some whole disk centered at c. Thus S is open. Finally, $S \ne \varnothing$, since it contains a.

Exercise 3.34 (i) *Deduce from* 3.32(i) *or* (v) *the so-called* Cauchy estimates: *If $c_{-n} = 0$ for all $n \in \mathbb{N}$, and if we set*

$$M(r) := \sup_{|z|=r} |f(z)|,$$

then for every non-negative integer k

$$\frac{\left|f^{(k)}(0)\right|}{k!} = |c_k| \le \frac{M(r)}{r^k},$$

and equality holds for some k if and only if f is a monomial of degree k.

The Measurement of a Circle

As we saw in Chapter 1, the awareness (on some level) that the area of a circle is proportional to the square of its radius, $A = \pi_1 r^2$ for some constant π_1, dates back to earliest times. Similarly, the proportionality between a circle's circumference and diameter, $C = \pi_2 d$ for some constant π_2, is an ancient one. However, it is not clear when it was first realized that the two proportionality constants are the same, $\pi_1 = \pi_2 = \pi$. In the *Measurement of a Circle*, Archimedes provided the first rigorous proof of this fact by showing that the area of a circle is equal to that of a triangle with base equal to its circumference and height equal to its radius,

$$A = \tfrac{1}{2} rC. \tag{1}$$

To see that (1) implies that $\pi_1 = \pi_2$, simply substitute $A = \pi_1 r^2$ and $C = 2\pi_2 r$. He then showed that

$$3\tfrac{10}{71} < \pi < 3\tfrac{1}{7} \tag{2}$$

by explicitly establishing this inequality for the ratio of the circumference of a circle to its diameter.

Formula (1) was certainly known before Archimedes, and it was probably deduced by regarding the circle as the union of indefinitely many isosceles triangles with the center as their common vertex, and with their bases forming an inscribed regular polygon with each of its indefinitely many sides almost coinciding with a small arc of the circle. Since the height of each triangle will virtually equal the radius of the circle, and the sum of their bases will virtually equal its circumference, this picture makes the truth of (1) seem evident.

This heuristic derivation supplies the motivation for Archimedes' rigorous proof. In it he extends the method of exhaustion to what has been termed the "method of compression." Instead of dealing only with inscribed polygons, he employs both inscribed and circumscribed polygons. The area of the circle is then "compressed" between the areas of inscribed and circumscribed polygons that closely approximate the circle (Fig. 1). The following two exercises are preliminaries to the proof.

EXERCISE 1. Consider a circle with circumference C, and let P and Q be inscribed and circumscribed polygons, respectively. Show that the perimeter of P is less than C, while the perimeter of Q is greater than C. Use the facts that $\sin\theta < \theta < \tan\theta$ if θ is an angle less than $\pi/2$ radians, and that a central angle of θ radians subtends an arc of length $r\theta$ in a circle of radius r.

EXERCISE 2. In Chapter 1 we saw that, given a circle with area A and $\epsilon > 0$, there is an inscribed regular polygon P with $a(P) > A - \epsilon$. Show similarly that there is a circumscribed regular polygon Q with $a(Q) < A + \epsilon$.

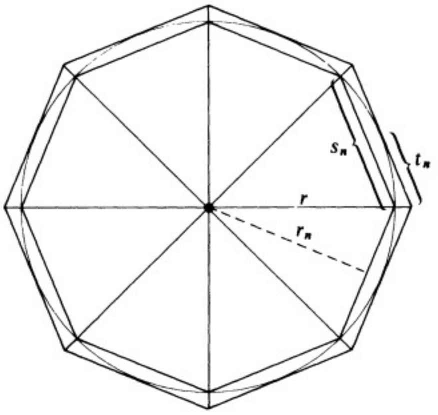

Figure 1

The proof of (1) is a typical *reductio ad absurdum* argument. Assuming that $A > \frac{1}{2}rC$, let $\epsilon = A - \frac{1}{2}rC$, and choose a regular n-sided polygon P inscribed in the circle such that

$$a(P) > A - \epsilon = \tfrac{1}{2}rC.$$

If s_n is the length of a side of P, and r_n is the length of a perpendicular from the center to a side of P, then

$$r_n < r \quad \text{and} \quad ns_n < C$$

by Exercise 1. Because P is the union of n isosceles triangles with base s_n and height r_n, it follows that

$$a(P) = n \cdot \tfrac{1}{2}r_n s_n = \tfrac{1}{2}r_n(ns_n) < \tfrac{1}{2}rC.$$

But this is a contradiction, so A is not greater than $\frac{1}{2}rC$.

Assuming that $A < \frac{1}{2}rC$, let $\epsilon = \frac{1}{2}rC - A$, and choose a regular n-sided circumscribed polygon Q such that

$$a(Q) < A + \epsilon = \tfrac{1}{2}rC.$$

For the purpose of subsequent computations, let t_n denote *half* the length of a side of Q. Then

$$a(Q) = n \cdot \tfrac{1}{2}r(2t_n) = \tfrac{1}{2}r(2nt_n) > \tfrac{1}{2}rC,$$

because the perimeter $2nt_n$ of Q is greater than C (Exercise 1). This contradiction completes the proof of (1). □

EXERCISE 3. Let A_n and C_n denote the area and perimeter, respectively, of a regular polygon with n sides inscribed in a circle of radius r. Show that

$$A_n = nr^2 \sin\frac{\pi}{n}\cos\frac{\pi}{n} \quad \text{and} \quad C_n = 2nr\sin\frac{\pi}{n}.$$

Deduce that $A = \frac{1}{2}rC$ by taking the limit of A_n/C_n as $n \to \infty$.

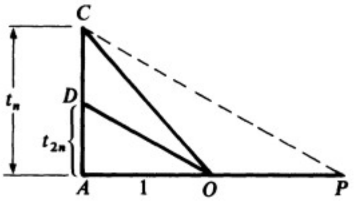

Figure 2

EXERCISE 4. With A_n and C_n as in Exercise 3, and r_n, s_n as in Figure 1, write $A_n = \frac{1}{2}nr_ns_n$ and $C_n = ns_n$. Deduce that $A = \frac{1}{2}rC$ without using trigonometric functions, by taking the limit of A_n/C_n as $n \to \infty$. What must you assume to be "obvious"?

In order to obtain the approximation (2) for π, Archimedes began with regular hexagons inscribed in and circumscribed about a circle of radius one. By successively doubling the number of sides he obtained pairs of inscribed and circumscribed regular polygons with 12, 24, 48, and 96 sides, and calculated their perimeters to find upper and lower bounds for π.

Consider first the circumscribed polygons. If t_n denotes *half* the length of a side of a regular circumscribed polygon with n sides, then the relationship between t_n and t_{2n} is indicated in Figure 2, where O is the center of the circle, and OD bisects angle AOC. If CP is parallel to OD, it is easily seen that $OP = CO$. Since triangles ADO and ACP are similar, it follows that

$$\frac{AD}{AO} = \frac{AC}{AO+OP} = \frac{AC}{AO+OC},$$

or

$$t_{2n} = \frac{t_n}{1+\sqrt{1+t_n^2}}. \tag{3}$$

Now consider the inscribed polygons. If s_n denotes the side of the regular inscribed polygon with n sides, the relationship between s_n and s_{2n} is indicated by Figure 3, where $s_n = BC$, $s_{2n} = BD$, and AD bisects angle BAC (Why?). It is easily checked that the triangles ABD, BPD, and APC

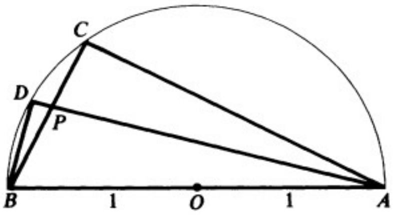

Figure 3

are similar. Hence

$$\frac{AB}{AD} = \frac{BP}{BD} \quad \text{and} \quad \frac{AC}{AD} = \frac{PC}{BD},$$

so

$$\frac{AB + AC}{AD} = \frac{BP + PC}{BD} = \frac{BC}{BD},$$

or

$$\frac{2 + \sqrt{4 - s_n^2}}{\sqrt{4 - s_{2n}^2}} = \frac{s_n}{s_{2n}}.$$

After cross-multiplying and squaring, the resulting equation yields

$$s_{2n}^2 = \frac{s_n^2}{2 + \sqrt{4 - s_n^2}}. \tag{4}$$

EXERCISE 5. Observe from the familiar geometry of the regular hexagon that $s_6 = 1$, $t_6 = 1/\sqrt{3}$. Apply formulas (3) and (4) to compute $s_{12}, s_{24}, s_{48}, s_{96}$ and $t_{12}, t_{24}, t_{48}, t_{96}$ recursively (using a hand calculator) so as to obtain

$$s_{96} = 0.065438 \quad \text{and} \quad t_{96} = 0.032737.$$

Since $48 s_{96} < \pi < 96 t_{96}$, conclude that

$$3\tfrac{10}{71} < \pi < 3\tfrac{1}{7}.$$

Hence $\pi = 3.14$, rounded off to two decimal places.

Of course, Archimedes did not have a hand calculator available. He started with the approximation

$$\tfrac{265}{153} < \sqrt{3} < \tfrac{1351}{780}$$

and proceeded manually, carefully rounding down in calculating the s_n's and rounding up in calculating the t_n's, finally obtaining

$$3\frac{10}{71} < \frac{6336}{2017\frac{1}{4}} < \pi < \frac{14688}{4673\frac{1}{2}} < 3\frac{1}{7}.$$

It is generally believed that the extant *Measurement of a Circle* is only a fragment of Archimedes' original and more comprehensive treatment of the circle. In a recent article W. R. Knorr [10] argues persuasively that, to obtain a more accurate approximation to π, Archimedes started with inscribed and circumscribed decagons (regular 10-sided polygons) and successively doubled sides six times to obtain inscribed and circumscribed regular polygons with 640 sides.

Exercise 6. Starting with the fact that the side of a regular decagon inscribed in the unit circle is $s_{10} = 2\sin 18° = (\sqrt{5} - 1)/2$, apply formulas (3) and (4) to recursively calculate s_{640} and t_{640}, carrying 8 decimal places on a hand calculator. Thence verify that $\pi = 3.1416$, rounded off to 4 decimal places.

Exercise 7. Let p_n and P_n denote the perimeters of the inscribed and circumscribed regular n-sided polygons for the unit circle. Noting that

$$s_n = 2\sin\frac{\pi}{n} \quad \text{and} \quad t_n = \tan\frac{\pi}{n},$$

show that

$$p_{2n} = \sqrt{p_n P_{2n}} \quad \text{and} \quad P_{2n} = \frac{2p_n P_n}{p_n + P_n}.$$

Starting with $p_4 = 4\sqrt{2}$ and $P_4 = 8$ for inscribed and circumscribed squares, use these recursive formulas to calculate p_{64} and P_{64}. What bounds on π does this computation give?

Exercise 8. If a_n and A_n are the areas of the inscribed and circumscribed polygons in the previous exercise, show that

$$a_{2n} = \sqrt{a_n A_n} \quad \text{and} \quad A_{2n} = \frac{2a_{2n} A_n}{a_{2n} + A_n}.$$

The Quadrature of the Parabola

A *segment* of a convex curve is a region bounded by a straight line and a portion of the given curve (Fig. 4). In the preface to the *Quadrature of the Parabola*, Archimedes remarks that earlier mathematicians had successfully attempted to find the area of a segment of a circle or hyperbola, but that apparently no one had previously attempted the quadrature of a segment of a parabola—precisely the one that can be carried out by the method of exhaustion.

The parabola was originally defined by the Greeks as a conic section. That is, given a circular (double) cone with vertical axis, a parabola is the

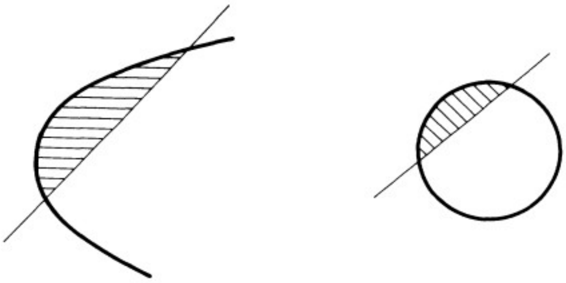

Figure 4

D -256- - -* ! - / ! ! 2 ! 3 1 L
! 1"
(/ $$

Remarks: (i) There is an alternative proof of the limit in 3.21 which is short and transparent but a bit less elementary, and affords no estimate of the speed of convergence. Let L be the function L_1 of 3.19. For integers $n > N > 0$, $z \in \overline{D}(0, N) \setminus \{0\}$ implies $1 + z/n \in D(1, 1)$. Consequently, by 3.19

$$nL(1 + z/n) = z \cdot \frac{L(1 + z/n) - L(1)}{z/n} \to zL'(1) = z \quad \text{as} \quad n \to \infty,$$

uniformly in such z, whence $(1+z/n)^n = [\exp L(1+z/n)]^n = \exp(nL(1+z/n)) \to \exp(z)$. [Similarly, $(1 + z_n/n)^n \to e^z$ whenever $z_n \to z$.]

(ii) According to 3.21 the numbers $a_n := n!\,n^{-n}$ satisfy $a_{n+1}/a_n = (1 + 1/n)^{-n} \to 1/e$, in view of which 3.9 tells us that $a_n^{1/n} = n^{-1}(n!)^{1/n} \to 1/e$. After a little algebra, involving $n^{-1}\sum_{j=1}^{n} j = \frac{1}{2}(n+1)$, another interesting feature of e comes to light:

$$\frac{1}{2}e = \lim_{n\to\infty} \frac{\text{Arithmetic Mean of } \{1, 2, \ldots, n\}}{\text{Geometric Mean of } \{1, 2, \ldots, n\}}.$$

(A generalization to means of $\{1^s, 2^s, \ldots, n^s\}$ $(s > -1)$ was proved by different [elementary] means by Xu [2010].)

Although the constant π is ubiquitous in this subject (see Castellanos [1988]), one seldom needs estimates of it finer than (8) and (8)$'$ in the proof of 3.14. Nevertheless, we will look at a few of the myriad series and integrals by which it can be explicitly calculated.

Theorem 3.22 (Gregory-Leibniz series) $\dfrac{\pi}{4} = \displaystyle\int_0^1 \frac{dx}{1+x^2} = \sum_{n=0}^{\infty} \frac{(-1)^n}{2n+1}.$

Proof: The quadratic polynomial $X^2 - i$ has exactly two zeros in $\mathbb{C}$, $\pm(1 + i)/\sqrt{2}$. Since, in the notation of the proof of 3.14,

$$\left[C\left(\frac{\pi}{4}\right) + iS\left(\frac{\pi}{4}\right)\right]^2 = E\left(i\frac{\pi}{4}\right)^2 = E\left(i\frac{\pi}{2}\right) = i$$

and C, S are non-negative in $\left[0, \frac{\pi}{2}\right]$, it must be that

$$C\left(\frac{\pi}{4}\right) = S\left(\frac{\pi}{4}\right) = \frac{1}{\sqrt{2}}. \tag{1}$$

Since C is an even function and is never zero in $[0, \pi/2)$, by definition of π, we may form the function $T := S/C$ on $(-\pi/2, \pi/2)$ and have from equations (5) of the proof of 3.14 that

$$T' = \frac{S'C - SC'}{C^2} = \frac{C^2 + S^2}{C^2} = 1 + (S/C)^2 = 1 + T^2 > 0. \tag{2}$$

Therefore T is strictly increasing. Since $T(0) = 0$ and $T(t) \to +\infty$ as $t \uparrow \frac{\pi}{2}$, the range of the odd function T is $\mathbb{R}$. Now $T^{-1}\colon \mathbb{R} \mapsto (-\pi/2, \pi/2)$ exists and by (2)

$$\int_0^x \frac{1}{1+t^2}\,dt = \int_{T^{-1}(0)}^{T^{-1}(x)} \frac{T'}{1+T^2} = \int_{T^{-1}(0)}^{T^{-1}(x)} 1 = T^{-1}(x) \qquad \forall x \in \mathbb{R} \tag{3}$$

and in particular, because of (1),

$$\int_0^1 \frac{1}{1+t^2}\,dt = T^{-1}(1) = \frac{\pi}{4}. \tag{3$'$}$$

For every $N \in \mathbb{N}$, $t \in \mathbb{R}$

$$\sum_{n=0}^{N-1} \left(-t^2\right)^n = \frac{1-\left(-t^2\right)^N}{1-(-t^2)} = \frac{1}{1+t^2} - \frac{(-1)^N t^{2N}}{1+t^2}$$

and therefore

$$\begin{aligned} \left|\sum_{n=0}^{N-1} \frac{(-1)^n x^{2n+1}}{2n+1} - \int_0^x \frac{1}{1+t^2}dt\right| &= \left|\int_0^x \left[\sum_{n=0}^{N-1} \left(-t^2\right)^n - \frac{1}{1+t^2}\right]dt\right| \\ &= \left|\int_0^x \frac{(-1)^{N-1} t^{2N}}{1+t^2}dt\right| \qquad \forall x \in \mathbb{R}. \end{aligned} \tag{4}$$

The trivial inequalities $\frac{1}{2}t^{2N} \le t^{2N}(1+t^2)^{-1} \le t^{2N}$ for $t \in [-1,1]$ let us estimate the last integral in (4), below and above, yielding for $x \in [-1,1]\,, N \in \mathbb{N}$.

$$\frac{|x|^{2N+1}}{4N+2} \le \left|\sum_{n=0}^{N-1} \frac{(-1)^n x^{2n+1}}{2n+1} - \int_0^x \frac{1}{1+t^2}dt\right| \le \frac{|x|^{2N+1}}{2N+1}. \tag{5}$$

In particular, using (3)

$$T^{-1}(x) = \sum_{n=0}^{\infty} \frac{(-1)^n x^{2n+1}}{2n+1} \qquad \forall x \in [-1,1]\,. \tag{6}$$

Now equations (3)$'$ and (6) prove the theorem, but (3)$'$ and (5) also furnish the estimate

$$\frac{1}{4N+2} \le \left|\sum_{n=0}^{N-1} \frac{(-1)^n}{2n+1} - \frac{\pi}{4}\right| \le \frac{1}{2N+1} \qquad \forall N \in \mathbb{N}. \tag{7}$$

Remarks: (i) See 3.37(vii), 3.38(viii) and 11.37(viii) [with $z := 1/2$] for different proofs. This series converges excruciatingly slowly, as (7) shows; for one converging to π with geometric rapidity, see 5.82(ii). After checking (see 3.30(ii) Hints) that $T(\pi/6) = 1/\sqrt{3}$, one can also take $x := 1/\sqrt{3}$ in (6) and get the even more rapidly converging representation

$$\frac{\pi}{6} = \frac{1}{\sqrt{3}} \sum_{n=0}^{\infty} \frac{(-1)^n}{2n+1} \cdot \frac{1}{3^n}. \tag{8}$$

In 3.45(v) we will see that for each $x \in \overline{\mathbb{D}} \setminus \{-i, i\}$ the series (6) converges to a solution w of the equation $\tan w = x$. (See def. 3.27.)

(ii) Besides using the partial sums of the series or Riemann-sum approximations to the integral, there is a third (more efficient?) way to exploit 3.22 for rational approximations to π. Each $n \in \mathbb{N}$ determines a polynomial p_n with integer coefficients such that $x^{4n}(1-x)^{4n} = p_n(x)(1+x^2) + (-4)^n$. (One checks that $p_1(x) := x^6 - 4x^5 + 5x^4 - 4x^2 + 4$ works and the rest is induction.) Therefore $\int_0^1 x^{4n}(1-x)^{4n}(1+x^2)^{-1}dx$ is a rational number minus $(-4)^{n-1}\pi$. This integral is positive and less than $[\max\{x(1-x) : 0 \le x \le 1\}]^{4n} = 4^{-4n}$. A rational approximation to π closer than $4^{-4n-(n-1)} = 4^{-5n+1}$ emerges. In case $n = 1$, $\int_0^1 x^4(1-x)^4(1+x^2)^{-1}dx = 22/7 - \pi$. Since

$$\frac{1}{630} = \int_0^1 x^4(1-x)^4 dx > \int_0^1 x^4(1-x)^4(1+x^2)^{-1}dx > \int_0^1 x^4(1-x)^4 2^{-1}dx = \frac{1}{1260},$$

we get $1/630 > 22/7 - \pi > 1/1260$, and so

$$3 + \frac{10}{71} < \frac{22}{7} - \frac{1}{630} < \pi < \frac{22}{7} - \frac{1}{1260} < 3 + \frac{1}{7}.$$

This is from DALZELL [1944], with more in LUCAS [2009]. The extreme inequalities are Archimedes' famous estimate; his geometric construction can be found on pp. 31–34 of C. H. EDWARDS [1979].

(iii) Yet a fourth way to utilize 3.22 is to express $\pi/4 = \arctan(1)$ as a rational linear combination of $\arctan(\varepsilon_j)$ for small ε_j (for which the series is more rapidly convergent). One of these goes back to Euler: $\pi/4 = 4\arctan(1/5) - \arctan(1/70) + \arctan(1/99)$. There are numerous such relations; see pp. 274–275 of BERGGREN, BORWEIN and BORWEIN [2004], pp. 59–65 of EYMARD and LAFON [2004] and pp. 90–98 of CASTELLANOS [1988].

(iv) In 1755, Euler found a series which, in contrast to (6), converges to $T^{-1}(x)$ throughout $\mathbb{R}$:

$$T^{-1}(x) = \frac{x}{1+x^2} \sum_{k=0}^{\infty} \frac{2^{2k}(k!)^2}{(2k)!} \; \frac{1}{2k+1} \left(\frac{x^2}{1+x^2}\right)^k \qquad \forall x \in \mathbb{R}. \tag{9}$$

To confirm it, change the variable of integration in (3) via $t =: xC(\theta)$, $x \neq 0$, $\theta \in [0, \pi/2]$, to get

$$(1+x^2)/(1+t^2) = 1/[1 - \frac{x^2}{1+x^2} S^2(\theta)] = \sum_{k=0}^{\infty} \left(\frac{x^2}{1+x^2}\right)^k S^{2k}(\theta).$$

After commuting the uniformly converging series in $S(\theta)$ with the integration, the k^{th} coefficient is $\int_0^{\pi/2} S^{2k+1}(\theta) d\theta$; that it equals $2^{2k}(k!)^2/(2k+1)!$ is confirmed by induction, reduction of k being accomplished by an integration by parts. [The Yin & Yang relation between (9) and 5.82(iv) is noteworthy.]

(v) Since $(T^{-1})'(t) = 1/(1+t^2)$, we have

$$\frac{1}{2}(T^{-1}(x))^2 = \int_0^x T^{-1}(t)/(1+t^2)\ dt.$$

Use (9) on the integrand, permute integration and summation, and make the change of integration variable $u := t^2/(1+t^2)$. You get a combinatorially remarkable companion to (9):

$$(9)^2 \qquad (T^{-1}(x))^2 = \sum_{k=0}^{\infty} \frac{2^{2k+1}(k!)^2}{(2k+2)!} \left(\frac{x^2}{1+x^2}\right)^{k+1} \qquad \forall x \in \mathbb{R}.$$

Exercise 3.23 *With the convention $0^0 := 1$, the function x^{-x} is continuous on $[0,1]$. (Cf. 3.18(4) and recall the customary definition $x^{-x} := e^{-x \log x}$ for $x > 0$.) Prove the satisfyingly symmetric formula*

$$\int_0^1 x^{-x}\, dx = \sum_{n=1}^{\infty} n^{-n}.$$

Hints: $x^{-x} = \sum_0^{\infty} (-1)^n (x \log x)^n / n!$. Interchange summation and integration and evaluate $\int_0^1 x^n \log^n(x)\, dx$ by repeated integration-by-parts.

Exercise 3.24 *Consider $f(x) := \int_0^1 (1+t^2)^{-1} e^{-x^2(1+t^2)} dt$ and $g(x) := \int_0^x e^{-t^2}\, dt$, $x \in [0, \infty)$.*

(i) *Show that $0 < f(x) < e^{-x^2} f(0)$ for all $x > 0$.*

(ii) *Use 2.19(i) to show that $f'(x) = -2e^{-x^2} g(x)$ for all $x \geq 0$; that is, $f' = \left(-g^2\right)'$.*

(iii) *Prove that $\int_0^{\infty} e^{-t^2}\, dt = \sqrt{\pi}/2$.*

here, the definition of cos and sin!] can consult the two-volume work of Naux [1966], [1971] (being wary of its deficiencies, as pointed out in the *Zentralblatt* reviews) and the numerous papers of J. W. L. Glaisher, Florian Cajori, and Joseph E. Hofmann.

3.22 inspired Leibniz to quote Virgil (on gambling!): "Numero Deus impari gaudet." Its interesting history and independent discovery by an Indian mathematician are detailed in the prize-winning paper Roy [1990]; also Parameśwaran [1992]. A beautiful elementary derivation is given by Kazarinoff [1964], Matsumoto [1995] and Zheng [2002]. Essentially the first equality in 3.22 was adopted by Weierstrass (in 1841) as his *definition* of π.) (This was also the definition adopted in the alternative treatment of the exponential function given in 2.22.) The present definition of π as "twice the least positive zero of the cosine function" dates at latest from an 1875 textbook of Richard Baltzer, and appears in Pringsheim [1925] and E. Landau [1950]. When Landau used it in his Göttingen lectures in 1934, it occasioned a vicious attack by the Nazis—see chapter 6 of Ebbinghaus, *et al.* [1990].

3.23 is from the Euler-Johann Bernoulli correspondence (see **MR** 88f:01011, **Zbl** 631.01011 for its history); different proofs may be found in Hoppe [1877] and Selberg [1933], and the 3.23 method is pushed a little farther in Glaister [2001]. Lord [2003a] shows that many other continuous functions g satisfy $\int_0^1 g(x)\,dx = \sum_{n=1}^{\infty} g(n)$, including $g(x) := c^x$ for a unique $c > 0$.

A very nice alternative proof of 3.25 can be found on page 35 of Guichardet [1968] or page 235 of Stromberg [1981]. Yet another proof runs thus: use an analog of 4.1 to find a continuous function $\phi\colon \mathbb{R} \mapsto \mathbb{C}$ such that $f = e^{\phi}$ and $\phi(0) = 0$. Deduce that ϕ is additive, whence $\phi(r) = r\phi(1)$ for all rational r, whence by continuity $\phi(x) = cx$ for all $x \in \mathbb{R}$ $(c := \phi(1))$. The integration trick in the text originates with Schimmack [1908], rediscovered by Kac [1936/37]. It is further capable of showing that the only endomorphisms of $(\mathbb{R}, +)$ which are integrable over $[0, 1]$ are the constant multiples of the identity. Since the rate of change of many quantities in nature is (approximately) a constant multiple of their momentary magnitude, 3.25(i) is the reason for the ubiquity of the exponential function in science.

Though proofs of 3.32(i) appear in Gutzmer [1887], [1888], [1889], the result pre-dates this; he acknowledges the priority of A. Harnack, but in fact the formula goes back to an 1806 memoir of M. A. Parseval (see §23 of Burkhardt [1914]) and is customarily referred to in the literature as Parseval's formula. See remark (iii) following 5.20 and Chapter XI. The Cauchy estimates date from 1831 and were discovered independently in 1841 by Weierstrass (*Werke* I, pp. 67–68 and II, pp. 224–226 and Ullrich [1990]), who gave an integral-free treatment. On the latter see also Méray [1891b], pp. 278, 280, 606 of Pringsheim [1925], A. Kneser [1920], Montel [1936], and pp.

Observe that for $0 < x \leq 2$ and $n \geq 1$

$$\frac{x^2}{(4n)!} \leq \frac{4}{(4n)(4n-1)(4n-2)!} < \frac{1}{(4n-2)!}$$

and so

$$\begin{aligned} C(x) &= 1 + \left[\frac{x^2}{4!} - \frac{1}{2!}\right] x^{4-2} + \sum_{n=2}^{\infty} \left[\frac{x^2}{(4n)!} - \frac{1}{(4n-2)!}\right] x^{4n-2} \\ &< 1 + \left[\frac{x^2}{4!} - \frac{1}{2!}\right] x^{4-2}. \end{aligned}$$

Therefore $C(\sqrt{3}) < -\frac{1}{8}$. Since $C(0) = \operatorname{Re} E(0) = 1$, we have that $C\big[0, \sqrt{3}\,\big]$ is a connected subset of $\mathbb{R}$ which contains positives and negatives and hence zero; that is, the compact set $\big[0, \sqrt{3}\,\big] \cap C^{-1}(0)$ is not void. Let $\pi/2$ denote its least element:

$$\pi/2 := \min\Big(\big[0, \sqrt{3}\,\big] \cap C^{-1}(0)\Big). \tag{7}$$

Thus

$$0 < \pi/2 < \sqrt{3} \quad \text{and} \quad C(\pi/2) = 0. \tag{8}$$

[The notation π, meant to suggest "perimeter" (of a circle having unit diameter), anticipates the remarks following 3.16.] An insertion-of-parentheses argument similar to the above shows that

$$C(x) > 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} =: P(x), \quad x \in \big(0, 3\sqrt{10}\big].$$

This polynomial is decreasing on $\big[0, \sqrt{6}\big]$ (look at its derivative), so

$$C(x) > P(x) \geq P(3/2) > 0 \qquad \forall x \in (0, 3/2]\,.$$

We infer that $\pi/2 > 3/2$, i.e.,

$$\pi > 3. \tag{8$'$}$$

From (8) and (6) we get

$$S(\pi/2) = \pm 1. \tag{9}$$

However by (5) and the definition of π

$$S' = C > 0 \quad \text{in } [0, \pi/2)\,, \tag{10}$$

the fact (see the Remarks following 3.16) that every $x+iy \in \mathbb{T}_+$ is $\cos\theta + i\sin\theta$ for a unique $\theta \in (0,\pi)$, and this θ is the length of the counterclockwise *arc* of $\mathbb{T}$ with initial point 1 and terminal point $x+iy$; so $\theta = \cos^{-1}(x)$ is an arclength.

Cosh and sinh are known as *hyperbolic trigonometric* functions. Notice that cosh is an even function which effects a strictly increasing mapping of $[0,\infty)$ onto $[1,\infty)$, and sinh is an odd function which effects a strictly increasing mapping of $\mathbb{R}$ onto $\mathbb{R}$. The inverses of these restrictions are denoted arcosh and arsinh, respectively. Just as $t \mapsto (\cos t, \sin t)$, $t \in [-\pi/2, \pi/2]$, parameterizes the right half of the circle $x^2 + y^2 = 1$, the function $t \mapsto (\cosh t, \sinh t)$, $t \in \mathbb{R}$, parameterizes the right half of the "equilateral" hyperbola $x^2 - y^2 = 1$. But the parameter t appears to lose its arclength significance in the latter case. Rather it is now an area: The sector bounded by the circle and its two radii $[0, x \pm iy]$ $(x > 0, y > 0)$ has area $\arccos(x) = \arcsin(y)$, while the analogous region bounded by the hyperbola and its "radii" $[0, x \pm iy]$ has area $\operatorname{arcosh}(x) = \operatorname{arsinh}(y)$, as the reader can routinely compute. These facts elucidate the use of the adjective "hyperbolic" and the fact that the prefix "ar" is intended to suggest "area".

In the spirit of *ars gratia artis* I want to briefly divert from business to offer the reader a glimpse into "the BOOK," Paul Erdös' famous fantasy repository of proofs that the Almighty itself judges to be *ne plus ultra.* The idea of this proof goes back to Charles Hermite, in 1873, but the exposition here follows AIGNER and ZIEGLER [2010]. T. W. JONES [2010], ZHOU and MARKOV [2010] and ZHOU [2011] analyze the mechanism of the π-proof and its evolution. They also show how these ideas can prove the irrationality of $\cos(r)$ and $\tan(r)$ for every non-zero rational r. Other elementary proofs will be found in HANČL [1986], DESBROW[1990] (via complex analysis), LACZKOVICH [1997], and HUYLEBROUCK [2001].

Theorem 3.28 *π^2 is irrational, and e^m is irrational for every $m \in \mathbb{N}$.*

Proof: A central role in both proofs is played by the $2n$-degree polynomial

$$p(x) := x^n(1-x)^n/n!, \tag{1}$$

$n \in \mathbb{N}$ to be specified later. The properties needed are

$$0 < p(x) < 1/n! \qquad \forall x \in (0,1), \tag{2}$$

$$p^{(k)}(0), p^{(k)}(1) \in \mathbb{Z} \qquad \forall k \in \mathbb{Z}_+. \tag{3}$$

Since $0 < x(1-x) < 1$ for $x \in (0,1)$, (2) is clear. Evidently the polynomial $q(x) := x^n(1-x)^n$ has the form $\sum_{j=n}^{2n} c_j x^j$ with coefficients $c_j \in \mathbb{Z}$ (use, say, induction on n), and so $q^{(k)}(0) = 0$ if $k < n$ or $k > 2n$. If, on the other hand, $n \le k \le 2n$, then $q^{(k)}(x) = \sum_{j=k}^{2n} j(j-1)\dots(j-k+1)c_j x^{j-k}$, so $q^{(k)}(0) = k!c_k$, an integer multiple of $n!c_k$. Hence $p^{(k)}(0) = q^{(k)}(0)/n! \in \mathbb{Z}$. And since $p(x) = p(1-x)$, $p^{(k)}(1) = (-1)^k p^{(k)}(0) \in \mathbb{Z}$.

Now suppose first that for some $m, a, b \in \mathbb{N}$

$$e^m = a/b. \tag{4}$$

Since the power series for e^{m^2} converges, we may pick $n \in \mathbb{N}$ so that

$$(m^2)^n/n! < 1/am. \tag{5}$$

With the p in (1) form

$$P := \sum_{k=0}^{2n} (-1)^k m^{2n-k} p^{(k)}.$$

Since $p^{(2n+1)} = \mathbf{0}$, we see that

$$\begin{aligned} P' = \sum_{k=0}^{2n-1} (-1)^k m^{2n-k} p^{(k+1)} &= \sum_{j=1}^{2n} (-1)^{j-1} m^{2n-(j-1)} p^{(j)} \\ &= -m \sum_{j=1}^{2n} (-1)^j m^{2n-j} p^{(j)} = -m[P - m^{2n}p]. \end{aligned}$$

Hence

$$\frac{d}{dx}[e^{mx}P(x)] = me^{mx}P(x) + e^{mx}P'(x) = m^{2n+1}e^{mx}p(x).$$

Consequently, the mean-value theorem supplies $x \in (0,1)$ such that $e^m P(1) - e^0 P(0) = m^{2n+1}e^{mx}p(x)$. That is, in view of (4),

$$N := aP(1) - bP(0) = bm^{2n+1}e^{mx}p(x), \tag{6}$$

which is an integer, due to (3) and the definition of P. From (2) and (6)

$$0 < N \le bm^{2n+1}e^m/n! \overset{(4)}{=} m^{2n+1}a/n! \overset{(5)}{<} 1,$$

inequalities which contradict the fact $N \in \mathbb{Z}$ and thus prove that (4) is untenable.

Turning to the π^2-claim, its proof being similar, a few computations can be left to the reader. Suppose then that for some $a, b \in \mathbb{N}$

$$\pi^2 = a/b, \tag{7}$$

and select $n \in \mathbb{N}$ such that

$$a^n/n! < 1/\pi. \tag{8}$$

With the p in (1) form

$$P := b^n \sum_{k=0}^{n} (-1)^k \pi^{2(n-k)} p^{(2k)}$$

and calculate that

$$P^{''} = -\pi^2 P + b^n \pi^{2n+2} p.$$

Use this to further calculate

$$\begin{aligned} \frac{d}{dx}\Big[\pi^{-1}P'(x)\sin\pi x - P(x)\cos\pi x\Big] &= \Big[\pi^{-1}P^{''}(x) + \pi P(x)\Big]\sin\pi x \\ &= b^n\pi^{2n+1}p(x)\sin\pi x \end{aligned}$$

and from this and the mean-value theorem get an $x \in (0,1)$ such that

$$N := P(1) + P(0) = b^n \pi^{2n+1} p(x) \sin \pi x. \tag{9}$$

Because of (7), $b^n \pi^{2(n-k)} \in \mathbb{N}$ for each $k = 0, 1, \ldots, n$ and therefore (3) and the definition of P tell us that $P(0)$, $P(1) \in \mathbb{Z}$. Hence $N \in \mathbb{Z}$. But from (9) and (2)

$$0 < N \le b^n \pi^{2n+1}/n! \overset{(7)}{=} a^n \pi/n! \overset{(8)}{<} 1,$$

inequalities which contradict $N \in \mathbb{Z}$ and thus prove that (7) is untenable.

I think readers will agree: a proof “from the BOOK.”

Exercise 3.29 (i) $|\sin x| \le |x|$ *for all real* x.

Hint: For each $x \neq 0$ the Mean-Value Theorem provides an x' such that

$$\left|\frac{\sin x}{x}\right| = \left|\frac{\sin(x) - \sin(0)}{x - 0}\right| = \left|\sin'(x')\right| = |\cos(x')| \le 1.$$

(ii) $\cos x \ge 1 - 2x/\pi$ *for all* x *in* $[0, \pi/2]$.

Hints: The function $g(x) := \cos x + 2x/\pi$ satisfies $g(0) = g(\pi/2) = 1$. Also $g' = 2/\pi - \sin$. From equation (10) in the proof of 3.14, sin increases on $[0, \pi/2]$ from $\sin(0) = 0$ to $\sin(\pi/2) = 1 > 2/\pi$. Therefore g' has a unique zero $x_0 \in [0, \pi/2]$, $g' > 0$ on $[0, x_0)$ and $g' < 0$ on $(x_0, \pi/2]$. It follows that g is increasing on $[0, x_0]$, decreasing on $[x_0, \pi/2]$ and so $\min g[0, \pi/2] = g(0) = g(\pi/2) = 1$.

Exercise 3.30 (i) *$\sin x \geq 2x/\pi$ for all $x \in [0, \pi/2]$.*

Hints: The function $h(x) := \sin x - 2x/\pi$ satisfies $h(0) = h(\pi/2) = 0$ and $h' = -2/\pi + \cos$. Now $\cos' = -\sin$ is negative on $(0, \pi/2]$, so h' decreases from $h'(0) = -2/\pi + 1 > 0$ to $h'(\pi/2) = -2/\pi < 0$. As in the hints of 3.29(ii), it follows that $\min h[0, \pi/2] = h(0) = h(\pi/2) = 0$. (For refinements of (i), see **MR** 2006m:26027.)

(ii) *$|\sin(\pi z)| > 1/2$ for all $z \in \mathbb{C} \setminus \bigcup_{n\in\mathbb{Z}} D(n, 1/4)$.*

Hints: Consider the hyperbolic sine function

$$h(t) := \frac{1}{2}\left(e^t - e^{-t}\right) = \sum_{k=0}^{\infty} \frac{t^{2k+1}}{(2k+1)!}, \quad t \in \mathbb{R}.$$

Evidently $h(|t|) \geq |t|$. By elementary algebra, if $x, y \in \mathbb{R}$ and $z := x + iy$, then $|\sin(\pi z)|^2 = \sin^2(\pi x) + h^2(\pi y)$. Suppose $|\sin(\pi z)|^2 \leq 1/4$. Then

$$\text{(1)} \qquad \sin^2(\pi x) \leq 1/4 \quad \text{and} \quad h^2(\pi y) \leq 1/4.$$

Since $(\sqrt{3} + i)/2$ and $e^{\pi i/6}$ each lie in $\mathbb{U} \cap \mathbb{H}$ and each is a cube root of i, they must be equal. So $\sin(\pi/6) = 1/2$. Since sin is an odd function, strictly increasing on $[-\pi/2, \pi/2]$, it follows that $t \in [-\pi/2, \pi/2]$ & $|\sin t| \leq 1/2 \Rightarrow |t| \leq \pi/6$. For the x in (1) choose $n \in \mathbb{Z}$ such that $|x - n| \leq 1/2$. Then $\pi x - n\pi \in [-\pi/2, \pi/2]$ and $|\sin(\pi x - n\pi)| = |\sin(\pi x)| \leq 1/2$, so $|\pi x - n\pi| \leq \pi/6$. Furthermore, since

$$(\pi y)^2 = |\pi y|^2 \leq h^2(|\pi y|) = h^2(\pi y),$$

inequality (1) yields $(\pi y)^2 \leq 1/4$ and so

$$\text{(2)} \qquad |z - n|^2 = (x - n)^2 + y^2 \leq \left(\frac{1}{6}\right)^2 + \frac{1}{4\pi^2}.$$

But by $(8)'$ in the proof of 3.14, $\pi > 3$, so (2) gives

$$|z - n|^2 < \left(\frac{1}{6}\right)^2 + \left(\frac{1}{6}\right)^2 < \left(\frac{1}{4}\right)^2.$$

Yet a fourth way to utilize 3.22 is to express

$\pi/4 = \arctan(1)$ as a rational linear combination of

$\arctan(\varepsilon_j)$ for small ε_j

(for which the series is more rapidly convergent).

One of these goes back to Euler:

$$\pi/4 = 4\arctan(1/5) - \arctan(1/70) + \arctan(1/99).$$

Pag. 180 (206) –

3.22 inspired Leibniz to quote Virgil (on gambling!):

"Numero Deus impari gaudet".

Essentially the first equality in 3.22 was adopted by Weierstrass (in 1841) as his definition of π.

(This was also the definition adopted in the alternative treatment of the exponential function give in 2.22).

The present definition of π as "twice the least positive zero of the cosine function"

c) The items 6)–8) introduce a further hypothesis on the origin of the *conatus explosivus*: it can be originated by an impulse, through which the gravific fluid is pushed out from earth's centre in straight lines towards any direction. Item 8) specifies how such a fluid could act to produce gravity. This can happen by transport of matter or by a wave.
d) Item 9) concerns the specific weight.
e) Item 10) is strictly connected to the hypothesis that gravity acts by straight lines as light. For, if one wishes to reduce the fact that gravity acts with an intensity which decreases as the square of the distance to the fact that light acts in this manner, he has to show that gravity acts with a mechanism similar to light's. This is the reason why Leibniz embraced the hypothesis of the *conatus explosivus*.

Some commentaries:

Aiton stresses that the fluid responsible for gravity is different from that causing the harmonic vortex.[42] He quotes a passage of the already mentioned letter to Huygens in which Leibniz explicitly claimed:

> I distinguish the aether which causes the gravity (*pesanteur*) (and perhaps also the direction of parallelism of the axes) from that which carries the planets, which is rather coarser.[43]

The quotation mentioned by Aiton is perfectly coherent with what Leibniz asserted in the *Zweite Bearbeitung*. For, if the earth is born by means of the condensation of a certain matter, it is quite plausible that the least dense part of the original matter—namely a liquid part—has been pushed outside. It met the original fluid responsible for the harmonic circulation and—being less dense than this fluid—begun to orbit around the earth. The dense harmonic vortex, which surrounded the terrestrial vortex, prevented it to escape along the tangent. Given this picture, it is then necessary to add, that the fluid necessary for Leibniz's theory were, in fact, three and not only two:

a) fluid responsible for the harmonic vortex;
b) fluid responsible for gravity;
c) fluid responsible for the different specific weights of the bodies.

For, in the previous quotation the word *pesanteur* seems clearly to refer to gravity as a general phenomenon, not to the different specific weights of the bodies.

What Leibniz explained in the *Zweite Bearbeitung* is interesting from many aspects and unsatisfactory for other aspects. First of all the argument is complex as far as the line of reasoning is concerned because there is a triple causal level: the

Nevertheless, using a similar treatment, we shall see later that string theory *can* account for the entropy but the associated microstates are *non*-perturbative. Even then, the accounting has so far only been successful for certain special types of black hole called 'extreme' black holes. We therefore first describe the features of extreme black holes that are important for understanding the microscopic origin of their entropy.

10.5 Extreme black holes

It might, in any case, be objected that associating perturbative string states with black holes is absurd. The former are obtained by quantizing the string in a flat background spacetime. How could they be equivalent to a black hole? Nevertheless, certain perturbative states *can* be associated with 'extreme' black holes. We have already noted the constraint $M \geq |Q|$ for the Reissner–Nordström (RN) metrics (10.33). Metrics saturating this constraint are called 'extreme' (RN) black holes. The usual (supersymmetric) perturbative states in string theory satisfy $M \geq |Q|$ and states saturating this inequality are called 'BPS states' after Bogomolnyi [14] and Prasad and Sommerfield [15]. They have the crucial property that their mass cannot receive quantum corrections and it is this that allows their association with extreme black holes. As the string coupling strength g_s increases, the mass M of the perturbative state is unaltered, since it is independent of g_s classically, and because of supersymmetry, there are no quantum corrections. However, the gravitational field of the state is determined by $G_N M$ (in four dimensions) and G_N is proportional to g_s^2. Thus, as g_s increases, the gravitational field increases, there is a back reaction on the perturbative state and, eventually, it may be described by a curved spacetime with large curvature. Thus, in principle at least, it might be possible to associate extreme black-hole spacetimes with perturbative states.

The RN black hole looks like a natural starting place in the search for black holes in string theory. We can think of the Einstein–Maxwell action (10.31) as the bosonic part of the $\mathcal{N} = 2$ supergravity theory in four dimensions. The (massless) gravity supermultiplet contains the graviton, two (fermionic) gravitinos and a vector boson called the 'graviphoton'. The supersymmetry algebra is [13]

$$\begin{aligned} \{Q^A_\alpha, \overline{Q}_{B\dot{\beta}}\} &= 2\delta^A_B \sigma^\mu_{\alpha\dot{\beta}} P_\mu \\ \{Q^A_\alpha, Q^B_\beta\} &= 2\epsilon_{\alpha\beta} Z^{AB} \end{aligned} \tag{10.91}$$

where Q^A_α, with $\alpha = 1, 2$ a (Weyl) spinor index and $A = 1, 2$, are the two supersymmetry generators; the $\overline{Q}$s are defined by $\overline{Q}_{A\dot{\alpha}} \equiv (Q^A_\alpha)^\dagger$; the 2×2 matrices σ^μ with $\mu = 0, 1, 2, 3$ are defined by $\sigma^\mu = (I_2, \sigma^i)$, with σ^i ($i = 1, 2, 3$) the standard Pauli matrices; $\epsilon_{\alpha\beta}$ and the 'central charge' Z^{AB} are antisymmetric with $\epsilon_{12} = +1$ and $Z^{12} \equiv Z$ and, without loss of generality, we may choose $Z \geq 0$. (The graviphoton is a $U(1)$ gauge boson coupled to a charge which is, in fact, the central charge.) For massive representations, we may work in the rest frame where $P_\mu = (M, \mathbf{0})$. Then it is easy to see (exercise 9) that we may form two linear combinations a_α and b_α of the generators that satisfy

$$\begin{aligned}\{a_\alpha, a_\beta^\dagger\} &= 4(M + Z)\delta_{\alpha\beta}\\ \{b_\alpha, b_\beta^\dagger\} &= 4(M - Z)\delta_{\alpha\beta}\\ \{a_\alpha, b_\beta^\dagger\} &= 0 = \{a_\alpha, b_\beta\}\end{aligned} \tag{10.92}$$

Up to a normalization factor, these are just the anticommutation relations obeyed by two independent sets of fermion annihilation and creation operators. In general, starting with a state $|\psi\rangle$ that is annihilated by a_α and b_α, we can construct a total of 16 states using the creation operators $a_\alpha^\dagger$ and $b_\alpha^\dagger$. Since $\langle\phi|\{a_\alpha, a_\alpha^\dagger\}|\phi\rangle \geq 0$ for any state $|\phi\rangle$ and, similarly, for b_α, the 'BPS bound'

$$M \geq |Z| \tag{10.93}$$

follows. The inequality is saturated by representations (BPS states) for which $|\psi\rangle$ is also annihilated by one set of creation operators ($b_\alpha^\dagger$ if $Z > 0$). Thus, such states are 'short' massive representations of the supersymmetry algebra, since they are constructed using only the $a_\beta^\dagger$ creation operators. They are invariant under half of the supersymmetry algebra.

The extreme RN black hole, obtained from (10.33) and (10.34) by setting $M = Q$, *is* part of such a short hypermultiplet [16]. In this case, the two horizons are both at $r = M = Q$ and, defining $\rho \equiv r - Q$, we may write the solution in the 'isotropic" form in which the spatial part of the metric is conformal to flat space:

$$ds^2 = H^{-2}\,dt^2 - H^2(d\rho^2 + \rho^2\,d\Omega_2^2) \tag{10.94}$$

$$A = (1 - H^{-1})\,dt \tag{10.95}$$

where

$$H \equiv 1 + \frac{Q}{\rho}. \tag{10.96}$$

Both the temporal and spatial 'warp' factors (the factors multiplying the two parts of the metric), as well as the electromagnetic vector-potential 1-form, are determined by a single (harmonic) function H. Extreme solutions have the important property that they are easily generalized to a case representing N extreme black holes with charges $q_i = m_i$ (with $i = 1, 2, \ldots, N$) by replacing the function H given in (10.96) by

$$H = 1 + \sum_{i=1}^{N} \frac{q_i}{|\mathbf{r} - \mathbf{r}_i|}. \tag{10.97}$$

By Gauss' law, the total charge is $Q = \sum_{i=1}^{N} q_i$ which, by the BPS bound, is also the total mass

$$M = \sum_{i=1}^{N} m_i = \sum_{i=1}^{N} q_i = Q. \tag{10.98}$$

There is, thus, no binding energy between the individual black holes: the gravitational binding is precisely cancelled by the electrostatic repulsion. Near the horizon $|\rho| \ll Q$, the metric is approximated by $\mathrm{Ad}S_2 \times S^2$ (exercise 11). Thus, the extreme black hole may also be regarded as a soliton that interpolates between the Minkowski vacuum when $\rho \gg Q$ and $AdS_2 \times S^2$ when $|\rho| \ll Q$. Generalizations of this special form, involving extra dimensions, extended objects and other charges, are important in what follows.

In particular, the simplest example of a string-theory black hole for which a microscopic description can be found is provided by a five-dimensional analogue of the RN solution (10.33) and (10.34). The static, solution of the five-dimensional Einstein–Maxwell equations outside of a (S^3)-spherically symmetric body of mass M and charge Q is

$$\mathrm{d}s^2 = \left(1 - \frac{2M}{r^2} + \frac{Q^2}{r^4}\right) \mathrm{d}t^2 - \left(1 - \frac{2M}{r^2} + \frac{Q^2}{r^4}\right)^{-1} \mathrm{d}r^2 - r^2\,\mathrm{d}\Omega_3^2 \quad (10.99)$$

and the gauge potential 1-form

$$A = \frac{Q}{r^2}\,\mathrm{d}t. \quad (10.100)$$

(The r^{-2} dependence of the potential arises, of course, because there are now four spatial dimensions.) As before, the extreme case where $M = Q$, with the horizon at $r = \sqrt{Q}$, may be cast in an isotropic form by using the coordinate $\rho \equiv \sqrt{r^2 - Q}$. Then the horizon is at $\rho = 0$ and

$$\mathrm{d}s^2 = H^{-2}\,\mathrm{d}t^2 - H(\mathrm{d}\rho^2 + \rho^2\,\mathrm{d}\Omega_3^2) \quad (10.101)$$

$$A = (1 - H^{-1})\,\mathrm{d}t \quad (10.102)$$

where now the harmonic function is

$$H = 1 + \frac{Q}{\rho^2}. \quad (10.103)$$

To connect this black hole with string theory, we need to consider the effective field theory describing string theory in the low-energy limit. This is a generalization of Einstein–Maxwell theory both with respect to the number of spacetime dimensions (ten) and the fields involved. The fields involved are just the massless modes that arise in (perturbative) string theory and the field theory that desribes them is type II supergravity.

10.6 Type II supergravity

The massless states that arise in superstring theory include both bosons and fermions. Black holes are, of course, solutions of the classical bosonic field

D -256- - -* ! - " ! I< 1"
! 5 !
(B 9 '

$$\begin{aligned} G_k(Sz) &= G_k\left(-\frac{1}{z}\right) = \sum_{\substack{c,\, d \in \mathbb{Z} \\ (c,d) \neq (0,0)}} \frac{1}{\left(c\left(-\frac{1}{z}\right) + d\right)^k} \\ &= z^k \sum_{\substack{c,\, d \in \mathbb{Z} \\ (c,d) \neq (0,0)}} \frac{1}{(dz - c)^k} = (1 \cdot z + 0)^k G_k(z). \end{aligned}$$

We have thus shown the necessary transformation property for the matrices S and T and hence all of $\mathrm{SL}_2(\mathbb{Z})$.

The holomorphicity in ∞ follows from the following statement about the Fourier expansion of the Eisenstein series.

Theorem 4.1 *Let $k > 2$ be even. It holds*

$$G_k(z) = 2\zeta(k) + \frac{2(2\pi i)^k}{(k-1)!} \sum_{n=1}^{\infty} \sigma_{k-1}(n) q^n,$$

where $q = e^{2\pi i n z}$, $\sigma_\ell(n) := \sum_{0<d|n} d^\ell$ denotes the divisor sum function, and $\zeta(s) = \sum_{n=1}^{\infty} n^{-s}$ denotes the Riemann zeta function.

Remark 4.1 In the following, we often consider the *normalized Eisenstein series* $E_k(z) = \frac{1}{2\zeta(k)} G_k(z)$ with Fourier expansion

$$E_k(z) = 1 - \frac{2k}{B_k} \sum_{n=1}^{\infty} \sigma_{k-1}(n) q^n.$$

Here, B_k denotes the kth Bernoulli number defined by $\frac{t}{e^t - 1} = \sum_{n=0}^{\infty} \frac{B_n}{n!} t^n$ and Euler's formula applies

$$2\zeta(k) = -\frac{(2\pi i)^k}{k!} \cdot B_k, \; k \geq 2 \text{ even}.$$

Example 4.1 We have

$$E_4(z) = 1 + 240\sum_{n=1}^{\infty}\sigma_3(n)q^n = 1 + 240q + 2160q^2 + 6720q^3 + \dots .$$

A simple conclusion from Corollary 3.1 is now that

$$M_k = \mathbb{C}E_k$$

for $k = 4, 6, 8, 10$.

Example 4.2 The following applies

$$E_4(z)^2 = E_8(z),$$

because the dimension of M_8 is 1 and both $E_4(z)^2$ and $E_8(z)$ have leading coefficient 1, so they agree.

From this follows directly the following relationship between divisor sum functions

$$\sum_{m=1}^{n-1}\sigma_3(m)\sigma_3(n-m) = \frac{\sigma_7(n) - \sigma_3(n)}{120}.$$

4.2 The Discriminant

We now come to the definition of the *discriminant*, a cusp form of weight 12.

Definition 4.2 The *discriminant* or Δ-*function* is defined by

$$\Delta(z) := \frac{E_4^3(z) - E_6^2(z)}{1728} = q - 24q^2 + 252q^3 + \dots .$$

Based on the definition and because of $\Delta(z) = q + \dots$, one immediately sees that $\Delta \in S_{12}$ holds.

Remark 4.2 One also denotes the Fourier coefficients of the discriminant by $\tau(n)$.

5.2 *L*-functions of Modular Forms

We first recall important results about the Riemann zeta function

$$\zeta(s) := \sum_{n=1}^{\infty} n^{-s},\ s \in \mathbb{C}, \Re(s) > 1.$$

This series converges normally (locally uniform and absolute) and the function defined by it is holomorphic. The function $\zeta(s) - \frac{1}{s-1}$ has a holomorphic continuation to $\mathbb{C}$.

It is easy to show that

$$\zeta(s) = \prod_{p \text{ prime}} \frac{1}{1 - p^{-s}},\ \Re(s) > 1,$$

and via this product expansion one obtains another proof for the fact that there are infinitely many primes. For if there were only finitely many primes, the above product would be finite and thus $\zeta(1)$ would be rational and in particular finite. But we have just noted that $\zeta(s)$ has a pole at $s = 1$.

Riemann realized that the connection between the arithmetic of primes and the analytic properties of the Riemann zeta function is much deeper, and that $\zeta(s)$ should provide the key to studying the distribution of primes. One compares with the corresponding versions of the Riemann conjecture.

Theorem 5.4 (Riemann) *The Riemann* ζ *-function has a meromorphic continuation to* $\mathbb{C}$. *The completed Riemann zeta function* $\zeta^*(s) := \pi^{-\frac{s}{2}}\Gamma\left(\frac{s}{2}\right)\zeta(s)$ *satisfies the functional equation*

$$\zeta^*(s) = \zeta^*(1-s).$$

Here $\Gamma(s) = \int_0^{\infty} e^{-t} t^{s-1} dt$ *is for* $\Re(s) > 0$ *the gamma function.*

Analogous to the Riemann zeta function, one now considers *L*-functions of cusp forms.

Definition 5.5 Let $f(z) = \sum_{n=1}^{\infty} a(n)q^n$, $q = e^{2\pi i z}$, be a cusp form of weight $k > 0$ for $\mathrm{SL}_2(\mathbb{Z})$. We call

$$L(f, s) := \sum_{n=1}^{\infty} a(n)n^{-s}, s \in \mathbb{C},$$

the *L-function* (or *L-series*) of f.

One can show that $L(f, s)$ converges normal (locally uniform and absolute) for $s \in \mathbb{C}$ with $\Re(s) > \frac{k}{2} + 1$. This follows directly from the estimate for the Fourier coefficients that we derived in Theorem 3.4.

Theorem 5.5 *Let $f \in S_k$. Then the associated L-function has a holomorphic continuation to all $\mathbb{C}$. The function*

$$\Lambda(f, s) := (2\pi)^{-s}\Gamma(s)L(f, s)$$

is entire and satisfies the functional equation

$$\Lambda(f, s) = (-1)^{\frac{k}{2}}\Lambda(f, k - s).$$

The function $\Lambda(f, s)$ is bounded on every vertical strip, that is, for every $T > 0$ there exists a $C_T > 0$ such that $|\Lambda(f, s)| \leq C_T$ for all $s \in \mathbb{C}$ with $\Re(s) \leq T$.

Similar to the Riemann zeta function, the L-functions of cusp forms also have a representation as an *Euler product.*

Theorem 5.6 *Let $f \in S_k$, $k > 14$, $a_f(1) = 1$. Then the following are equivalent:*

1. *f is a simultaneous eigenform with respect to all Hecke operators.*
2. *$L(f, s)$ has a product expansion of the form*

$$L(f, s) = \prod_{p \text{ prime}} \frac{1}{1 - a_f(p)p^{-s} + p^{k-1-2s}}$$

for $\Re(s) > 1 + \frac{k}{2}$.

The *modularity theorem* proved by Wiles et al. [Wil95, BCDT01] in the course of proving Fermat's Last Theorem establishes a far-reaching connection between the L-functions of newforms and those of elliptic curves.

Let E be an elliptic curve over $\mathbb{Q}$ given by the solutions $(x, y) \in \mathbb{Q}^2$ of the equation $y^2 = x^3 + ax + b$, with $a, b \in \mathbb{Q}$ such that $-4a^3 - 27b^2 \neq 0$, together with a point O at infinity.

Given E (of conductor N_E), we now define an L-function as follows. We set

$$L(E, s) = \prod_{p \text{ prime}} L_p(E, s),$$

where

$$L_p(E, s) = \begin{cases} \left(1 - a(p)p^{-s} + p^{1-2s}\right)^{-1}, & \text{if } p \nmid N_E, \\ \left(1 - a(p)p^{-s}\right)^{-1}, & \text{if } p \mid N_E,\ p^2 \nmid N_E, \\ 1, & \text{if } p^2 \mid N_E. \end{cases}$$

Here one defines $a(p) = p + 1 -$ (#points on E modulo p).

In the 1950s, Taniyama conjectured that such an L-function coincides with that of a weight 2 newform. In the 1960s, Eichler and Shimura showed that for any weight 2 newform with integer Fourier coefficients, one can find an elliptic curve E over $\mathbb{Q}$ such that $L(E, s) = L(G, s)$. The other direction was then proved in the 1990s by Wiles et al. [Wil95, BCDT01] and has far-reaching consequences for various areas of mathematics.

Theorem 5.7 (Modularity Theorem) *Let E be an elliptic curve over $\mathbb{Q}$ of conductor N_E. There exists a newform $G_E(z) = \sum_{n=1}^{\infty} a_E(n)q^n \in S_2(\Gamma_0(N_E))$ of weight 2 such that*

$$L(G_E, s) = L(E, s), s \in \mathbb{C}.$$

The gradient amplitude map of an I-frame can be defined as:

$$GM = \sqrt{[I \otimes h_x]^2 + [I \otimes h_y]^2}, \quad (4)$$

where I is a luminance channel of the I-frame, and $\otimes$ represents the convolution operation.

APPENDIX D

CLOSED-STRING INTEGRALS

The integral (12.109), which is required in order to evaluate the four-tachyon amplitude in the closed-bosonic-string theory, is a special case of the more general integral

$$I(\alpha, n; \beta, m) = \int \frac{\mathrm{d}^2 z}{\pi} |z|^{\alpha} |1 - z|^{\beta} z^{n} (1 - z)^{m} \tag{D1}$$

which is convergent for

$$\begin{aligned} &\mathrm{Re}(\alpha + \beta + m + n + 2) < 0 \\ &\mathrm{Re}(\alpha + n + 2) > 0 \\ &\mathrm{Re}(\beta + m + 2) > 0. \end{aligned} \tag{D2}$$

We substitute an integral representation of $|z|^{\alpha}$

$$|z|^{\alpha} = \frac{1}{\Gamma(-\alpha/2)} \int_0^{\infty} \mathrm{d}s\, s^{-\alpha/2 - 1}\, \mathrm{e}^{-s|z|^2} \tag{D3}$$

which follows from the standard definition of the Γ function

$$\Gamma(p) = \int_0^{\infty} \mathrm{d}u\, u^{p-1}\, \mathrm{e}^{-u} \tag{D4}$$

by changing the integration variable to $u = s|z|^2$. Similarly for $|1 - z|^{\beta}$. Then

$$I = \frac{1}{\Gamma(-\alpha/2)\Gamma(-\beta/2)} \int_0^{\infty} \mathrm{d}s\, s^{-\alpha/2 - 1} \int_0^{\infty} \mathrm{d}t\, t^{-\beta/2 - 1} \times \int \frac{\mathrm{d}^2 z}{\pi} z^{n} (1 - z)^{m}\, \mathrm{e}^{-s|z|^2 - t|1 - z|^2}. \tag{D5}$$

Next we do the z-integral. This is easily done using the generating integral

$$J(\lambda, \mu) \equiv \int \frac{\mathrm{d}^2 z}{\pi} \exp[-s|z|^2 - t|1 - z|^2 + \lambda z + \mu(1 - z)]. \tag{D6}$$

This integral separates into standard (Gaussian) integrals when Cartesian coordinates are used for $z = x + \mathrm{i}\, y$. Then

$$J(\lambda, \mu) = \frac{1}{s + t} \exp\left(\frac{\lambda t + \mu s - st}{s + t}\right) \tag{D7}$$

so the z-integral in (D5) is obtained by differentiating with respect to λ, μ:

$$\int \frac{\mathrm{d}^2 z}{\pi} z^n (1-z)^m \,\mathrm{e}^{-s|z|^2 - t|1-z|^2} = \frac{t^n s^m}{(s+t)^{n+m+1}} \mathrm{e}^{-st/(s+t)}. \tag{D8}$$

Of course this result follows only when n, m are integral, but we can continue to the case when they are non-integral. Next we change integration variables to u and x where

$$u = \frac{st}{s+t} \tag{D9a}$$

$$x = \frac{t}{s+t}. \tag{D9b}$$

The domain of integration is

$$0 \leqslant u < \infty \qquad 0 \leqslant x \leqslant 1. \tag{D10}$$

Then the required integral (D5) is$^{(1)}$

$$\begin{aligned} I &= \frac{1}{\Gamma(-\alpha/2)\Gamma(-\beta/2)} \int_0^1 \mathrm{d}x\, x^{n+\alpha/2} (1-x)^{m+\beta/2} \int_0^\infty \mathrm{d}u\, u^{-\alpha/2-\beta/2-2}\, \mathrm{e}^{-u} \\ &= \frac{\Gamma(1+n+\alpha/2)\Gamma(1+m+\beta/2)\Gamma(-\alpha/2-\beta/2-1)}{\Gamma(-\alpha/2)\Gamma(-\beta/2)\Gamma(2+m+n+\alpha/2+\beta/2)}. \end{aligned} \tag{D11}$$

and the coding features generated during the video coding process. The coding features mainly use the target bit-rate and the SATD value.

Target Bit-Rate Feature: It refers to the target bit-rate allocated to the current I-frame, denoted as R_t.

Sum of Absolute Transformed Difference Feature: SATD refers to the sum of the absolute values of transform coefficients, which is generated by the *Hadamard* transform. It is suggested in [3] as the content complexity evaluation value for the I-frame, which is adopted in HEVC and also utilized in VTM [13].

Here, the content complexity of an I-frame is defined as the sum of the SATD values of all 8 × 8 blocks in the frame. We use SATD as one of the input features, and its calculation is:

$$SATD = \sum_{i=1}^{8} \sum_{j=1}^{8} |c_{i,j}|, \tag{3}$$

where $c_{i,j}$ denotes the *Hadamard* transform coefficient.

Spatial Structure Feature: Gradient amplitude response can effectively detect most of the spatial structure information of the video frame. Some previous studies have proposed using gradient information to reflect the frame content complexity [7,8]. Therefore, the gradient feature is also considered as one of the input features. The gradient amplitude map of an I-frame can be defined as:

$$GM = \sqrt{[I \otimes h_x]^2 + [I \otimes h_y]^2}, \tag{4}$$

where I is a luminance channel of the I-frame, and $\otimes$ represents the convolution operation.

$h_d, d \in \{x, y\}$, represents the *Gaussian* partial derivative filter along the horizontal or vertical direction respectively. It is formulated as:

$$\begin{aligned} h_d(x, y|\sigma) &= \frac{\partial}{\partial d} g(x, y|\sigma) \\ &= -\frac{1}{2\pi\sigma^2} \frac{d}{\sigma^2} exp^{\{-\frac{x^2+y^2}{2\sigma^2}\}} \end{aligned} \tag{5}$$

where $g(x, y|\sigma)$ denotes the isotropic *Gaussian* function with a scale parameter of σ.

Then, the two-dimensional feature matrix GM is converted into the form of a histogram, and the feature data are divided into 10 groups to better retain the information of overall structure and local shape. The obtained feature vector is named HG.

Frequency-Domain Energy Feature: Luminance change is an important feature in expressing the frame content, and this change can be reflected more significantly in the frequency domain. We hence design a feature extraction method in the DCT transform [10]. First, the input I-frame is divided and transformed in the DCT domain with N × N blocks, and the obtained DC coefficients reflect the

h_d, $d \in \{x, y\}$, represents the Gaussian partial derivative filter along the horizontal or vertical direction respectively.

In accordance to this book's notation, deterministic approaches do not master stochastic uncertainty in a mathematical model. However, they may be suited to quantify and master incertitude, e.g. when only extreme values like minima and maxima are known or assumed, or when parts of a model are missing to detect ignorance, cf. Fig. 2.2. Probabilistic approaches, however, describe and master all three types of uncertainty. In the following, we give an overview of the two approaches.

Deterministic framework

On the one hand, a *deterministic* analysis can be used, for example, in fault diagnosis [56] to quantify uncertainty in the model equations. To do so, the model is adjusted by a model discrepancy function $\delta\eta$ which is assumed to stay within a bounded uncertainty set $\mathcal{U}_\eta$:

$$\eta(u, m) + \delta\eta(u) = z, \quad \delta\eta \in \mathcal{U}_\eta. \tag{2.6}$$

A standard residual analysis then enables the engineer to distinguish component failures from the effects of model uncertainty. However, this method strongly relies on the assumption that the model discrepancy function $\delta\eta$ stays within a bounded uncertainty set $\mathcal{U}_\eta$.

On the other hand, a deterministic analysis may be used in model verification and validation processes. In [9, 57], the possibility to approximate the residual between the model output and the observed quantity of interest via a polynomial p is mentioned. In this case, the polynomial p takes the role of the discrepancy function:

$$\eta(u, m) + p(u, m, \theta) = z. \tag{2.7}$$

This necessarily leads to an augmented parameter set (m, θ) consisting of the original physical axiomatic and empiric parameters m as well as the non-physical polynomial parameters θ, which do not give an enhanced physics-based understanding of the model's uncertainty or shortcoming in predicting reality [9]. The augmented parameter set needs to be calibrated, which is usually performed by an optimisation scheme.

Probabilistic framework

Within the probabilistic framework, *Bayesian inference-based* approaches are frequently used to assess the prediction quality of a mathematical model under given experimental data [9, 16, 52, 61]. In [34] or [37], Bayesian calibration techniques and a plausibility prior argument are used for model selection. Another important approach introduces a stochastic process δ for the discrepancy function [22]:

$$\eta(u, m) + \delta(u, m, \phi) + \varepsilon = z\,, \tag{2.8}$$

where ε is stochastic noise, usually produced by the measurement error, and ϕ are hyperparameters, which need to be tuned by an optimisation scheme. Based on this setting, [64] introduce a technique for model validation. A method designed for time-dependent systems is proposed in [3]. Combinations of a high- and a low-fidelity model and experimental data are used to construct a multi-fidelity model, which is proposed in [13] as an improved predictor. A scaled Gaussian Process is used in [17] for model calibration and prediction. It is claimed that the method bridges the gap between the least-squares calibration and the Gaussian Process calibration and, thus, is an improvement of the method introduced in [22]. Furthermore, a Bayesian interval hypotheses-based approach [36] and a Bayesian inference-based approach [37] are used to compare different models based on their internal functional relations from axiomatic or empiric assumptions, see also Sect. 4.3.3 for assessing model uncertainty in the Modular Active Spring-Damper System, see Sect. 3.6.1.

In order to apply the Bayesian methods, it is necessary to select prior distributions. Often, this is subjective and it is unclear how to choose them, which may lead to unrealistic assumptions. Furthermore, it is pointed out in [60] that the approach in [22] may lead to inadequate results in case of an imperfect computer model. As a consequence, further verification of the computer codes needs to be conducted.

From the *frequentist's* perspective, a simple approach to quantify model uncertainty is to use validation metrics, such as the area validation metric [35] or the Mahalanobis distance [68]. They give a quantitative measure of disagreement between the model output and the observed quantity of interest based upon observed measurements. In order to select the most adequate model, an arbitrary threshold on the metric is imposed, or classical hypothesis testing is performed. Surrogate models are often used to quantify the uncertainty in a technical system. Usually, these methods use computer simulations and a small sample of experimental data to estimate properties of probability distributions, such as quantiles [25–27] or densities [14, 23, 24]. A detailed description for a method based on an imperfect computer model is given in Sect. 4.3.8. A case where computer models are assumed to fit the reality is shown in Sect. 5.2.6. In [12], another method to detect model uncertainty is proposed which is based on optimum experimental design and hypothesis testing, see also Sect. 4.3.1. In [65], another approach to quantify the model error is developed. Here, the model discrepancy function is estimated on bootstrap samples via a regression estimation, e.g. smoothing splines or artificial neural networks.

However, the application of frequentist methods often demands a larger sample size, which can become a problem, since generating data is an expensive and time-consuming process.

(molecules, ...) in an arbitrarily short time at a time $t = 0$ into a constant flow Q. If the process has the volume V, then we measure the temporal change of the concentration given by $N/(V\bar{t})\ p(t)$ at the process output. Here, $\bar{t}$ is the mean residence time given by $\bar{t} = V/Q$. As always, things become clearer in a dimensionless representation: if we measure time in multiples of the mean residence time, i.e. $\theta := \frac{t}{\bar{t}}$, and concentration c in multiples of the typical concentration N/V, we measure $\delta(\theta) \rightarrow p(\theta)$, i.e. a Gaussian normal distribution for a purely diffusive process centred at $\theta = 1$. In a real experiment it is not possible to realise a Dirac delta function $\delta(\theta)$ but it is easy to realise a Heaviside function $\mathcal{H}(\theta)$. This is achieved by changing the concentration at the inlet at a time $\theta = 0$ suddenly from zero to one. In practice this means switching a valve. At the process outlet we then measure the cumulative density function $\mathcal{H}(\theta) \rightarrow P(\theta) = \int_0^\theta p(\tau)\mathrm{d}\tau$.

Secondly (ii), in the general case, the dependent variable θ is a nonlinear function of one, two or more independent variables $\theta = h(\theta_1, \theta_2)$. A perturbation of h at the operation point $(\theta_{10}, \theta_{20})$ marked by the index 0 is given by

$$h = h_0 + \left.\frac{\partial h}{\partial \theta_1}\right|_0 \delta\theta_1 + \left.\frac{\partial h}{\partial \theta_2}\right|_0 \delta\theta_2 + \mathrm{O}(\delta\theta^2).$$

Inserting this perturbation into the general convolution integral and neglecting terms of the order of magnitude $\mathcal{O}(\delta\theta^2)$ yields the Gaussian uncertainty propagation [29]

$$\sigma_{\mathrm{g}}^2 \approx \left[\frac{\partial h}{\partial \theta_1}\right]_0^2 \sigma_1^2 + \left[\frac{\partial h}{\partial \theta_1}\frac{\partial h}{\partial \theta_2}\right]_0 \sigma_{12}^2 + \left[\frac{\partial h}{\partial \theta_2}\right]_0^2 \sigma_2^2.$$

The index g indicates the Gaussian approximation of the variance. Here,

$$\sigma_{12}^2 := \int_0^\infty \int_0^\infty (\theta_1 - \bar{\theta}_1)(\theta_2 - \bar{\theta}_2) h(\theta_1, \theta_2)\, \mathrm{d}\theta_1 \mathrm{d}\theta_2 = \overline{\theta_1\theta_2} - \bar{\theta}_1\bar{\theta}_2$$

denotes the co-variance of the two independent variables.

The Gaussian uncertainty propagation is the simplest and most commonly used method of uncertainty propagation, but it is rarely critically questioned. From the derivation it is clear that the trust into the method should decrease with increasing nonlinearity in $h(\theta_1, \theta_2)$. This becomes clear for the simpler case $\theta = h(\theta_1)$. This coordinate transformation shown in Fig. 3.4b leads to a distortion of a symmetric input density function $p_1(\theta_1) \rightarrow p(\theta)$. As a result, the mean $\bar{\theta} = \int_0^\infty h(\theta_1) p_1(\theta_1)\, \mathrm{d}\theta_1$ differs from the approximation $\bar{\theta}_{\mathrm{g}} = h(\theta_{10})$ and further σ_{g}^2 is only an approximation of σ^2, Fig. 3.4b. In summary we recognise that the usage of the Gaussian approximation $(\delta\theta)^2 \approx (\delta\theta)_{\mathrm{g}}^2 = \sum (\frac{\partial h}{\partial}\theta_k)^2 (\delta\theta_k)^2$ for uncorrelated input data θ_k needs some justification.

For the strongly nonlinear process chain being treated in the following Sect. 3.3, the moment method, i.e. the Gaussian uncertainty propagation is not adequate. In Sect. 3.3 we use the bootstrapping method [10]. Other methods and examples for uncertainty propagation are found in Sect. 6.1.6.

3.3 Five Complementary Methods for Mastering Uncertainty in Process Chains

Peter F. Pelz

In Sect. 3.2 we applied moment methods of uncertainty propagation to process chains. In several parts of the book we resume these and use more in-depth methods of uncertainty propagation, cf. Sect. 6.1.6. Uncertainty quantification includes uncertainty propagation [30]. Uncertainty propagation is often recognised as uncertainty

$p^\star$ and covariance matrix C. Then the set K is an n_p-dimensional ellipsoid determined by the covariance matrix C:

$$K(p^\star, C, \alpha) := \left\{ p \in \mathbb{R}^{n_\mathrm{p}} : \left(p - p^\star\right)^\top C^{-1}\left(p - p^\star\right) \leq \chi^2_{n_\mathrm{p}}(1-\alpha) \right\},$$

where $\chi^2_{n_\mathrm{p}}$ is the quantile function of the χ^2 probability distribution with n_p degrees of freedom. We consider the following approximations for the covariance matrix C coming from a Gauss–Newton approach [19, 38] and a sensitivity analysis [10, 38], respectively:

$$C_\mathrm{GN} = \left(J^\top \Omega \Sigma^{-1} J\right)^{-1}, \qquad C_\mathrm{S} = H^{-1} J^\top \Omega \Sigma^{-1} J H^{-\top},$$

where J is the total derivative of the residual vector r with respect to the model parameters p and

$$H := J^\top \Omega \Sigma^{-1} J + \sum_{i=1}^{n_z} r_i \Omega_{ii} \Sigma_{ii}^{-1} \frac{\mathrm{d}^2 r_i}{\mathrm{d}p^2}. \tag{4.17}$$

Our choice is determined depending on the application and the computational effort for the Hessian H, which requires the calculation of second order derivatives of the solution operator, compare Eq. (4.17) with Eq. (4.15).

Optimal design of experiments

In general, the goal in optimum experimental design is to minimise the confidence region of the parameter estimates by changing the experimental setup, namely, sensor locations and types represented by the variable ω, boundary and initial conditions described by the inputs u_j, etc. Since we employ a linear approximation of the confidence region the aim is to minimise the "size" of the covariance matrix C. There exists extensive research on different design criteria Ψ that measure the "size" of a matrix in the context of optimum experimental design [49, 143, 158]. We list a few prominent options:

$$\Psi_A(C) = \mathrm{trace}\,(C), \qquad \Psi_D(C) = \det\,(C), \qquad \Psi_E(C) = \lambda_\mathrm{max}\,(C).$$

Depending on the application, the computational effort, and the adaptability of the experimental setup, we formulate slightly different optimisation problems. If the calculation of the Hessian H is fast, the number of sensors is small and the experimental setup is limited to adapting sensor positions only, we consider the matrix C_S from above in the optimisation model:

$$\begin{aligned} \min_{\omega} \quad & \Psi\left[C_\mathrm{S}(\omega, p(z,\omega), \mathcal{S}(u, p(z,\omega)))\right] \\ \text{s.t.} \quad & \omega \in \{0,1\}^{n_\mathrm{s}}, \quad G(\omega) \leq 0. \end{aligned} \tag{4.18}$$

where $\bar{\mathcal{F}}$ is a set of functions.

The improved surrogate model is constructed as in Sect. 4.3.7, i.e. it is defined by

$$\hat{m}_n(x) = \hat{m}_{L_n}(x) + \hat{m}_n^{\epsilon}(x) \quad (x \in \mathbb{R}). \tag{4.69}$$

In order to estimate the probability density function g of Y, the kernel density estimator of [123, 135] is applied on the sample $\hat{m}_n(\bar{X}_{N_{n,1}+1}), \ldots, \hat{m}_n(\bar{X}_{N_{n,1}+N_{n,2}})$, i.e. it is defined by

$$\hat{g}_{N_{n,2}}(y) = \frac{1}{N_{n,2} \cdot h_{N_{n,2}}} \sum_{i=N_{n,1}+1}^{N_{n,1}+N_{n,2}} K\left(\frac{y - \hat{m}_n(\bar{X}_i)}{h_{N_{n,2}}}\right), \tag{4.70}$$

for some bandwidth $h_{N_{n,2}} > 0$ and some kernel $K\colon \mathbb{R} \to \mathbb{R}$, which is usually chosen as a symmetric and bounded density, e.g. the Gaussian kernel $K(t) = \frac{1}{\sqrt{2\pi}} \exp(-\frac{1}{2}t^2)$.

Application

As an example we consider a lateral vibration attenuation system with piezo-elastic supports. A visualisation of the technical system can be found in [103, Fig. 1].

This system consists of a beam with circular cross-section embedded in two piezo-elastic supports A and B. Support A is used for lateral beam vibration excitation and support B for lateral beam vibration attenuation, as proposed in [61]. The two piezo-elastic supports A and B are located at the beam's end; each consists of one elastic membrane-like spring element made of spring steel, two piezoelectric stack transducers arranged orthogonally to each other and mechanically prestressed with disc springs, as well as the relatively stiff axial extension made of hardened steel that connects the piezoelectric transducers with the beam. For vibration attenuation in support B, optimally tuned electrical shunt circuits are connected to the piezoelectric transducers [63].

Our aim is to quantify uncertainty, i.e. to estimate the probability density function of the maximal amplitude of the vibration occurring in an experiment with this attenuation system. Five parameters vary during the construction of the attenuation system and influence the maximal vibration amplitude: the lateral stiffness $k_{lat,y}$ and $k_{lat,z}$ in direction of y and z, the rotatory stiffness $k_{rot,y}$ and $k_{rot,z}$ in direction of y and z, and the height of the membrane h_x. In our setting these five values are the input X of the experiment with the technical system. A computer model (above denoted by m) is available with which we can compute an approximation $m(X)$ of the maximal vibration amplitude Y to a corresponding input value X. To apply the density estimator (4.70) we measured the corresponding parameters for ten real built systems. As a result we got the data in Table 4.4.

Since the parameters vary in scale, it does not make sense to estimate the surrogate model $\hat{m}_{L_n}$ on $U_{i,n} \sim U([-c \cdot \log(L_n), c \cdot \log(L_n)]^d)$. Instead we rescale the

Johnson [15] solved Eqs. (31), (32), (36), and (37), **Figures 4** and **5** compare the numerical and analytical solutions for the SLS and Maxwell models, respectively. The solid lines are the numerical solutions obtained by the author, and the dashed lines are the analytical solutions solved by Johnson [15]. In **Figures 4** and **5**, r_h is the contacting region at time zero, p_h is the maximum contacting pressure at time zero, and T is the relaxation time.

Figures 4 and **5** indicate the deviation between the numerical and analytical results is less than 10%. Therefore, the numerical code can be used to simulate the visco-elastic deformations of rough fractures. For the two validation cases, the numerical simulation accuracy is not strongly dependent on the total number of elements, but on the time interval Δt. The deviation between numerical and analytical solutions will be smaller if the time interval Δt is reduced.

3. One example: visco-elastic deformations of rough rock fractures

3.1 Brief introduction of Brown's (1995) model

In this chapter, synthetic fracture surface pairs are generated based on Brown's model [10]. Brown's probabilistic model assumes that the surface is self-affine, and the surface height distribution follows Gaussian distribution [10]. The surface geometry can be completely described by three parameters: the Hurst exponent H, the mismatch length λ_σ and the root mean square roughness RMS.

Mathematically, a self-affine surface is defined as:

$$z(x) \sim \varepsilon^{-H} z(\varepsilon x) \tag{38}$$

where H is the Hurst exponent, z is the surface height, and ε is a constant for scaling at the x-direction. The H value is between 0 and 1, and it describes local roughness. A smaller H value corresponds to a rougher local surface profile.

The H value can be obtained from the power spectrum of surface height. The power spectrum of a surface can be obtained by decomposing the surface profile into a series of sinusoidal waves via Fourier transform, and each sinusoidal wave has its own amplitude A, wavelength λ, and phase. **Figure 6** shows the schematic of the decomposition process. The power (A^2) is defined as the square of the amplitude A; and the plot of power versus the wavelength number (the inverse of wavelength, which is 2π/λ) is defined as the power spectrum. **Figure 7** shows the schematic of power spectrum.

For a self-affine fracture surface, the power C ($=A^2$) can be related to the wavelength number q (=2π/λ) as:

$$\mathrm{C(q)} \sim q^{-2(1+H)} \tag{39}$$

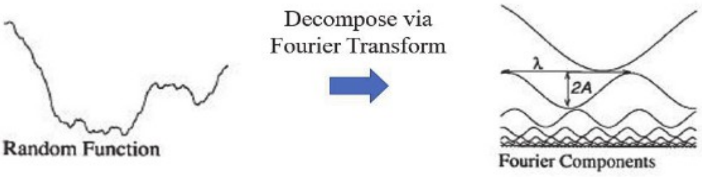

Figure 6.
Schematic of wave decomposition via Fourier transform (Kang et al. [13]).

In **Figure 7**, the q has an upper bound and a lower bound. For the lower bound, $q_{min} = 2\pi / \lambda_L$, where λ_L is the surface dimension; for the upper bound, $q_{max} = 2\pi/\lambda_1$, where λ_1 is the surface measurement resolution.

The second parameter is the mismatch length, λ_c. As illustrated in **Figure 6**, each wave component has its own wavelength λ. Glover et al. [16] and Brown [10, 17, 18] stated that for most natural rock joints, the two surfaces have relative shear displacements. At long wavelengths, the wave components match well; at short wavelengths, the wave components are not identical. Based on the above observation, Brown [10] proposed a parameter: critical wavelength λ_c, which is also called the mismatch length scale. Brown [10] assumed that above the mismatch wavelength, the decomposed wave components of two surfaces match perfectly; they have the same amplitudes, wavelengths, and phases. On the contrary, below the mismatch wavelength, the decomposed wave components of two surfaces do not match; they have the same amplitudes and wavelengths, but the phases are independent. **Figure 8** illustrates the concept of the mismatch wavelength.

The third parameter is the root mean square roughness, RMS. It represents the absolute scale of surface asperity elevation. Mathematically, the RMS is defined as:

$$\sigma^2 = \int_{q_{min}}^{q_{max}} C(q)dq \tag{40}$$

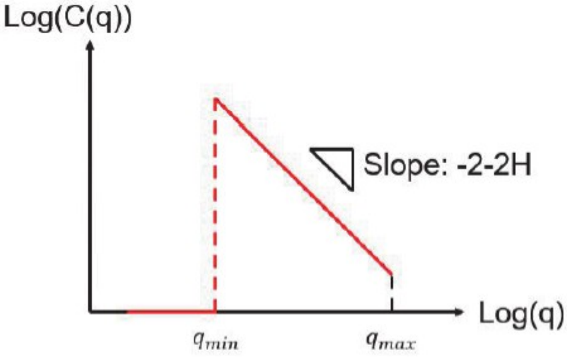

Figure 7.
Schematic of a power spectrum (Kang et al. [13]).

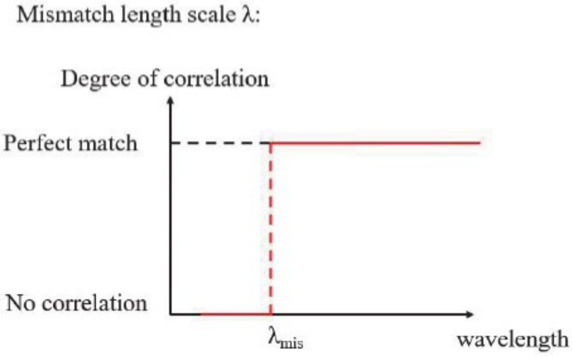

Figure 8.
Illustration of the mismatch wavelength (Kang et al. [13]).

where C is the power, q is the wavelength number, and σ is the RMS value. When generating the synthetic surface, the surface heights are normalized by its own RMS value, σ_{ini}, and then multiplied by the designated RMS value, σ_{des}:

$$z_{des} = z_{ini}\,\frac{\sigma_{des}}{\sigma_{ini}} \tag{41}$$

where z_{ini} is the initial surface height and z_{des} is the surface height after linear scaling. In this chapter, only the key mathematical concepts of Brown's [10] model is introduced; other details can be found in [10].

3.2 Generated synthetic surface pairs

Brown [10] measured the Hurst exponent H, mismatch length λ_σ and RMS for 23 natural rock joints. His measurement results imply that the H value is normally between 0.5 and 1.0; the normalized λ_c value (λ_c /fracture profile length) is normally between 0.02 and 0.2, and the normalized RMS value (RMS/fracture profile length) is normally between 0.005 and 0.015. Based on the above conclusion, seven synthetic fracture surface pairs are generated, with different H, λ_c, and RMS values. **Table 1** summarizes the parameters of the seven synthetic surface pairs. It is worth noting that surface pair No. 2 is the reference surface pair.

Table 1 shows that between surface pairs 1, 2, and 3, the H value is varied; between surface pairs 2, 4, and 5, the λ_c value is varied; between surface pairs 2, 6, and 7, the RMS value is varied. For each surface pair, the aperture distribution field can be plotted. **Figure 9** plots the aperture fields for surface pairs 1, 2, and 3; **Figure 10** plots the aperture fields for surface pairs 2, 4, and 5, and **Figure 11** plots the aperture fields for surface pairs 2, 6, and 7.

Based on **Figures 9–11**, we have the following observations:

1. According to **Figure 9**, when H increases, the average and standard deviation of the aperture decreases;

2. According to **Figure 10**, when λ_c deceases, the average and standard deviation of aperture decreases;

3. According to **Figure 11**, the average and standard deviation of aperture scales linearly with the RMS value.

Surface Pair No.	Profile length L (mm)	H	λ_c		RMS	
			λ_c/L	Absolute value (μm)	RMS/L	Absolute value (μm)
1	10	0.6	0.1	1000	0.005	50
2	10	0.8	0.1	1000	0.005	50
3	10	1.0	0.1	1000	0.005	50
4	10	0.8	0.2	2000	0.005	50
5	10	0.8	0.3	3000	0.005	50
6	10	0.8	0.1	1000	0.010	100
7	10	0.8	0.1	1000	0.015	150

2.1 Numerical approximation

This subsection is devoted to the numerical approximation of the obtained IBVP (17) for $\alpha = 0$ and B given in (20). Our strategy is to seek numerical simulations that permits to avoid any boundary reflections and in some way renders the fully discrete scheme unconditionally stable.

Let N, M be integers, we define time step $\Delta t = \frac{T}{M}$ and spatial step $h = \frac{b-a}{N}$. The grids $t_n = n\Delta t, 0 \leq n \leq M$ and $x_i = a + ih, 0 \leq i \leq N$ are used to discretize Ω_T. Throughout this paper, we denote u_i^n the considered approximation of $u(t_n, x_i)$ and the set $\mathbb{N}_k^l = \{m \in \mathbb{N},\ k \leq m \leq l\}$.

2.1.1 Approximation of the governing equation

We describe a discretization for the BBM equation by the Crank-Nicholson time scheme as follows

$$\frac{u(t_{n+1},x) - u(t_n,x)}{\Delta t} - \beta \frac{\partial_{xx}u(t_{n+1},x) - \partial_{xx}u(t_n,x)}{\Delta t} + \gamma \frac{\partial_x u(t_{n+1},x) + \partial_x u(t_n,x)}{2} = 0, \tag{21}$$

$$u(t_0,x) = u_0(x), \qquad n \in \mathbb{N}_0^{M-1}.$$

For the space finite difference scheme, we use the approximations

$$\partial_x u(t,x) \approx \frac{1}{2h}(u(t,x+h) - u(t,x-h)),$$
$$\partial_{xx} u(t,x) \approx \frac{1}{h^2}(u(t,x+h) - 2u(t,x) + u(t,x-h)).$$

The fully discretization then writes,

$$\begin{aligned} &\frac{u_i^{n+1} - u_i^n}{\Delta t} - \beta \frac{\left(u_{i+1}^{n+1} - 2u_i^{n+1} + u_{i-1}^{n+1}\right) - \left(u_{i+1}^n - 2u_i^n + u_{i-1}^n\right)}{h^2 \Delta t} \\ &\qquad + \gamma \frac{\left(u_{i+1}^{n+1} - u_{i-1}^{n+1}\right) + \left(u_{i+1}^n - u_{i-1}^n\right)}{4h} = 0, \quad (i,n) \in \mathbb{N}_1^{N-1} \times \mathbb{N}_0^{M-1} \\ &u_i^0 = u_0(x_i), \qquad\qquad i \in \mathbb{N}_0^N. \end{aligned} \tag{22}$$

2.1.2 Approximation of the boundary condition

The constructed boundary conditions (BC) contains time convolutions that are non-local and introduces many difficulties, for example, using a direct implementation leads to long and low accuracy. Several techniques have been used to overcome these problems by trying to localize the BC, see [5–8] for more details. The resulting localized BC are easy to implement and more efficient but tends to depend sensitively on the initial data. In our case, we utilize the Discrete Galerkin Method. The BC are formulated as Fredholm integral equations of second kind. The basic idea is to write the boundary condition on (20) in the form

$$\partial_n u(t,a) - \int_0^t \overline{K}_1(t,s)u(s,a)ds = 0, \tag{23}$$

$$\partial_n u(t,b) - \int_0^t \overline{K}_2(t,s)u(s,b)ds = 0. \tag{24}$$

where, the introduced Kernels $\overline{K}_1, \overline{K}_2$ represent a linear combination of the two Bessel functions of order 0 and 1 at the time $(t - s)$. After a space discretization we obtain

$$u(t, x_0) - \int_0^t K_1(t, s) u(s, x_0) ds = u(t, x_1), \tag{25}$$

$$u(t, x_N) - \int_0^t K_2(t, s) u(s, x_N) ds = u(t, x_{N-1}), \tag{26}$$

where $K_1 = -h\overline{K}_1$ and $K_2 = h\overline{K}_2$. Both resulting Eqs. (25) and (26) can be identified to the linear integral equation

$$y(t) - \int_D K(t, s) y(s) d\sigma(s) = z(t), \quad t \in D. \tag{27}$$

The Eq. (27) is a Fredholm integral equation of second kind, where D is a closed bounded set in $\mathbb{R}^m$, with $m \geq 1$. The approximation of such integral equation could be made by a discrete Galerkin method using the quadrature rule of Gauss-Legendre as presented in [9]. Based on this, the BC can be similarly discretized while considering the domain D as the time interval $[0, t]$. Precisely, we use the Gauss Legendre Quadrature of order q, labeled GLQ_q with zeros ξ_j and weights w_j being in the interval $[-1, 1]$ for $j \in \mathbb{N}_0^q$. Let $i \in \mathbb{N}_0^{N-1}$, we introduce the following transformation

$$\begin{array}{llll} F_i: & [-1, 1] & \rightarrow & [t_i, t_{i+1}] \\ & \xi & \mapsto & t_i \dfrac{1-\xi}{2} + t_{i+1} \dfrac{1+\xi}{2} \end{array} \tag{28}$$

The approximation of the BC is now given by

$$u(t_{n+1}, x_0) - \int_0^{t_{n+1}} K_1(t_{n+1}, s) u(s, x_0) ds = u(t_{n+1}, x_1) \tag{29}$$

$$u(t_{n+1}, x_N) - \int_0^{t_{n+1}} K_2(t_{n+1}, s) u(s, x_N) ds = u(t_{n+1}, x_{N-1}) \tag{30}$$

that is

$$u_0^{n+1} - \int_0^{t_{n+1}} K_1(t_{n+1}, s) u(s, x_0) ds = u_1^{n+1} \tag{31}$$

$$u_N^{n+1} - \int_0^{t_{n+1}} K_2(t_{n+1}, s) u(s, x_N) ds = u_{N-1}^{n+1} \tag{32}$$

For the seek of simplicity, we rewrite the integral terms of (31) and (32) in the form

$$\begin{aligned} \int_0^{t_{n+1}} K_i(t_{n+1}, s) u(s, x_k) ds = A_i \int_0^{t_{n+1}} u(s, x_k) ds + B_i \int_0^{t_{n+1}} J_0^c(t_{n+1} - s) \left(\int_0^s u(r, x_k) dr \right) ds \\ + D_i \int_0^{t_{n+1}} J_0^c(t_{n+1} - s) u(s, x_k) ds \\ := A_i I_1(t_{n+1}, x_k) + B_i I_2(t_{n+1}, x_k) + D_i I_3(t_{n+1}, x_k), \end{aligned}$$

such that $(i, k) \in \{(1, 0), (2, N)\}$, $A_1 = A_2 = -hC_1, B_2 = -B_1 = hC_2$ and $D_1 = -D_2 = hC_3$, all constants C_i are defined in (??). Thus, basing on the approach presented in [9], the GLQ_q applied to the integrals previously defined is described by the following, for $n \in \mathbb{N}_0^{M-1}$ and $k \in \{0, N\}$,

$$I_1(t_{n+1}, x_k) = \frac{\Delta t}{2} \sum_{i=0}^{n} \sum_{j=0}^{q} w_j u\Big(F_i\big(\xi_j\big), x_k\Big). \tag{33}$$

The second integral is more complicated since it involves two composing integrals, using Gauss-Legendre quadrature twice yields

$$I_2(t_{n+1}, x_k) = \frac{\Delta t^2}{4} \sum_{i=0}^{n} \sum_{j=0}^{q} w_j J_0\Big(t_{n+1} - F_i\big(\xi_j\big)\Big) \sum_{l=0}^{j} \sum_{m=0}^{q} w_m u(F_l(\xi_m), x_k) \tag{34}$$

and the remained integral is approximated by

$$I_3(t_{n+1}, x_k) = \frac{\Delta t}{2} \sum_{i=0}^{n} \sum_{j=0}^{q} w_j J_1\Big(t_{n+1} - F_i\big(\xi_j\big)\Big) u\Big(F_i\big(\xi_j\big), x_k\Big). \tag{35}$$

From approximations (33)–(35), the numerical solution on the interface of (17) can be given by

$$u_0^{n+1} = u_1^{n+1} + f_1^{n+1}, \tag{36}$$

$$u_N^{n+1} = u_{N-1}^{n+1} + f_2^{n+1}. \tag{37}$$

We accomplish this by simply adding (36) and (37) to the discretization of the interior governing Eq. (22). We obtain an implicit scheme that we illustrate by the following system in matrix form

$$\begin{cases} \big(I + \tilde{A} + \tilde{B}\big) U^{n+1} = (I + A - B) U^n + F^n, \quad n \in \mathbb{N}_0^{M-1}, \\ u_0^{n+1} = u_1^{n+1} + f_1^{n+1}, \\ u_N^{n+1} = u_{N-1}^{n+1} + f_2^{n+1}. \end{cases} \tag{38}$$

with

$$U^n = \begin{pmatrix} u_1^n \\ \vdots \\ u_{N-1}^n \end{pmatrix} \quad I = \begin{pmatrix} 1 & & 0 \\ & \ddots & \\ 0 & & 1 \end{pmatrix}, \quad F^n = \begin{pmatrix} \left(C_{d_1} + C_{d_2}\right)\left(f_1^n - u_1^n\right) \\ 0 \\ \vdots \\ 0 \\ \left(C_{d_1} - C_{d_2}\right)\left(f_2^n - u_{N-1}^n\right) \end{pmatrix},$$

$$A = C_{d_1} \begin{pmatrix} 2 & -1 & 0 \\ -1 & \ddots & -1 \\ 0 & -1 & 2 \end{pmatrix}, \quad B = C_{d_2} \begin{pmatrix} 0 & 1 & 0 \\ -1 & \ddots & 1 \\ 0 & -1 & 0 \end{pmatrix}$$

and

$$\tilde{A} = C_{d_1}\begin{pmatrix} 2 - C_{d_1} & -1 & 0 \\ -1 & \ddots & -1 \\ 0 & -1 & 2 - C_{d_1} \end{pmatrix}, \quad \tilde{B} = C_{d_2}\begin{pmatrix} -C_{d_2} & 1 & 0 \\ -1 & \ddots & 1 \\ 0 & -1 & C_{d_2} \end{pmatrix}.$$

where the discretization constants are $C_{d_1} = \frac{\beta}{h^2}, C_{d_2} = \frac{\gamma \Delta t}{4h}$.

3. Non standard boundary conditions for the BBM equation

In [4], we have presented a new method to derive transparent boundary conditions for the BBM equation. These boundary conditions have the advantage of being local in time but needs an additional function construct the BC which means bigger system to be solved. We recall that the problem designed to be the restriction in Ω_T of the BBM initial Eq. (1) with $\alpha = 0$ is given by

$$\begin{cases} \partial_t u - \beta \partial_{txx} u + \gamma \partial_x u = f & \text{in}]0, T] \times]a, b[\\ \partial_t v - \beta \partial_{txx} v + \gamma \partial_x v = g & \text{in}]0, T] \times]a, b[\\ \partial_x u = v & \text{on}]0, T] \times \{a, b\} \\ \beta \partial_{tx} v - \gamma v = \partial_t u - f & \text{on }]0, T] \times \{a, b\} \\ u(0, x) = u_0(x) & \text{on} [a, b] \\ v(0, x) = v_0(x) & \text{on } [a, b] \end{cases} \tag{39}$$

4. Numerical examples

We take an initial condition as solitary wave like function locally supported in Ω. The evolution of the solutions are plotted in different time steps before, under and after traveling the right boundary of the considered bounded domain. We save a reference solution that is numerically calculated in a broaden domain of Ω with Dirichlet boundary condition. We compute infinite error between numerical solutions using both formulations presented in this paper and the reference solution. We denote GLQ_i for approached solution with BEM and Gauss Legendre Quadrature in (2) for $i \in \{0, 1, 2\}$, while NSBC refers to numerical solution with non standard boundary conditions given in (3). We define the following errors

$$\|(u - u_{ref})(t, a)\|_\infty = \sup_{t \in [0, T]} |u(t, a) - u_{ref}(t, a)|, \tag{40}$$

$$\|(u - u_{ref})(t, b)\|_\infty = \sup_{t \in [0, T]} |u(t, b) - u_{ref}(t, b)|, \tag{41}$$

$$\|(u - u_{ref})(t, x)\|_\infty = \sup_{(t, x) \in [0, T] \times]a, b\left[|u(t, x) - u_{ref}(t, x)|.\right.} \tag{42}$$

Let $\beta = \gamma = 1$, $T = 10$ and $u_0(x) = sech^2(x)$. The considered initial data is locally supported in the interval $\Omega =]-10, 10[$, since $u_0(10) = u_0(-10) \approx 8,25.10^{-9}$. We fix $h = 10^{-2}$ and we vary the time step Δt. For a better comparison of these methods, we compute CPU time, in seconds, needed for each one to obtain numerical solution.

spatial profile of the light. The VeCSEL is composed of a semiconductor chip, an output coupler, and in most cases an optical pump (electrical pumping is often possible) [9]. The semiconductor chip embeds both the gain medium and a multilayer High-Reflectivity (HR) backside mirror. The mm–cm long cavity can be adjusted for the continuous-wavelength tunability purposes, over wide spectral ranges (close to THz demonstrated [10]). In the following, we focus on the design parameters of a VeCSEL that demonstrates tunability, compactness, and high coherence.

4.2 The “Ideal” Laser

The purpose of what we call here “the ideal laser” in continuous-wave regime is to generate a high-power light (from some mW to multiwatt operation), which is strongly confined on three physical observable quantities:

- *Space*: the generated light has to be focusable in the smallest possible spot, as predicted.[2] by the diffraction. This property is called “spatial coherence” and leads to “brightness” in the case of high-power lasers. The spatial coherence also induces the possibility to collimate the beam over a very long distance. Most spatially coherent lasers emit solely the *transverse* TEM_{00} mode from the Laguerre–Gauss or Hermite–Gauss basis [11], (see Figure 4.2a). An exact TEM_{00} emission is said to be “diffraction limited.” Any mismatching observed between the emitted light profile and the exact TEM_{00} mode is usually estimated by means of the propagation factor $M^2 \geq 1$. $\sqrt{M^2}$ can be understood like the unexpected radius increase of the beam [12], compared with the diffraction-limited (theoretical) one, defined to be w_0 in near field and θ_0 in far field.[3] Both are related

---

[2] In extreme focusing conditions, its radius tends to be $2\lambda/\pi^2 \approx 0.2\lambda$ where λ is the wavelength.
[3] Both w_0 and θ_0 are evaluated at $1/\exp(2)$ from the maximum on the intensity profile. However, choosing an appropriate indicator to define the size of a beam is not something easy. We encourage the reader to examine the very interesting work of Siegman [12] for free-space beams, and the works of Petermann [13, 14] for confined/guided light.

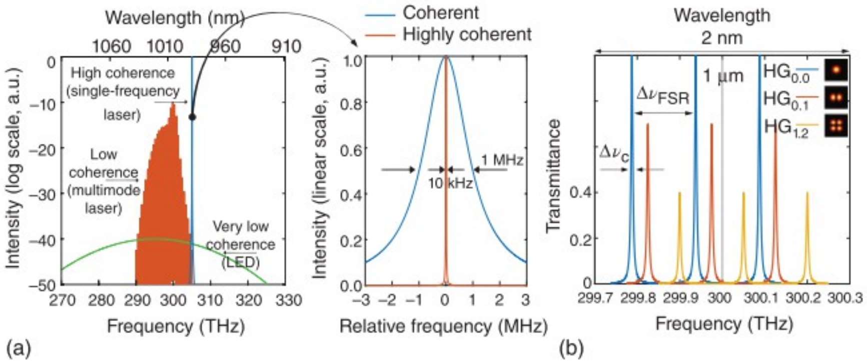

Figure 4.3 (a) Various degrees of time coherence, depending on multimode operation and also on the ability of the cavity to filter the spontaneous emission, thus on its Finesse $\mathcal{F}$. Please note the range ratio ($\approx 10^7$) between the two frequency ranges. (b) Longitudinal resonances of HG_{00} (TEM_{00}) for a passive Fabry–Perot cavity, as well as the resonances of two higher-order transverse modes. We also depict two fundamental parameters of the cavity transmittance spectrum: its periodicity $\Delta\nu_{FSR}$ and its FWHM linewidth $\Delta\nu_c$.

by the invariant parameter from the Gaussian beam theory $w_0\theta_0 = \lambda/\pi M^2$ [11]. However, it makes more sense, for better quantification or physical analysis, to perform a more advanced investigation, by observing the unexpected phase variations in the transverse plane, as well as performing a Zernike decomposition of the wavefront [15].

- *Time/spectrum*: the spectrum of the light source must be as narrow as possible. This property is called "monochromatic wave" or "long coherence time" and means that the electric field follows a perfect, pure, and unmodulated sine wave oscillation at the optical frequency ν_0,[4] that was born a long time ago and that will die in a very far future. Whatever the physical origin of the spectral width (multimode operation and/or temporal phase distortion, see Figure 4.3a and b), a classical way to quantify this time coherence is the Full-Width-Half-Maximum (FWHM) of the laser spectrum, which is, from high to low coherence, in the kHz–GHz range for most single-frequency free-running lasers.[5] However, because the possible physical reasons for broadening are many, studying the coherence of a laser by means of the spectrum FWHM is not always relevant. For better analysis and more accuracy, one may look at the time-domain fluctuations of the laser field instant frequency, often quantified its the Allan Variance, but more usually through its spectral density [17]. That's what we do in the following.
- *Polarization*: the polarization state of the electrical field must be unique in space and time. In most cases, it will be linear, following a specific direction, but it can also be circular, left or right-handed, or elliptical. This property is called "polarization coherence."

---

[4] This frequency is in the 100–1000 THz range for usual ultraviolet to infrared wavelengths.

[5] It can go close to Hz level for lasers actively locked on a frequency reference [16].

Aiming at this kind of coherence, the laser design will have to *induce the selection of a single transverse, longitudinal, and polarization mode* of the cavity (see Figure 4.3b). Of course, this ability for the laser strongly depends on its technology and design; however, *reaching a single-mode operation is only the first step*: it is necessary but not sufficient for high coherence, and it needs to be discussed in the following. These two topics are the purpose of the two next sections.

4.3 Toward Single-Mode Operation

In most cases, each mode of a passive cavity is identified by a specific optical resonance frequency (see Figure 4.3b). These resonances can however be displayed in a more convenient way (see Figure 4.4a-c), by using the dispersion relation that exists between the wave vector k and the optical frequency ν in free space:

$$\nu = c/\lambda = c/2\pi \times k \tag{4.1}$$

On the longitudinal axis, these resonance frequencies are well-known (-a) as each longitudinal mode resonates at a frequency located by one of the tooth of a frequency comb, periodicity of which is given by the Free Spectral Range, defined as follows:

$$\Delta\nu_{\text{FSR}} = c/(2nD) \tag{4.2}$$

where c is the speed of light in vacuum, n the optical index of the medium in the cavity, and D the cavity length.

Each mode of the transverse plane supports a frequency comb with exactly the same periodicity $\Delta\nu_{\text{FSR}}$ on the longitudinal axis. However, the frequency comb associated to a given transverse mode is shifted by an offset that depends on the base of modes supported by the cavity. For a VeCSEL, it is usually the Hermite–Gauss or

(% ' ' 1! ! 7! ! 9=

So, we made the theoretical proof as well as the experimental proof of the exceptional purity of the single-mode operation of the VeCSEL. We revealed its excessively pure photon state on all the three coherence axis thanks to the radio-frequency metrology, which offers much stronger measurement dynamics (by decades compared with usual methods!).

4.10 Spatial Coherence

As demonstrated above, VeCSELs can select a single transverse mode, which is a first important step to reach spatial coherence. However, this pure mode can be polluted by some spatial noise, (see Figure 4.7a). In this section we get a closer look at this *transverse spatial noise*, i.e. the static (time-domain independent) fluctuations superimposed on an ideal wavefront beam: the *time domain phase fluctuations* will be investigated in the next section.

We can consider that a real-world Gaussian TEM_{00} mode is an ideal spherical Gaussian wave, wavefront of which is polluted by some "spatial phase noise" in the transverse dimension of the wave, as illustrated in Figure 4.14. This leads to M^2 propagation factors higher than 1. In the case of VeCSELs, we measured that the wavefront deformation, compared with an ideal spherical Gaussian wave, is less than 1%, leading to excellent M^2 values (typically lower than 1.2). This kind of wavefront deformation typically originates from some residual, nonspheric, thermal lensing, or from the slight irregularities of various surfaces that the beam meets inside the cavity.

4.11 Time Domain Coherence and Noise

An accurate mean for the quantification of the time domain coherence is the study of noise. When talking about laser coherence, two kinds of fluctuations need to be discussed: *magnitude fluctuations* $A(t)$ (or *intensity fluctuation*) and *phase fluctuations* $\varphi(t)$ of the total electrical field $E(t) = (A_0 + A(t))\exp(j(\omega_0 t + \varphi(t)))$ as a function of the time.

The main characteristic of $A(t)$ and $\varphi(t)$ is that they are random functions of the time, i.e. not predictable, so they are called "noise." The word "noise" is often thought in terms of parasitics, which are external to the device. This is a narrow way of thinking: noise has fundamental reasons to be ingrained by the very physics of the device. Lasers are no exception.

4.11.1 Noise in Photonics: Basics

For example, *about* $A(t)$, the mere fact that a photonic source emits photons at random instants[19] leads to *intensity noise*. Actually, the optical power can be described in

---

[19] This is the case of most of them, even most lasers. A few counter-example exist in the literature, see a pedagogical example with high-efficiency Light-Emitting Diode [41] or in the case of lasers [42, 43].

a pure corpuscular vision like a flux of photons going through a surface, for example, the laser output coupler itself, or the surface of a detector. It is then defined like:

$$P_{\text{out}} = h\nu \frac{N}{\tau} \tag{4.15}$$

where N is the number of photon going through the considered surface during the time τ of the experiment. This is a very high rate signal: for a monochromatic emission of 1 mW at $\lambda = 1\ \mu\text{m}$, this leads to $N \approx 10^{16}$ for an observation of one second, with an intensity modulation of 100%, because at each instant, a photon is emitted or not, randomly. As we use bandwidth-limited detectors, we filter this high rate signal and observe an average value with moderated fluctuations (see Figure 4.15a). Due to its random nature, it is complex to speak about the time function of a noise because the magnitude in time is totally unpredictable, and we thus prefer to work with a statistically stable indicator such as its variance, or the square root of the variance, called effective value or RMS (Root Mean Squared) value.

Whatever the physical origin of the noise for a given photonic source, it should always be compared with a fundamental, nearly unavoidable, noise reference: *the shot noise*. The shot noise is nearly unavoidable, because optical attenuation,

whatever its origin (attenuator, absorption, beam-splitter, diffraction, …), is nearly inescapable in practical photonic systems. Because attenuation selects randomly the photons that can pass, it alters the statistic of the attenuated beam, compared with the incident one. In the case of lasers, and especially for high finesse cavity lasers, the shot noise is usually unavoidable because the intracavity power experiences a huge attenuation when being coupled to the outside of the cavity [44] (see Figure 4.15b). We must point out that, in most usual cases, the magnitude of the shot noise is low compared with other kinds of noise, and for that reason the existence of the shot noise is rarely a limit[20]: it is more to be understood like a practical reference level of noise. This shot noise is quite easy to quantify. We simply have to evaluate the average value and the variance of N_1, the amount of photons passing through an attenuator of transmittance T [44]:

$$\overline{N_1} = T \times \overline{N} \quad \text{and} \quad \overline{\Delta N_1^2} = \overline{\left(N_1 - \overline{N_1}\right)^2} = \overline{N_1^2} - \overline{N_1}^2 \tag{4.16}$$

Assuming all the attenuation events are independent, we can calculate $\overline{\Delta N_1^2}$ for a single photon and apply a scaling factor by $\overline{N}$ to take into account all the photon selection events: $\overline{\Delta N_1^2} = \overline{N}T(1 - T)$. Then, Eq. (4.15) leads to the fluctuation that occurs on an optical power $P_{\text{att}} = P_{\text{out}} \times T$ that experienced some attenuation [44]:

$$\overline{P_{\text{att}}} = h\nu\frac{\overline{N_1}}{\tau} \quad \text{and} \quad \overline{\Delta P_{\text{att}}^2} = h^2\nu^2\frac{\overline{\Delta N_1^2}}{\tau^2} = \frac{h\nu}{\tau}\overline{P_{\text{out}}}T(1 - T) \tag{4.17}$$

This relation is dependent on the observation time τ, which is not practical. Usually, people prefer to work with the power spectral density $S_\text{P}(f)$ of the signal $P(t)$, which is simply related to the variance or its square root P_{RMS} as follows:

$$P_{\text{RMS}} = \sqrt{\overline{\Delta P^2}} = \sqrt{\int_{f_{\text{low}}}^{f_{\text{high}}} S_P(f)\text{d}f} \tag{4.18}$$

$S_\text{P}(f)$ can be understood like the spectral distribution of the noise.[21]

Because observing a signal over a time τ is equivalent to observing it with a spectral bandwidth[22] $\Delta f = (2\tau)^{-1}$, we can deduce from Eqs. (4.17) and (4.18) that the spectral density due to the shot noise is given by $S_{\text{shot}} = 2h\nu\overline{P_{\text{out}}}T(1 - T)$. In the case of laser experiments, strong attenuations are usual ($T \rightarrow 0$), and thus $T(1 - T) \rightarrow T$, which leads to:

$$S_{\text{shot}}(f) = 2h\nu\overline{P_{\text{att}}} \tag{4.19}$$

---

[20] Except in extreme setup like spin noise spectroscopy [45], or in very long-range doppler detection [46].

[21] As depicted above, due to its random nature, the time function of a noise is complex to describe with mathematics. It is exactly the same for the Fourier transform of the noise because it exhibits the same random feature as the time function. We thus use the power spectral density $S_\text{P}(f)$, which is a stable indicator of the spectral repartition of the noise.

[22] This equivalence is due to the fact that the Fourier transform of a time window τ is a cardinal sine which width is $\Delta f = (2\tau)^{-1}$.

This expression does not depend on the frequency, and this means that the shot noise spectrum is flat, with uniform value for all frequencies: it is a *white noise*. Intuitively, we feel that there is no reason for an attenuation process to have a specific time constant associated. If we take a source with a self noise, spectral density of which is $S_{\text{laser}}(f)$, because the attenuation process is not dependent on the source statistics, the observation of this source through the attenuator should lead to:

$$S_{P_{\text{att}}}(f) \approx S_{\text{laser}}(f) \times T^2 + 2h\nu\overline{P_{\text{out}}} \times T \tag{4.20}$$

Finally, increasing the attenuation ($T \to 0$) leads to observe only shot noise and hides the contribution of $S_{\text{laser}}(f)$.

When detected by a photodiode, a quantum efficiency $\eta_q < 1$ can be understood as if all the photon events were not transfered into electron events. This is similar to the detection with an ideal photodiode (that means $\eta_q = 1$, thus a sensitivity $= hc/q\lambda$ in A/W) placed after an optical attenuator, transmittance of which is equal to the quantum efficiency η_q. And so the simple detection process with a real-life detector can introduce a shot noise contribution too. Because of all the possible attenuation processes described above, it is usually assumed that the detected current contains a part of shot noise, value of which is $S_{\text{shot}}(f) = 2qi_{\text{ph}}$, where i_{ph} is the average detected photocurrent. For that reason, intensity noise is usually evaluated by the "Relative Intensity Noise" (RIN), which does take into account the fact that the shot noise may come from the measurement setup itself:

$$\text{RIN} = \frac{S_{\text{iph}} - 2qi_{\text{ph}}}{i_{\text{ph}}^2} \tag{4.21}$$

where S_{iph} is the spectral density of the photocurrent measured in an experiment similar to the one depicted in Figure 4.15b.

The measurement is usually performed thanks a low-noise-amplified photodiode, output of which will be processed to perform power spectral density spectra averaging. Averaging is necessary because the power spectral density is evaluated during a finite measurement time (the one of the experiment); so, its experimental estimation undergoes a statistical error, which can be reduced M times by accumulating M averages (due to the law of the large numbers). The power spectral density may be estimated by a RF sweeping spectrum analyzer or by measuring the time signal with an acquisition card and some Fast-Fourier-Transform (FFT) processing [47, 48]. The latter is more interesting, when possible, because in most practical cases, the computational efficiency of the FFT algorithm leads to petty computation times.[23] For that reason, the time necessary for the acquisition of a single spectrum is the one necessary for the acquisition of the time domain signal, defined as RBW^{-1} where RBW is the Resolution BandWidth of the spectrum. It is far quicker than with a RF sweeping analyzer, which requires at least $K \times \text{RBW}^{-1}$ with K the amount of points in the spectrum. This necessary time for the acquisition is an important topic because, as explained, accurate noise measurements rely on averaging spectra. An example of result of this process is given for S_{iph}, as well as for the corresponding RIN spectrum, in Figure 4.16a.

---

[23] This is true in lots of practical cases, when the wanted spectral resolution is narrow. In very specific cases, dedicated electronics can be involved to speed up the FFT computation [45].

To sum up, noise is usually quantified through the *power spectral density*, which indicates the spectral repartition of its fluctuations. The attenuation impedes an accurate laser power spectral density measurement because the *shot-noise* is superimposed. For that reason, the intensity noise is usually given by the RIN that takes into account the impact of the shot-noise on the measurement.

4.11.2 Intensity Noise of a VeCSEL

Like in most lasers, the VeCSEL noise has a fundamental cause: the spontaneous emission. However, this contribution is weak due to the high Finesse cavity design, and other technical noise, mainly coming from the pump, usually has a much stronger contribution (see Figure 4.16b and c). The pump noise itself depends on the kind of pump: usually single-mode laser diodes experience mainly $1/f$ noise at low frequency [49] due to the impact of the semiconductor cristal defects on the electronic transport [50]. Multimode pumps can deliver much higher power but may produce extra contributions to noise for optical reasons, coming from the multimode operation itself [51].

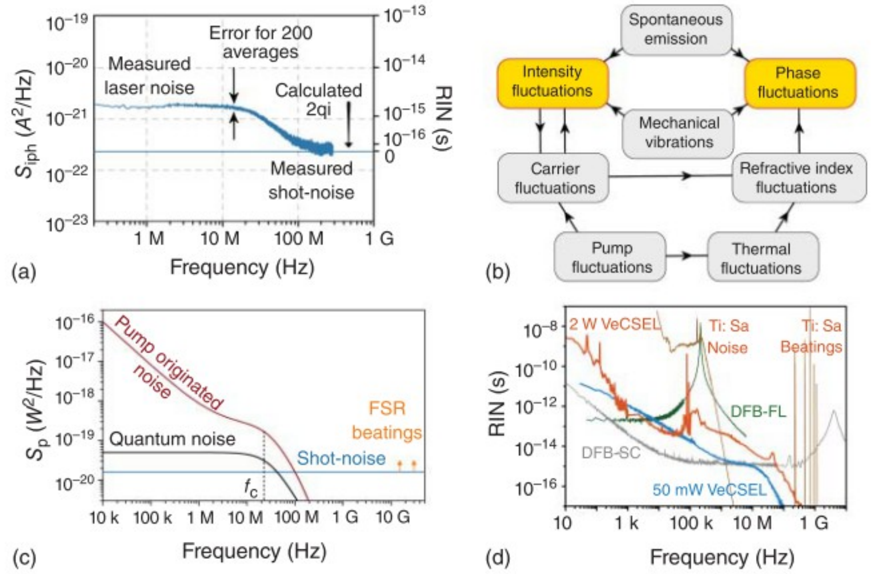

Figure 4.16 (a) Example of noise spectrum, exhibiting both RIN and spectral density. (b) Model of the VeCSEL Noise [18]. (c) Result from the model described in *(b)* in the case of intensity noise. (d) VeCSEL intensity noise compared with other technologies. For the VeCSEL, the cutoff is always below 100 MHz, and the intensity noise inside the VeCSEL bandwidth depends on the kind of pump: single-mode for the 50 mW VeCSEL, multimode in the case of the 2 W VeCSEL. The VeCSEL beatings were outside of the available spectral range (beyond 10 GHz) at the moment of the experiment.

($ %% 7! ! " D /

normalised ***Doppler broadened lineshape*** and is, in fact, a Gaussian distribution:

$$g(\nu) = \frac{c}{\nu_0}\left(\frac{M}{2\pi k_B T}\right)^{1/2} \exp\left[\frac{-Mc^2}{2k_B T \nu_0^2}(\nu - \nu_0)^2\right] \tag{7.19}$$

where M is atomic mass. We can now obtain the transition rate for monochromatic light at a single frequency $W_i(\nu)$ by replacing the spectral energy density $\rho(\nu)$ in Eq. 7.15 with that for monochromatic light density ρ_ν and also by including line shape broadening:

$$W_i(\nu) = \frac{c^3 \rho_\nu}{8\pi n^3 h \nu^3 \tau_{21}} g(\nu) \tag{7.20}$$

Equation 7.20 can be written in terms of the optical intensity I_ν, in (W/m^2):

$$\begin{aligned} I_\nu &= c\rho_\nu / n \\ W_i(\nu) &= \frac{c^2 I_\nu}{8\pi n^2 h \nu^3 \tau_{21}} g(\nu) = \frac{\lambda^2 I_\nu}{8\pi n^2 h \nu \tau_{21}} g(\nu) \end{aligned} \tag{7.21}$$

where c is the speed of light, n is the refractive index and λ is the wavelength in vacuum.

Example A light bulb is operated at a temperature of $T = 1000$ K and has an average emission wavelength of 0.5 µm. Calculate the ratio of the stimulated emission to spontaneous emission rates.

Average emission frequency:

$$\nu = \frac{c}{\lambda} = \frac{3 \times 10^8 m/s}{0.5 \times 10^{-6} m} = 6 \times 10^{14}\,Hz$$

From Eq. 7.14 the ratio of stimulated and spontaneous emission rates are:

$$\frac{W_{21}^i}{W_{21}} = \frac{1}{\exp\left(\frac{6.626 \times 10^{-34} Js \times 6 \times 10^{14} s^{-1}}{1.38 \times 10^{-23} J/K \times 1000} K\right) - 1} = 3.1 \times 10^{-13}$$

This simple exercise proves that, for a system in thermal equilibrium, spontaneous emission will always dominate the stimulated emission. Ordinary light sources emit light in a wide spectrum and their emission is incoherent.

In order to produce coherent radiation, the stimulated emission rate needs to be increased. This implies that for a two level system, in Eq. 7.7, the population of the higher energy level (N_2) has to be increased over that of the lower energy level (N_1).

XXV

The Paradoxes of the Infinite

> *We admit, in geometry, not only infinite magnitudes, that is to say, magnitudes greater than any assignable magnitude, but infinite magnitudes infinitely greater, the one than the other. This astonishes our dimension of brains, which is only about six inches long, five broad, and six in depth, in the largest heads.*
>
> VOLTAIRE

Tristram Shandy was hopelessly perplexed. He had begun to write his autobiography and found that he could record only half a day's experiences in one day of writing. Consequently, even if he were to start writing at birth and even if he were to live forever, he could not record his whole life, for at any time only half of his life would be recorded. And yet if he did live on indefinitely he ought to be able to record his whole life, for the experiences of his first ten years would be recorded by the end of his twentieth year; the experiences of his first twenty years by the end of his fortieth year; and so on. Thereby every year of his life would be reached at some time. Hence, depending on which way he reasoned, he could or could not complete his autobiography. The longer Tristram puzzled over this paradox the more confused he became and the farther he appeared to be from a decision.

Tristram's inability to resolve the paradox was really to be expected, for his problem involved an infinitude of time. The greatest mathematicians and philosophers from Greek times on had been plagued with problems involving infinite quantities and had not fared any better. For example, Galileo recognized that the number of whole numbers is infinite; that is, the number of these whole numbers is greater than any finite number that can be named. He recognized, also, that the number of even whole numbers is also infinite. Which of these two infinite sets, he asked, is the larger one? On the one hand, it seemed as though the first should be, for it contains all the numbers of the second set and more besides. On the other hand, to each number in the first set there corresponds exactly one number in the second, as 5 corresponds to 10. Also, to each number in the second set there corresponds exactly one in the first, as 10 corresponds to 5. In view of this *one-to-one correspondence* between the two sets there should be as many in the first as in the second. Galileo concluded that it was impossible to compare infinite quantities and abandoned further thought on the subject. He says 'infinity and indivisibility are in their very nature incomprehensible to us.' Leibniz, too, considered the very same question and concluded that the notion of the number of whole numbers is self-contradictory and should be rejected.

Not many years before a successful attack was finally made on the problems of the infinite, the supreme nineteenth-century mathematician, Karl Friedrich Gauss, expressed a horror of infinite quantities: 'I protest against the use of infinite magnitude . . . which is never permissible in mathematics.'

However much mathematicians recoiled from or repudiated the thought of infinite quantities, by the middle of the nineteenth century mathematics could no longer dispense with the concept. During the period from 1600 to 1850 mathematics had made gigantic strides. In this heroic age great intellectual adventurers had dared to leap over chasms of difficulties to goals envisaged by their genius and farsightedness. These trail blazers expected that others would build the bridges to support the circumscribed steps of the more cautious thinkers who were to follow.

But the bridges were not easily built. The attempts to fill the gaps left during the heroic age were frustrated by paradoxes, contradictions, and more paradoxes. There developed an imperative need for critical thinkers with imagination and daring of another kind, the kind that would be able to dispense with and even override intuition and 'common sense.' This need was finally met. Neither the more circumspect workers, however, nor the trail blazers could have anticipated the astonishing and profound disclosures which the critical efforts brought forth.

The first successful attack on the problems of the infinite was made by Georg Cantor. His father had urged him to study engineering, a more profitable pursuit than teaching, and Cantor had started to follow this down-to-earth career; he ended by contributing to the the most abstract regions of mathematics. His work got the reception that innovation and originality usually encounter—neglect, ridicule, and even abuse. One fellow-mathematician, Leopold Kronecker, attacked it viciously. Somewhat milder and more typical of the response to it was the remark made in 1908 by Henri Poincaré, the most famous of the late nineteenth-century mathematicians: 'Later generations will regard [Cantor's] *Mengenlehre* as a disease from which one has recovered.' Mathematicians, let it be known, are often no less illogical, no less closed-minded, and no less predatory than most men. Like other closed minds they shield their obtuseness behind the curtain of established ways of thinking while they hurl charges of madness against the men who would tear apart the fabric. So severe were the attacks on his work that Cantor began to doubt himself, became depressed, and suffered mental breakdowns.

Toward the end of his life (he died in 1918), the uncommon sense of his logic finally gained some recognition from a few colleagues. It is comforting to contrast Poincaré's statement above with one made just a little later by David Hilbert, the greatest mathematician of this century: 'No one shall expel us from the paradise which Cantor has created for us.' Today Cantor's work is so widely and completely accepted that many profound mathematicians are quite willing to devote themselves to the solution of further problems which the acceptance of Cantor's work brought in its train.

And now let us see how Cantor attacked the problem of infinite quantities. The most familiar examples of infinite collections are the collection of whole numbers, the collection of fractions, and the collection of all real numbers, that is, whole numbers, fractions, and irrational numbers such as $\sqrt{2}$, $\sqrt{3}$, and π. To obtain the number of objects in such collections by counting is impossible because the process is endless. On the other hand, describing them as infinite sheds very little light on them, for all this word says is that they are not finite. Such a description is about as informative as the statement that *Pithecanthropus erectus* is not a cow. We must substitute, if possible, a positive answer to the question of how many objects there are in infinite collections.

Cantor recognized, of course, that the number of objects in an infinite collection or class cannot be obtained by counting. He also recognized the deeper significance of another seemingly superficial observation. Suppose we have two classes of objects such that to each object in the first class there corresponds one and only one object in the second and conversely. For example, if a squad of soldiers, each carrying a gun, were to pass before us there would be just such a correspondence between soldiers and guns. Technically, the relation between the two classes, soldiers and guns, is described by the phrase *one-to-one correspondence.* Obviously, two classes that are in one-to-one correspondence must contain the same number of objects. Moreover, it is not necessary to count the classes to reach this conclusion.

Cantor's greatness lies in his perception of the importance of the one-to-one correspondence principle and in his courage to pursue its consequences. *If two infinite classes can be put into one-to-one correspondence then,* according to Cantor, *they have the same number of objects in them.* For example, the class of positive whole numbers

$$1 \quad 2 \quad 3 \quad 4 \quad 5 \quad 6 \quad \ldots$$

and the class of reciprocals of these numbers

$$1 \quad \tfrac{1}{2} \quad \tfrac{1}{3} \quad \tfrac{1}{4} \quad \tfrac{1}{5} \quad \tfrac{1}{6} \quad \ldots$$

are in the one-to-one correspondence whereby each number in the first class corresponds to one and only one number in the second, namely, its reciprocal. In like manner, to each number in the second class there corresponds one and only one in the first. Hence, these two classes have the same number of objects in them. The number that represents the quantity of objects in these particular classes Cantor designated by $\aleph_0$ (aleph-null). It is called a transfinite number.

To say that the number of positive integers, as well as the number of any set of objects in one-to-one correspondence with the positive integers, is $\aleph_0$ does not seem to answer the fundamental question of how many there are in each set. The reader may say that $\aleph_0$ is a stranger to him and gives him no information on the number of positive integers. The objection is not a valid one. This number is as informative as the number one billion billion. The latter number is no more than a symbol representing the quantity of objects in a particular collection just as $\aleph_0$ represents the number of positive integers.

XXVI

New Geometries, New Worlds

> *I have made such wonderful discoveries that I am myself lost in astonishment: Out of nothing I have created a new and another world.*
>
> JOHN BOLYAI

The first man to challenge Euclid was Euclid himself. The creator of the most widely and most completely accepted system of thought—the abode of truth, and the birthplace of philosophies and sciences—doubted his results even before he issued them to the world. Euclid's questioning of himself marked the beginning of a two-thousand-year 'behind the scenes' attack on the obvious.

It is well known that Euclidean geometry is founded on ten axioms whose truth appears so self-evident that no 'sane' man would dare question them. From this sound basis impeccable logic produced more 'truths' just as appealing and as immediately acceptable as the axioms. Two millenniums of application climaxed by the successes of the Newtonian era added practically incontrovertible evidence of the soundness and reliability of these truths. Century after century buttressed logic with experience and common sense with tradition, until Euclid's system acquired inviolate sanctity. By 1800 educated people were far more likely to swear by the theorems of Euclid than by any statement in the Bible.

Whether a person appealed to experience, accepted the Kantian philosophy, or inclined to the obvious, the inescapable conclusion appeared to be that Euclid was truth and truth, Euclid. Despite this enviable position, which Euclidean geometry possessed from the outset and which time enhanced, a few thinkers, including Euclid, were not at ease. They were disturbed by two apparently innocent axioms.

The first of these says that a line segment can be extended *as far as one pleases* in either direction. The second one is the axiom on parallels, which says that through a point P not on a line L there passes one and only one line M (in the plane of P and L) that does not meet L *no matter how far M and L are extended* (fig. 77). If the axioms of Euclidean geometry are accepted because experience with physical space warrants our doing so, then these axioms are open to some doubt. No man has had direct experience with what happens in space more than a few miles beyond the Earth. All we can really say is that these axioms appear to be true in the limited regions in which we actually move. And even here we cannot be too sure of our assertions, for it was pointed out in the chapter on projective geometry that we never *see* parallel lines even in the portion of space immediately around us. As we look into the distance along lines Euclid refers to as parallel, we find that they seem to meet.

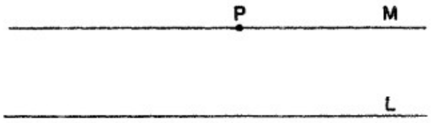

Figure 77. Euclid's parallel axiom

Euclid reveals his concern about these axioms by the manner in which he uses them. He does not use the parallel axiom, which is the more questionable of the two, until he has proved as many theorems as he can without it. He is equally cautious about the unlimited extensibility of the straight line. An examination of the theorems of his geometry shows that he uses line segments (portions of lines between two points) but never supposes that he has an infinite straight line to start with. When necessary he extends a segment in either direction only as far as the theorem requires. It should not be inferred that Euclid doubted the truth of these axioms; rather, because of their seemingly weighty implications, he would have preferred, no doubt, to derive their contents as consequences of simpler axioms.

A few hypercritical thinkers in every age following that of Euclid also hesitated to use as axioms statements on which any hard-headed businessman would bet his bottom dollar. To eliminate any lingering qualms these men from Missouri all tried the same thing. They concentrated on the parallel axiom and sought either to deduce it from the other axioms or to find a more acceptable substitute. Several hundred such worthy attempts on the part of the best mathematicians ended in failure, however. By 1800 the parallel axiom had come to be labeled the scandal of geometry.

It is hardly desirable, nor would it be too profitable, to review most of the efforts. The work of one man, however, the Jesuit priest Girolamo Saccheri, a professor of mathematics at the University of Pavia and a keen student of logic, merits our attention. Saccheri had a brand new idea. His novel attack on the problem of the parallel axiom was to argue in effect: Given a line L and a point P, then either (a) there is exactly one parallel to L through P, or (b) there are no parallels to L through P, or (c) there are at least two parallels to L through P. Alternative (a) was Euclid's parallel axiom. Suppose it were replaced by alternative (b), and the latter together with the other nine axioms of Euclid were shown to lead to contradictory theorems. Then surely alternative (b) could not be correct. Similarly, if the use of alternative (c) and the other nine Euclidean axioms led to contradictory theorems, then alternative (c) could not be correct. Then it would follow that Euclid's parallel axiom is the only possible one.

By using alternative (b) together with the other nine Euclidean axioms Saccheri did deduce theorems that contradicted each other. But he failed to deduce contradictions from the nine Euclidean axioms and the alternative axiom postulating the existence of at least two parallels. Though his efforts were determined and extensive, and though some of his deductions were indeed strange when compared with analogous results in Euclidean geometry, contradiction there was not.

Saccheri was on the threshold of an epoch-making discovery but he refused to step over it. For the moment we shall leave it to the reader to determine the conclusion Saccheri should have drawn from his failure to deduce inconsistencies. As for Saccheri himself, he was so unprepared for the strange theorems he established from his set of axioms that he decided Euclid's parallel axiom must be right. Accordingly, in 1733 he published his results in a book titled *Euclid Vindicated from All Defects*. Apparently when one man sets out to vindicate another he will most likely do so regardless of the facts.

One explanation for Saccheri's failure as well as the many others is that great as the mathematicians were who approached the problem presented by the parallel axiom, none was discerning enough to recognize and reject a two-thousand-year-old habit of thought. But within the mathematical world of the early nineteenth century a change in the intellectual milieu took place, bringing with it a sweeping, critical re-examination of fundamental beliefs. Undoubtedly this change accounts for the fact that three men, Gauss, Lobatchevsky, and Bolyai, with no knowledge of each other's thoughts, discovered the correct interpretation of Saccheri's work at about the same time; Lobatchevsky and Bolyai published their results within a few years of each other.

Of these three the greatest, and one who ranks with Newton and Archimedes, was Karl Friedrich Gauss. Karl showed unbelievable precocity in many fields and a particular predilection for mathematics. When as a young man he proved that the regular polygon of 17 sides could be constructed with straightedge and compass, he was so delighted that he abandoned his intention of becoming a philologist in order to study mathematics. He soon contributed masterful work to many branches of the subject and also achieved note as an inventor and experimentalist. Though his contributions were no less numerous and no less profound than those of other mathematicians, Gauss was extremely modest. He said, 'If others would but reflect on mathematical truths as deeply and as continuously as I have, they would make my discoveries.' Those who believe that genius is 99 per cent perspiration as well as those who despair of their mathematical abilities may find comfort in Gauss's statement.

Gauss was still a youth when the problem of the parallel axiom first came to his attention. At first he worked hard to replace the parallel axiom by a simpler one, and he failed. He then followed Saccheri's line of thought by adopting a parallel axiom contradicting Euclid's--essentially Saccheri's third alternative--and by deducing consequences from this new axiom and the other nine of Euclid's. Like Saccheri he arrived at strange theorems. Instead of allowing the strangeness to frighten him Gauss fought fire with fire. He drew the brand new, astounding conclusion which the great and near-great had failed to consider. He decided that *there can be other geometries as valid as Euclid's.*

Gauss had the intellectual courage to create non-Euclidean geometry but not the moral courage to face the mobs who would have called the creator mad, for the scientists of the early nineteenth century lived in the shadow of Kant whose pronouncement that there could be no geometry other than Euclidean geometry ruled the intellectual world. Gauss's work on non-Euclidean geometry was found among his papers after his death.

Of the two other men who deserve honor for the creation of non-Euclidean geometry the first was the gifted Nicholas Lobatchevsky. Born in 1793 to a poor Russian family, he studied at the University of Kasan and at the age of twenty-three became a full professor there. Lobatchevsky, too, was attracted to the problem of the parallel axiom. He says that he was struck by the fact that two thousand years of effort by the greatest mathematicians had failed to produce a better axiom. And so, like Saccheri and Gauss, he built a new geometry on the basis of a parallel axiom contradicting Euclid's. The almost unbelievable theorems to which he was led did not discourage him any more than they had Gauss. Sound reasoning had led to them and sound reasoning was the unquestionable guide. And so Lobatchevsky, too, affirmed the radical but inescapable conclusion: There are geometries different from Euclid's and just as valid.

The man who shares honors with Lobatchevsky for the discovery and the courage to publish his work on non-Euclidean geometry is the Hungarian, John Bolyai. Like the other two he was blessed by the gods and, in addition, was encouraged and developed by his father Wolfgang, also a mathematician. Wolfgang had himself been bitten by the bug of the parallel axiom problem and had spent many vain years in work upon it. He bequeathed it to his son who, in 1825, at the age of twenty-three, suddenly saw the light. There are axioms contradicting Euclid's, he contended, that can nevertheless serve as the basis for new geometries. John proceeded to build one. On the urging of his father, he published his work in 1833 as an appendix to his father's text.

How were the epoch-making documents of Lobatchevsky and Bolyai received? How did scientists react to the startling news that Euclidean geometry now had rivals? How did the very rational philosophers greet the most thoroughgoing refutation of the leading philosophy of the times? The works of Lobatchevsky and Bolyai were completely neglected. Moreover, in 1847 Lobatchevsky was dismissed by the University, despite brilliant contributions and unselfish devotion to his work. If Bolyai had been a professor rather than an Austrian army officer, he might have suffered the same fate.

About thirty years after Lobatchevsky and Bolyai published their monumental work, Gauss's correspondence on non-Euclidean geometry was published posthumously along with other papers. His name attracted attention to the subject and shortly thereafter the mathematical world began to read Lobatchevsky and Bolyai.

To appreciate their work on the problem of the parallel axiom we must go back for a moment. Consider any straight line L (fig. 78) and any point P not on L. Euclid's parallel axiom asserts that there is one and only one line K through P which does not meet L. Now let Q be any point on L. As Q moves to the right, the line PQ revolves counterclockwise about P and seems to approach the line K. In like manner, as Q moves to the left along L, the line PQ rotates clockwise about P and again approaches K. In each case, then, PQ approaches one and the same limiting line K.

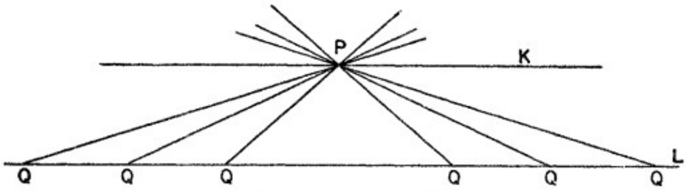

Figure 78. Euclid's parallel as a unique limiting line

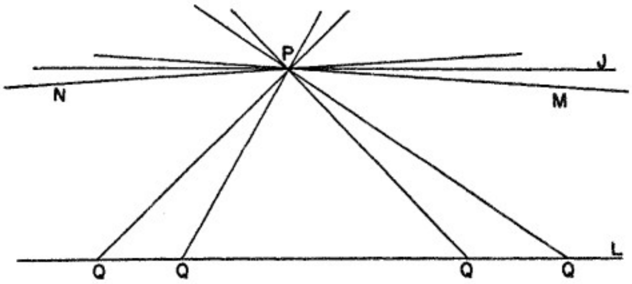

Figure 79. The parallel axiom of Lobatchevsky and Bolyai

Bolyai and Lobatchevsky, however, assumed that the two limiting positions of PQ are not the same line K but two different lines through P, and that these limiting lines, M and N (fig. 79), do not meet L. Moreover, they assumed that *every* line through P and between M and N, such as J, does not meet L. Hence Bolyai's and Lobatchevsky's parallel axiom affirms the existence of an infinite set of parallels to L through P. (These men reserved the word parallel for just the limiting lines M and N, but we shall use it to denote any line through P that does not meet L.)

The reader will perhaps feel, along with the mathematicians of Bolyai's and Lobatchevsky's time, that this is a ridiculous assumption to make. The diagram suggests that M and N will meet L if all three lines are extended far enough. Let us remember, however, that Bolyai and Lobatchevsky were interested in picking an axiom which, regardless of whether or not it describes the space we believe we live in, would be a logical alternative to Euclid's. And since the theorems to be derived from this axiom and the remaining Euclidean axioms would depend only on reasoning and not at all on accord with diagrams, the failure of the axiom to correspond with visual sensations is irrelevant.

What theorems were Bolyai and Lobatchevsky able to prove with their axioms? Of course, all the theorems of Euclid's geometry proved without the use of his parallel axiom are, automatically, theorems in Bolyai's and Lobatchevsky's geometry, since these men retained the other axioms of Euclid. As examples of such theorems we might mention these: Vertical angles are equal; from a point P at most one perpendicular can be drawn to a straight line; and, in a triangle with equal sides, the angles opposite these sides are equal.

Astonishing is the word for the theorems in the geometry of Bolyai and Lobatchevsky that do depend on their parallel axiom and therefore are not found in Euclid. These theorems, like all mathematical theorems, are proved by deductive methods of reasoning familiar to the reader; unlike the case in Euclidean geometry, however, figures are not nearly so useful in suggesting the steps of the proofs or in illustrating the meanings of the theorems.

Most unexpected is the theorem that *the sum of the angles of any triangle is always less than 180°*. Moreover, *of two triangles, the one with a larger area has a smaller angle sum*. Even more surprising is the fact that the new geometry wipes out a vital concept of Euclidean geometry, that is, that two geometric figures may have the same shape but different sizes. We say, in such a case, that the figures are similar but not congruent. In the new geometry *two similar triangles must also be congruent*. As a final example of a new theorem, we mention this one: *The distance between two parallel lines approaches zero in one direction along the lines and becomes infinite in the other direction.*

Bolyai and Lobatchevsky had succeeded in erecting a new geometry with many surprising theorems. But was their work any more than an exercise in logic? Let us realize, first, that hundreds of deductions in the new geometry had produced no theorems contradicting each other. This meant that the old parallel axiom could not be deduced from the other Euclidean axioms; otherwise the assumption of the new one would surely have led to contradictions within the system. It was not exactly news that the Euclidean parallel axiom could not be deduced from other Euclidean axioms. This fact had been suspected before.

The second implication in the work of Bolyai and Lobatchevsky was not anticipated. It is that we could not hope to establish the incontrovertible truth of the Euclidean parallel axiom by showing that any alternative produced contradictions. It was clear, therefore, that both of the schemes used by earlier mathematicians to vindicate the parallel axiom would never have been successful.

But the greatest significance of the new geometry was completely unexpected. Though the logical exercise was over the conclusion lingered on in people's minds: *There are geometries different from Euclid's.* A mathematician who possessed this knowledge was like a boy with an air rifle in his hands. The temptation to use it was too strong to resist. Euclidean geometry was known to be an accurate description of physical space. The non-Euclidean geometry of Bolyai and Lobatchevsky, on the other hand, did not seem and was not intended to apply to the physical world—but could it?

First reactions to this question are generally negative. If Euclidean geometry is correct, how can this new, conflicting geometry also be correct? Moreover, how can such absurd theorems apply to our familiar world? A little thought indicates that first reactions may be too hasty. What guarantee do we have that Euclidean geometry is correct? True it has been used for thousands of years. It also has the favor of long-established habits of thought. But let us recall Euclid's own reason for being concerned about the parallel axiom. Was it not that it makes an affirmation about regions of space far removed from man's daily experience, a space so vast that the accessible regions are in comparison only a dot on the surface of the Earth?

Who of us knows the geometry of the universe in the vicinity of Mars, or for that matter even ten miles above the surface of the Earth? By what right do we assume that it must be the same as what seems to apply on Earth? Euclidean geometry may be no better than the hundreds of scientific laws that served well enough in their day but ultimately had to be discarded.

After carefully considering just this problem Gauss suggested a criterion for determining the truth of Euclidean geometry. The sum of the angles of a triangle equals 180° in this geometry but is less than 180° in the new geometry. Hence measuring the angles of a triangle should decide which geometry fits the physical world. For two reasons a very large triangle had to be chosen. In the first place, the error in sighting is greater in a smaller triangle. In the second place, it is a theorem of Lobatchevsky's and Bolyai's geometry that the angle sum of a triangle approaches 180° as the triangle shrinks in size. For a small triangle the sum might be so close to 180° that measuring instruments might not be sensitive to the difference.

Gauss, himself, performed the experiment. He stationed an observer on each of three mountain peaks. Each observer measured the angle formed by his lines of sight to the other two observers. The sum of the angles of the triangle turned out to be within 2″ of 180°, so close that the difference could be charged to errors of measurement. Hence the experiment was not decisive.

The provoking aspect of Gauss's triangle test is that even under the best of experimental conditions it could never prove that space is Euclidean, for even if the measured angle sum should be 180° allowance would always have to be made for errors of measurement and hence for the *possibility* that the true sum is less than 180°. Actually the test involved two unwarranted assumptions, either one of which could invalidate a conclusion drawn from it. The first of these was that the triangle formed by three mountain tops is large enough to be decisive. The second assumption was that the light rays which formed the sides of the triangle follow straight lines. The rays may actually curve slightly but imperceptibly.

While Gauss's test can be dismissed as an interesting but inconclusive experiment, the larger question of the applicability of non-Euclidean geometry still deserves attention. The surprising fact that emerges from all attempts to decide which of the two geometries fits physical space is that both fit *equally well.* We have already indicated that in a small triangle the new geometry calls for an angle sum close to 180° and the smaller the triangle the closer must the sum be to 180°. If we applied non-Euclidean geometry and accordingly used angle sums that are slightly less than 180° no harm would be done from the practical standpoint. Similarly, no harm would be done if we assumed that given a point *P* and a line *L* an infinite number of parallels to *L* exist through *P* and in the plane of *P* and *L*.

We might think that the new geometry cannot be applied to the physical world because it asserts that similar triangles must be congruent. It certainly seems possible to construct two physical triangles that are similar but not congruent. In fact, one triangle could be made very large and the other very small. No matter how carefully the two triangles are constructed, however, we cannot be sure they really are similar—that is, that corresponding angles are exactly equal. The smaller triangle could have a larger angle sum, in accordance with the new, non-Euclidean geometry, but the difference might not be measurable. Hence for all practical purposes it would not matter whether we accepted the assertion of the new geometry. In other words, there is no way of deciding which geometry applies to physical space; either one could be used. Our prejudices and habits favor Euclidean geometry, which may also be somewhat simpler than the non-Euclidean geometry. But these reasons for preferring it do not discredit the applicability of the new geometry.

No doubt the reader is not satisfied. Perhaps he can be diverted with other, more pleasant arguments which show that non-Euclidean geometry can be applied to the physical world.

Let us return for a moment to Euclidean geometry. Imagine an enormous sheet of paper extending indefinitely in all directions. This sheet of paper is a physical illustration of the mathematical plane, the plane in which the theorems of Euclid's geometry hold. Now suppose we alter the shape of this vast sheet of paper by bending the left and right sides upward somewhat (fig. 80) so that it forms a curved surface, which, however, continues to extend indefinitely in all directions as did the plane. Such a surface is known as a cylindrical surface. As a result of the change in shape, most straight lines of the former plane become curves which, like the straight lines in the plane, are the shortest paths between the points they join on the surface. We shall call such curves *geodesics*. Two straight lines that were parallel in the plane become parallel geodesics, that is geodesics which do not meet on the surface. Triangles of the original plane become figures formed by arcs of geodesics on the surface. We shall call the new figures 'triangles' also. Circles on the plane give rise to figures we shall call 'circles.'

We come now to a very startling fact. Every axiom of Euclidean geometry holds for the figures on the cylindrical surface with the one provision—that we interpret the words line, triangle, and circle as

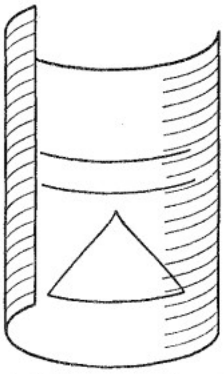

Figure 80. A new pictorial interpretation of Euclidean geometry

just suggested above. Hence *the theorems of Euclidean geometry, which follow from the axioms by deductive reasoning, a process completely independent of the pictures we may draw, also hold for figures on the curved surface.* To take one instance, the sum of the angles of a 'triangle' on the surface is 180°.

The reader may object to the argument above on the ground that straight lines and figures defined in terms of straight lines no longer have the proper meaning; they have lost their straightness. Now, however, we take advantage of a fact first pointed out in Chapter IV, namely, that the basic concepts of geometry such as point and line are undefined. We use only the properties of these concepts that are explicitly stated in the axioms. Hence if some new physical picture of line, say, has the properties required by the axioms, it is possible to adopt this new picture. Therefore it is logically justifiable to associate a completely new physical picture with all of Euclidean geometry.

The argument just made for the new physical interpretation of Euclidean geometry applies as well to non-Euclidean geometry. And if we do take advantage of our liberty to choose the physical interpretation of the line and other figures we obtain an intuitively acceptable interpretation of the new geometry.

Figure 81 illustrates a surface known as a *pseudosphere*. The curves on the pseudosphere which are the shortest paths between points on the surface—these special curves are also called geodesics—have the properties that straight lines possess in the axioms of Lobatchevsky and Bolyai. For example, the axiom that two points determine one and only one straight line applies to these geodesics. Two points on the pseudosphere (C and D in fig. 81) determine one and only one geodesic, or shortest path, between them. In like manner, the parallel axiom of Lobatchevsky and Bolyai, which says that through a point P not on a line L there is an infinite number of lines that do not meet L, applies to the geodesics on the pseudosphere.

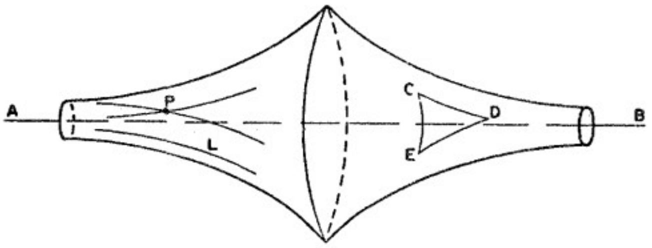

Figure 81. Pictorial interpretation of Lobatchevsky's and Bolyai's non-Euclidean geometry

Because the axioms of Lobatchevsky and Bolyai fit the geodesics on the pseudosphere, the theorems, as logical consequences of the axioms, must also apply. Thus the theorem that the sum of the angles of a triangle is less than 180° holds for triangle CDE formed by the arcs of geodesics. We have therefore obtained a visualization of the non-Euclidean geometry at the cost merely of a slight and justifiable change in the picture of the straight line.

Having made 'sense' of the new geometry let us return to our original question. Can the new geometry be descriptive of the physical world in which we live? The answer, as the reader may have anticipated, is that the geometry of physical space depends on the physical meaning we attach to the concept of straight lines. Experience tells us that if straight line is taken to be a stretched string, Euclidean geometry applies very well. It is neither necessary nor desirable, however, to allow straight line to mean a stretched string in all physical applications. Let us consider for a moment people who live in mountainous country and who are interested in the geometry of the surface of their country. The most useful physical interpretation of the straight line for them is the geodesic, that is, the curve of shortest distance between two points. The first surprising fact about these 'straight lines' is that they change shape from one part of the country to another, depending on the shapes of the hills and valleys. What axioms do these 'straight lines' obey? Almost surely not the Euclidean ones. For example, the topography of the area may be such that there are several shortest paths between some pairs of points. There may be many geodesics through a given point that do not meet a particular geodesic; and so forth.

In astronomical measurements, too, the stretched string is not the practical interpretation of the straight line. Here the light ray must serve instead. And what geometry fits best when light rays are used as straight lines? We shall leave this question with the reader until the next chapter. Meanwhile, we had better return to the mathematical account of non-Euclidean geometry. There are more mathematical worlds to be examined.

Lobatchevsky and Bolyai concentrated on Euclid's parallel axiom but accepted the other axiom in Euclid that is almost as questionable, namely, the axiom that says a line segment can be extended indefinitely in either direction. Here, too, is an axiom purporting to describe what happens in space trillions of miles from our Earth. How can we be sure of its truth, that is, its applicability to the physical world?

Not long after the work of Bolyai and Lobatchevsky on the concept of parallelism, the piercing glances of mathematicians lighted on the infiniteness of the straight line and sought to determine the wisdom of this axiom. The sickly, precocious Bernhard Riemann (1826-66), who had to beg his father, a German Lutheran pastor, for permission to abandon his training for the ministry so that he might study mathematics, undertook to pursue possible alternatives to this axiom.

One of his novel thoughts was that we must distinguish between endlessness and infiniteness. For example, the equator on the Earth is endless but finite. In view of this distinction Riemann proposed an alternative to Euclid's axiom on the infiniteness of the straight line, namely, the axiom that all lines are finite in length but endless.

This thought was then followed by reflections on the parallel axiom similar to those of Lobatchevsky and Bolyai but leading in this case to a different conclusion. As *R* moves to the left along *L* (fig. 82) and as *Q* moves to the right, both points must ultimately meet, for Riemann supposed the line *L* to be finite. The line *PR* will, as a result, rotate around *P* into *PQ* without ever losing contact with *L*. That is, there should be *no* line through *P* parallel to *L*. Figure 82 does not tell us how this complete rotation of *PR* about *P* is possible with our usual conception of the straight line, but the drawing is not intended to do more than suggest Riemann's thought. These reflections suggested to Riemann that he adopt along with the finiteness of the straight line an axiom to the effect that there are no parallel lines.

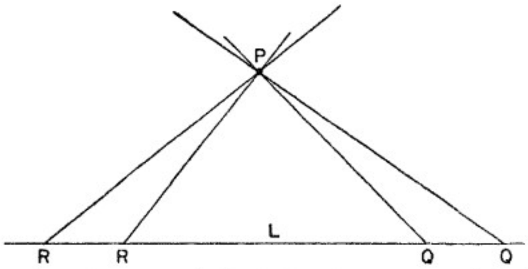

Figure 82. The geometrical basis for Riemann's parallel axiom

As if two radical departures from Euclid were not enough, Riemann proposed a third one: instead of requiring that two points determine one and only one line, Riemann adopted the axiom that two points may determine more than one line.

Before proceeding we remind the reader that these axioms are to be accepted for the moment purely as the basis for a logical development of a new geometry. The relation between this rather arbitrary system and the real world will be considered later.

The geometry of Riemann, like that of Lobatchevsky and Bolyai, has some theorems in common with those of Euclid. The theorem that vertical angles are equal and the theorem that angles opposite equal sides of a triangle are also equal hold in all three geometries, because these theorems depend only on axioms that are common to the three geometries.

Some of the theorems in Riemann's geometry that differ from Euclid's are striking. For example: *All the perpendiculars to a straight line meet in a point* (fig. 83). Another fact in this strange new world is that *two straight lines enclose an area* (fig. 84). As in the geometry of Lobatchevsky and Bolyai we find that *triangles which are similar are also congruent.* Two other theorems might almost be anticipated. The first states that *the sum of the angles of any triangle is greater than 180°.* The second states that *of two triangles the one with larger area has the greater angle sum.*

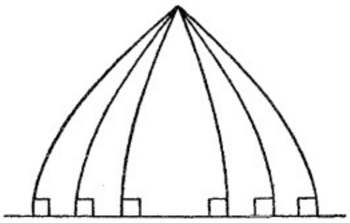

Figure 83. All the perpendiculars to a line meet in one point

Figure 84. Two straight lines enclose an area

We may now raise the same question that we raised with regard to the geometry of Lobatchevsky and Bolyai. Has Riemannian geometry any possible significance beyond that of an intellectual exercise for the mathematicians? Here again the answer is yes. It is possible to apply Riemann's geometry to the physical world with the usual understanding of straight line and never detect any differences between the assertions of the geometry and the physical situation. The argument here is precisely the one that was made in connection with the geometry of Lobatchevsky and Bolyai.

Moreover, by changing the picture of the straight line we may find other, intuitively satisfying interpretations of Riemann's geometry. Just as we were able to picture Euclidean geometry on a cylindrical surface and Lobatchevsky's and Bolyai's geometry on a pseudosphere, so we may picture Riemann's geometry on the familiar sphere. The curve that connects two points on a sphere by the shortest route—that is, the curve that will be our picture of the straight line—is the arc of the great circle through the two points. By a great circle we mean one whose center is also the center of the sphere. Thus of the two circles through *A* and *B* (fig. 85), the circle *ABCDE* is the great circle whereas the circle *ABFGH* is not.

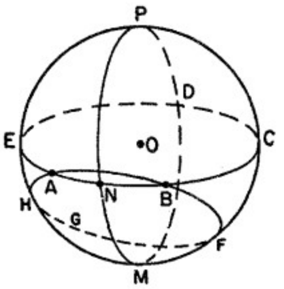

Figure 85. A pictorial interpretation of Riemann's geometry

Let us see whether the axioms of Riemann's geometry apply to the sphere, provided we interpret straight line of the axioms to mean great circle on the sphere. In the first place, great circles are endless and finite in length. Second, there are no parallel lines on the sphere, for any two great circles meet. In fact, they meet not once but twice. For example, the great circles *ABCDE* and *MNPD* meet at *N* and *D*. The axiom that two points may determine more than one line is also fulfilled on the sphere. Two points such as *N* and *D* in figure 85 have more than one great circle through them, while through two points such as *A* and *B* only one great circle passes.

Since the axioms of Riemann's geometry correctly describe facts about the sphere, the theorems, which are derived by valid deductive reasoning, must also be true on the sphere. Let us check a few. One theorem states that all the perpendiculars to a straight line meet in a point. Taking the great circle *L* of figure 86 as our straight line, we find that all the perpendiculars to *L* meet at *P*. If, for example, *L* were the equator on the Earth, *P* would be the North or South Pole.

Another theorem states that the sum of the angles of a triangle is greater than 180°. Since the straight lines of our axioms are great circles, a triangle is the figure formed by arcs of great circles. Such a triangle is illustrated by *ABP* in figure 86. Since two of the angles of this triangle are right angles, the sum of the three angles is necessarily greater than 180°. This fact is true of every 'triangle' on a sphere.

It is not necessary to labor an already obvious point. *Every theorem of Riemann's geometry can be interpreted on the sphere merely by thinking of the straight lines in the theorems as great circles on the sphere.* Hence we can give geometrical and intuitively satisfying meaning to Riemann's geometry. More than that, this geometry supplies exact answers to practical and scientific problems involving geometrical relationships *on the surface* of the sphere. Hence it is, certainly to that extent, a geometry of the physical world. In fact, every argument for the theory that our physical world could be non-Euclidean in the sense of Lobatchevsky's and Bolyai's geometry applies equally well to Riemann's geometry. The applicability of non-Euclidean geometries to the world in which we live will be discussed further under the subject of relativity.

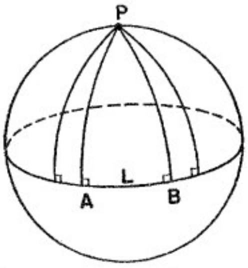

Figure 86. All the perpendiculars to a great circle on a sphere meet in one point

In retrospect, the history of the creation of non-Euclidean geometries is the history of the blindness of human beings, great and small. Man lives on the surface of the Earth. Suppose he were to set about constructing a geometry to fit *this surface directly* instead of regarding it as a special surface in the three-dimensional Euclidean world. What kind of geometry would he develop? The 'line' in this geometry for the surface of a sphere should obviously be the curve that joins any two points by the shortest route, for this curve would be the most useful. This curve, as we have seen, is the great circle joining the points. On the other hand, the straight line in the familiar sense of Euclidean geometry would certainly not be chosen as the basic curve, for it does not even exist *on* the surface of a sphere.

What axioms would a geometer choose for his great circles? Why, none other than those Riemann selected, a system of axioms in which no parallel lines exist and in which the line is finite in length. In other words, the natural geometry, the practical geometry, the common-sense geometry for us earth-bound mortals is Riemannian geometry.

For thousands of years this geometry has been right under the feet of man. Yet during all those years the greatest mathematicians never once sought to test their attack on the parallel axiom by checking with the geometry of the sphere. And as a climax to these thousands of years the great Kant built his profound philosophy on the incontrovertible truth of Euclidean geometry, indeed on the impossibility of conceiving of any other geometry. Yet all this time he was living *on*, if not in, a non-Euclidean world.

How is it, then, that though geometry arose from measurements made on the Earth, Euclidean geometry was developed first? The answer is that to human beings living in a very limited region, the Earth does indeed appear flat, and the shortest distance on a flat surface is indeed the straight line in the commonly accepted sense of the term. With this stretched-string picture of the line the axioms and theorems of Euclidean geometry followed naturally. Once the geometry of flat surfaces was developed, the sphere had to be introduced within the framework of Euclidean geometry. No one, not even the Greeks, who were especially fond of the sphere, thought to approach the geometry of the sphere through a set of axioms designed to fit such a surface directly. This history shows that men are ruled as much by habits of thought as by physical habits, social customs, and conventions. Surely the unsuccessful precursors of Lobatchevsky and Bolyai did not lack technical skill or the ability to master difficult mathematics. They failed to solve the problem of the parallel axiom only because they were unable to break a habit of thought—Euclidean geometry. The history of this mental inertia is an excellent example of what Lecky, in his *History of Rationalism in Europe*, has described as that spirit, that *Zeitgeist* of an age, which predisposes people to points of view or beliefs independent of arguments for or against. So it was with Kant and all the mathematicians up to 1800. The belief in the truth, the unassailableness, the uniqueness of Euclidean geometry precluded anyone from even considering the possibility of another geometry, even though a non-Euclidean geometry lay right before them.

The importance of non-Euclidean geometry in the general history of thought cannot be exaggerated. Like Copernicus' heliocentric theory, Newton's law of gravitation, and Darwin's theory of evolution, non-Euclidean geometry has radically affected science, philosophy, and religion. It is fair to say that no more cataclysmic event has ever taken place in the history of all thought.

First, the creation of non-Euclidean geometry brought into clear light a distinction that had always been implicit but never recognized—the distinction between a mathematical space and physical space. The original identification of the two was due to a misunderstanding. Fleeting visitors to our minds, sensations of sight and touch, suggested that the axioms of Euclidean geometry were true of physical space. The theorems deduced from these axioms were checked with further sensations of sight and touch and, behold, they checked perfectly—at least as far as these sensations could reveal. Euclidean geometry was therefore held to be an exact description of physical space. This habit of thought became so well established over hundreds of years that the very notion of a new geometry failed to make sense. Geometry meant the geometry of physical space and that geometry was Euclid's. With the creation of non-Euclidean geometry, however, mathematicians, scientists, and laymen were ultimately compelled to appreciate the fact that *systems of thought based on statements about physical space are different from that physical space.*

This distinction is vital to an understanding of the developments in mathematics and science since 1880. We must say now that a mathematical space takes on the nature of a scientific theory. It is applied to the study of physical space as long as it fits the facts of experience and serves the needs of science. However, if one mathematical space can be replaced by another in closer agreement with the expanding results of scientific work, then it will be replaced just as the Ptolemaic theory of the motion of the heavenly bodies was replaced by the Copernican theory. Nor should the reader be surprised if he discovers that this possibility has materialized by the time he reaches the next chapter.

We should regard any theory about physical space, then, as a purely subjective construction and not impute to it objective reality. Man constructs a geometry, Euclidean or non-Euclidean, and decides to view space in those terms. The advantages in doing so, even though he cannot be sure space possesses any of the characteristics of the structure he has built up in his own mind, are that he can then think about space and use his theory in scientific work. This view of space and of nature generally does not deny that there is such a thing as an objective physical world. It merely recognizes the fact that man's judgments and conclusions about space are purely of his own making.

The creation of non-Euclidean geometry cut a devastating swath through the realm of truth. Like religion in ancient societies mathematics occupied a revered and unchallenged position in Western thought. In the temple of mathematics reposed all truth, and Euclid was its high priest. But the cult, its high priest, and all its attendants were stripped of divine sanction by the work of the unholy three: Bolyai, Lobatchevsky, and Riemann. It is true that in undertaking their research these audacious intellects had in mind only the logical problem of investigating the consequences of a new parallel axiom. It certainly did not occur to them at the outset that they were challenging Truth itself. And as long as their work was regarded merely as an ingenious bit of mathematical hocus-pocus, no serious questions were raised. The moment men realized, however, that the non-Euclidean geometries could be valid descriptions of physical space, an inescapable problem presented itself. How could mathematics, which had always claimed to present the truth about quantity and space, now offer several contradictory geometries? No more than one of these could be the truth. Indeed, and even more disturbing, perhaps the truth was different from all these geometries. The creation of the new geometries, therefore, forced recognition of the fact that there could be an 'if' about all mathematical axioms. *If* the axioms of Euclidean geometry are truths about the physical world then the theorems are. But, unfortunately, we cannot decide on *a priori* grounds that the axioms of Euclid, or of any other geometry, are truths.

In depriving mathematics of its status as a collection of truths, the creation of non-Euclidean geometries robbed man of his most re-calculation suggests a general statement, namely, that the sum of the first n odd numbers, where n is any positive integer, is the square of n. Of course this possible theorem is not proved by the calculations above. Nor could it ever be proved by such calculations, for no mortal man could make the infinite set of calculations that would be required to establish the conclusion for *every* n. The calculations do, however, give the mathematician something to work on.

Consider another instance of generalization as a source of suggestions for theorems. A triangle is a polygon of three sides. Now in Euclidean geometry the sum of the angles of a triangle is 180°. Is it not natural to ask whether any general theorem could be found about the sum of the angles of any polygon? This question is answered by a very old theorem. The sum of the angles of any polygon is found by subtracting two from the number of sides and then multiplying the result by 180°.

We have already seen how the purely logical problem of deducing the assertion contained in Euclid's parallel axiom from more acceptable axioms led to non-Euclidean geometry. Once the idea of such geometries was grasped numerous suggestions for theorems were obtained by seeking the analogues of theorems that held in Euclidean geometry. For example, what is the analogue of the theorem that the sum of the angles of a quadrilateral is 360°?

These few indications of how the mathematician secures suggestions for theorems do not tell the whole story. Even if we add the more fortuitous sources such as pure chance, guesswork, and blundering about until a theorem is found, we still have left out the most valuable source of possible theorems—the imagination, intuition, and insight of creative genius. Most people could look at a quadrilateral indefinitely without becoming aware that if the midpoints of the four sides are joined (fig. 88), the figure formed is a parallelogram. Such knowledge is not the product of logic but of a sudden flash of insight.

In the domains of algebra, calculus, and advanced analysis especially, the first-rate mathematician depends on the kind of inspiration that we usually associate with the composer of music. The composer feels that he has a theme, a phrase which, when properly developed and embroidered, will produce beautiful music. Experience and a knowledge of music aid him in developing it. Similarly the mathematician divines that he has a conclusion which will follow from the

Some of the axioms of Euclidean geometry are that two points determine a line, all right angles are equal, and the axiom on parallel lines. The non-Euclidean geometry of Gauss, Lobatchevsky, and Bolyai contains the same axioms as Euclidean geometry does, except for the parallel axiom. From the concepts and axioms, theorems are deduced. Hence, from the standpoint of structure, the concepts, axioms, and theorems are the essential components. We shall discuss these in turn.

The basic concepts of the elementary branches of mathematics are abstractions from experience. Whole numbers and fractions were certainly suggested by obvious physical counterparts. But it is noteworthy that many more concepts are introduced which are, in essence, creations of the human mind with or without partial help from experience. Irrational numbers, such as $\sqrt{2}$, were forced upon mathematicians to represent all the lengths occurring in Euclidean geometry, for example, the length of the hypotenuse of a right triangle whose arms are both one unit long. The notion of a negative number, though perhaps suggested by the need to distinguish debits from credits, is nevertheless not wholly derived from experience, for the mind had to conceive of the notion of an entirely new type of number to which operations such as addition, multiplication, and the like can be applied. The notion of a variable to represent the quantitative values of some changing physical phenomenon, such as temperature or time, is also at least one mental step beyond the mere observation of change. The concept of a function, or a relationship between variables, is almost entirely a mental creation. The farther one proceeds with the mathematics of number, the more remote from experience are the concepts introduced and the larger is the creative role played by the mind. The derivative of a function, for example, the instantaneous rate of change of distance compared with time, is a wholly man-made and, one might also say, an ingenious construction. We do not experience instants or instantaneous velocities but, rather, small intervals of time and speeds over small intervals of time.

The gradual introduction of new concepts which more and more depart from forms of experience finds its parallel in geometry. Though point, line, triangle, circle, and a few other elementary concepts are no more than abstractions from experience, this is not true of most of the curves which geometry considers. The approach to the conic sections as sections of a cone made by a plane or by the locus definitions (Chapter 6) subsequently used to define parabola, ellipse, and hyperbola was conceived by the mind. The notions of projection and section of projective geometry and many of the specific concepts of projective geometry such as cross ratio are entirely mental creations.

This brief review of the origin of mathematical concepts may serve to emphasize several major facts. The first of these is growth. As mathematicians continue to work in any given branch, they discover new concepts which are worth introducing and developing. Secondly, as their work advances, the new concepts are less and less drawn from experience and more and more from the recesses of human minds. Moreover, the development of concepts is progressive, later concepts being built on earlier ones. These facts have unfortunate consequences. Because the more advanced ideas are purely mental creations rather than abstractions from immediate experience and because they are defined in terms of prior concepts, it is more difficult to comprehend them. At least, one cannot usually find simple and familiar physical pictures or experiences to illustrate their meanings.

Axioms constitute the second major component of any branch of mathematics. The axioms of the mathematics of number and of Euclidean geometry were suggested by experience. Up to the introduction of non-Euclidean geometry, the idea that man chose axioms suggested by experience would have been regarded as absurd. Axioms were understood to be basic, self-evident truths about the concepts involved. While minor variations in the choice and wording were tolerated, the universal belief was that man had to accept what was clearly true. These truths were supposed to be written into the universe and were considered to be inescapable. Some philosophers, such as Plato and Descartes, believed that these truths were already planted in our minds by God. We know now that this view must be discarded. The seemingly self-evident nature of the axioms of the mathematics of number and of Euclidean geometry is really the consequence of limited experience and relatively superficial observation. In the simpler uses of numbers and in the limited regions of the universe accessible to man until recent times, the well-known axioms of number and Euclidean geometry seemed inescapably true. But we can choose other axioms and produce other geometries and even other number systems. Though we can make arbitrary choices, we do not do so because we wish our new axioms to yield systems of mathematics as significant and as useful as the older systems. Were we able to continue our study of mathematics proper, we would find that there are many other systems of axioms which lead to important branches of mathematics.

The fruit of mathematical activity consists of the theorems deduced from a set of axioms. The theorems offer new knowledge by no means immediately discernible in the axioms. Whether or not the reader may prize the knowledge, he learns by pursuing the implications of the Euclidean axioms that the sum of the angles of a triangle is 180° and that the area of a circle is π times the square of the radius. The amount of information that can be deduced from some sets of axioms is almost incredible. Euclid deduced about 500 theorems from his set. The axioms of number give rise to the results of algebra, properties of functions, the theorems of the calculus, the solutions of various types of differential equations, and many other results we have not surveyed.

Mathematical theorems, as we know, must be deductively established. Since observation, measurement, induction, and a variety of other methods of obtaining knowledge are available and are used in all other scientific pursuits, trying to replace Euclid's parallel axiom by a more acceptable one, that is, one which did not involve any assertion about what must happen far off in space. But he did not succeed. He also appreciated at the age of 15, as he told his friend Schumacher, that one could not hope to prove an assertion about parallel lines on the basis of the other nine axioms. That is, he realized that these nine axioms did not in themselves dictate the form of the parallel axiom. Gauss was too brilliant a man to overlook the implication of this fact. If there was some freedom in the choice of a parallel axiom, then one might choose an axiom different from Euclid's and build a new kind of geometry. Gauss did just this. He pursued the logical implications of a system of axioms which included the assumption that *more than one* parallel to a given line passed through a given point, and thus created non-Euclidean geometry. (Gauss himself finally adopted the term non-Euclidean after having called his system anti-Euclidean geometry, and later astral geometry.)

Though Gauss realized that such a geometry could conceivably apply to physical space and hence was indeed significant, he did not publish his results. Gauss was far ahead of his times in concluding that Euclidean geometry was not necessarily the correct description of physical space and that some non-Euclidean geometry might prove as accurate. Hence he feared that he would be laughed at. In a letter written in 1829 to his friend, the mathematician Friedrich Wilhelm Bessel, Gauss confessed that he feared the clamor of the Boeotians, a figurative reference to the dull-witted, for the Boeotians had been one of the more simple-minded Greek tribes. Gauss's work on non-Euclidean geometry was found among his papers after his death in 1855.

The men who usually receive credit for creating non-Euclidean geometry because they published their results are Nicholas I. Lobachevsky (1793–1856) and John Bolyai (1802–1860). Lobachevsky, born to a poor family and displaying brightness even as a youngster, attended the University of Kazan in Russia. One of his teachers was the German mathematician J. M. C. Bartels, a friend of Gauss, and it is very likely that the problem of the parallel axiom was called to Lobachevsky's attention by Bartels. Lobachevsky became a professor at Kazan at the age of 23 and continued to work on the problem. By 1823 he realized that there can be other geometries and that Euclidean geometry need not be the correct description of physical space. He said later that two thousand years of fruitless attempts to put the parallel axiom on an unquestionable basis had led him to suspect that it could not be done. From 1829 on Lobachevsky published books and papers in which he expounded the theorems that hold in his non-Euclidean geometry. Despite valuable services to mathematics, his university, and the Russian government, he was dismissed in 1846, but continued to work in his field until his death.

Bolyai, a Hungarian, was an Austrian army officer. He learned mathematics from his father, Wolfgang Bolyai, who set his son thinking about the parallel axiom. In 1823 John arrived at the same conclusion that had been

for instance, the *Fundamental Lemma of Riemannian Geometry,* pertaining here to the *existence of* an *$\mathcal{A}$-connection compatible with a* given *Riemannian $\mathcal{A}$-metric,* for every *Riemannian vector sheaf,* when the corresponding *differential triad,* as in (i) above, is *suitably adapted* to the present (riemannian) framework.

On the other hand, by contrast with the previous situation, concerning the existence of an $\mathcal{A}$-connection, one realizes that, *given an $\mathcal{A}$-connection, we can always associate with it* what we might consider here as the analogue of the classical notion of *curvature.* Thus, the study of this concept, together with the deduction of several standard results, within the present axiomatic framework, connected with the latter notion, constitute the subject matter of Chapter VIII. In this concern, we further note that, in order to formulate the same notion, one has to supplement the initially given differential triad, as in (i) above, with what we call a *curvature datum*

$$(viii) \qquad (\mathcal{A}, \partial, \Omega^1, d, \Omega^2).$$

Thus, in effect, by another *"differential operator"*

$$(ix) \qquad d \equiv d^1 : \Omega \equiv \Omega^1 \longrightarrow \Omega^2 \equiv \wedge^2\Omega^1,$$

satisfying the appropriate *compatibility conditions,* with respect to ∂. We also speak then of a *curvature space* X. So the curvature of a given $\mathcal{A}$-connection D is now defined by the formula

$$(x) \qquad R(D) \equiv D^1 \circ D,$$

where D^1 is the *1st prolongation of* D, by analogy with the classical case, the previous operator $d^1 \equiv d$ being thus the *1st prolongation of* ∂. So one of the compatibility conditions between d and ∂, referred to above, is the assumption that

$$(xi) \qquad R(\partial) \equiv d^1 \circ \partial \equiv d \circ \partial = 0,$$

that is, the *flatness of the* given *$\mathcal{A}$-connection* ∂ of $\mathcal{A}$ (in the strict sense of the word, or else that the *curvature of* ∂ is *zero*). We also examine *flat $\mathcal{A}$-connections,* in general, in the sense that the corresponding curvature, as in (x) above, vanishes. The notion of *flatness* is further related with the analogues here of other classical concepts, as, for example, with those of *complete parallelism, integrability* and *triviality* of the corresponding $\mathcal{A}$-connections; yet, with the *flatness of* a given *vector sheaf* E, relative to the so-called *co-*

Le origini della geometria proiettiva

> Devo confessare apertamente che non ho mai avuto gusto per lo studio e per la ricerca né in geometria né in fisica se non in quanto esse potevano servirmi come mezzi per arrivare a una qualche sorta di conoscenza delle cause prossime... per il bene e la comodità della vita, nel mantenere la salute, nella pratica di qualche arte... avendo osservato che buona parte delle arti si basa sulla geometria, come fra le altre il taglio delle pietre in architettura, l'arte delle meridiane e in particolare l'arte della prospettiva.
>
> GIRARD DESARGUES

1. *La rinascita della geometria.*

In geometria il risorgere di un'attività creativa significativa venne in ritardo rispetto all'algebra. A parte la creazione del sistema matematico della prospettiva e le ricerche geometriche incidentali degli artisti rinascimentali (cfr. cap. XII, § 2), pochissimi risultati degni di nota vennero ottenuti in geometria dai tempi di Pappo fino al 1600 circa. Un certo interesse fu suscitato dalla pubblicazione di numerose edizioni a stampa delle *Sezioni coniche* di Apollonio, in particolare della notevole traduzione latina dei libri I-IV di Federigo Commandino (1509-75) apparsa nel 1566. Altri tradussero i libri V-VII e un certo numero di studiosi, compresi Vieta, Willebrord Snell (1580-1626) e Ghetaldi, intrapresero il lavoro di ricostruzione dell'ottavo libro che era andato perduto.

Quelli che erano necessari, e che in effetti si presentarono, per dirigere le menti dei matematici entro nuovi canali erano dei problemi nuovi. Uno di questi era già stato sollevato da Alberti: quali proprietà geometriche hanno in comune due sezioni della stessa proiezione di una figura reale? Un gran numero di problemi venne dalla scienza e dalle necessità pratiche. L'uso fatto da Kepler delle sezioni coniche nella sua opera del 1609 diede un enorme impulso al riesame di queste curve e alla ricerca di loro proprietà utili per l'astronomia. L'ottica, che aveva destato l'interesse dei matematici fin dai tempi dei Greci, ricevette un'attenzione molto piú viva dopo l'invenzione del telescopio e del microscopio avvenuta all'inizio del Seicento. La progettazione delle lenti di questi strumenti divenne un problema fondamentale; esso implicava un aumento d'interesse per le forme delle superfici o, poiché si trattava di superfici di rotazione, per le curve che le generano. Le esplorazioni geografiche avevano creato un gran bisogno di carte e un interesse per lo studio delle rotte delle navi quali sono rappresentate sulla sfera e sulla carta. L'introduzione del concetto del moto della Terra richiedeva nuovi principî di meccanica che dessero conto delle traiettorie degli oggetti mobili e anche questo implicava lo studio di curve. Fra gli oggetti mobili i proiettili diventarono sempre piú importanti perché i cannoni potevano ora lanciare le loro palle a centinaia di metri di distanza ed era vitale essere in grado di predirne la traiettoria e la gittata. Il problema pratico del calcolo delle aree e dei volumi incominciò ad attrarre un'attenzione sempre maggiore. La *Nova stereometria doliorum vinariorum* (1615) di Kepler diede inizio a una nuova esplosione di attività in questo campo.

Un altro tipo di problemi si presentò come conseguenza dell'assimilazione delle opere greche. I matematici cominciarono a rendersi conto che i metodi di dimostrazione greci mancavano di generalità, in quanto bisognava escogitare un metodo speciale quasi per ogni problema. Questa osservazione era stata fatta da Agrippa di Nettesheim (1486-1532) fin dal 1527, e da Maurolico, che aveva tradotto delle opere greche e aveva scritto libri sulle sezioni coniche e su altri argomenti matematici.

Molte delle risposte date ai nuovi problemi si ridussero a variazioni minime su vecchi temi. Venne cambiato l'approccio alle sezioni coniche. Le curve erano definite fin dall'inizio come luoghi piani invece che come sezioni di un cono, come avveniva in Apollonio. Guidobaldo Del Monte, ad esempio, nel 1579 definí l'ellisse come il luogo dei punti tali che la somma delle loro distanze dai fuochi sia costante. Vennero ristudiate non soltanto le coniche ma anche altre antiche curve greche quali la concoide di Nicomede, la cissoide di Diocle, la spirale di Archimede e la quadratrice di Ippia. Vennero anche introdotte nuove curve, in particolare la cicloide (cfr. cap. XVII, § 2). Mentre tutte queste ricerche risultarono utili per diffondere i contributi greci, nessuna di esse forní nuovi teoremi o nuovi metodi di dimostrazione. La prima innovazione portatrice di importanti conseguenze venne in risposta ai problemi sollevati dai pittori.

2. *I problemi sollevati dalle ricerche sulla prospettiva.*

L'idea fondamentale nel sistema di prospettiva focale creato dai pittori è il principio di proiezione e sezione (cfr. cap. XII, § 1). Una scena

La geometria non euclidea

> … poiché sembra essere vero che molte cose hanno, per cosí dire, un'epoca in cui vengono scoperte simultaneamente in molti luoghi, proprio come le viole sbocciano da tutte le parti in primavera.
>
> WOLFGANG BOLYAI

> Il carattere di necessità ascritto alle verità matematiche e anche la peculiare certezza ad esse attribuita sono un'illusione.
>
> JOHN STUART MILL

1. *Introduzione.*

Fra tutte le creazioni tecnicamente complesse della matematica dell'Ottocento, la piú profonda, la geometria non euclidea, fu anche la piú semplice dal punto di vista tecnico. Questa creazione diede origine a nuove importanti branche della matematica, ma la sua conseguenza piú significativa sta nel fatto che obbligò i matematici a rivedere radicalmente le loro idee sulla natura della matematica e sui suoi rapporti con il mondo fisico. Essa diede anche origine a problemi nei fondamenti della matematica con i quali sta ancora lottando il xx secolo. Come vedremo, la geometria non euclidea fu il culmine di una lunga serie di sforzi nel campo della geometria euclidea. I frutti di questo lavoro furono colti all'inizio del xix secolo, nel corso degli stessi decenni in cui rinasceva e si estendeva la geometria proiettiva. Tuttavia, le due discipline non erano in quel momento collegate.

2. *Lo stato della geometria euclidea intorno al 1800.*

Nonostante i Greci avessero riconosciuto che lo spazio matematico astratto è distinto dalle percezioni sensoriali dello spazio e Newton avesse sottolineato questo punto[1], tutti i matematici fino al 1800 circa erano convinti che la geometria euclidea fosse l'idealizzazione corretta delle proprietà dello spazio fisico e delle figure di questo spazio. In effetti, come abbiamo già notato, vi furono molti tentativi per costruire l'aritmetica, l'algebra e l'analisi, la cui fondazione logica era oscura, sulla geometria euclidea, garantendo cosí anche la verità di queste discipline.

---

[1] I. NEWTON, *Principia*, libro I, def. 8, scolio.

Molti matematici proclamarono ad alta voce la loro fiducia nella verità della geometria euclidea. Isaac Barrow, ad esempio, che costruí la sua matematica, compreso il calcolo infinitesimale, sulla geometria, elenca otto ragioni in favore della certezza della geometria: la chiarezza dei concetti, le definizioni non ambigue, la sicurezza intuitiva e la verità universale degli assiomi, la chiara possibilità e la facile immaginabilità dei suoi postulati, il piccolo numero dei suoi assiomi, la chiara concepibilità del modo in cui sono generate le grandezze, il facile ordine delle dimostrazioni e l'assenza di cose non note.

Barrow si chiese: come possiamo essere sicuri che i principî geometrici si applicano alla natura? La sua risposta fu che essi sono derivati dalla ragione innata e gli oggetti sensibili sono dei semplici agenti che li risvegliano in noi. Inoltre, i principî della geometria erano stati confermati costantemente dall'esperienza e avrebbero continuato ad esserlo perché il mondo, progettato da Dio, è immutabile. La geometria è quindi la scienza perfetta e certa.

È degno di nota il fatto che i filosofi della fine del Seicento e del Settecento sollevarono pure il problema di come si potesse essere certi che il corpo di conoscenze piú ampio prodotto dalla scienza newtoniana fosse vero. Quasi tutti, e in particolare Hobbes, Locke e Leibniz, risposero che le leggi matematiche, come la geometria euclidea, erano inerenti al disegno dell'universo. Leibniz lasciò qualche spazio al dubbio quando tracciò la distinzione fra mondi attuali e mondi possibili, ma l'unica eccezione significativa fu David Hume, che nel *Treatise of Human Nature* (1739) negò l'esistenza di leggi o di successioni necessarie di eventi nell'universo, sostenendo che dall'osservazione di queste successioni gli esseri umani erano indotti a concludere che esse si sarebbero sempre ripetute nello stesso modo. La scienza è quindi puramente empirica. In particolare, le leggi della geometria euclidea non sono verità fisiche necessarie.

L'influenza di Hume fu controbattuta e in effetti soppiantata da Immanuel Kant. La risposta data da Kant, nella *Critica della ragion pura* (1781), al problema di come si può essere sicuri che la geometria euclidea si applica al mondo fisico è molto originale. Egli sosteneva che le nostre menti forniscono certi modi di organizzazione (che chiamava intuizioni) dello spazio e del tempo e che l'esperienza viene assorbita e organizzata dalle nostre menti in accordo con queste intuizioni. Le nostre menti sono costruite in modo tale da obbligarci a vedere il mondo esterno in un unico modo. Di conseguenza, certi principî concernenti lo spazio sono anteriori all'esperienza; questi principî e le loro conseguenze logiche, che Kant chiamava giudizi sintetici a priori, sono quelli della geometria euclidea. La natura del mondo esterno ci è nota soltanto nella maniera in cui le nostre menti ci obbligano a interpretarla. Sulle basi ora descritte, Kant affermava, e i suoi contemporanei lo accettarono, che il mondo fisico deve essere euclideo. In ogni caso, sia che si facesse appello all'esperienza basata sulle verità innate, sia che si accettasse l'opinione di Kant, la conclusione comune era l'unicità e la necessità della geometria euclidea.

3. *Le ricerche sull'assioma delle parallele.*

Sebbene la fiducia nella geometria euclidea come idealizzazione corretta dello spazio fisico sia rimasta inalterata dal 300 a.C. fino al 1800 circa, una preoccupazione tenne occupati i matematici durante quasi tutto questo lungo periodo. Gli assiomi adottati da Euclide erano considerati verità evidenti sullo spazio fisico e sulle figure di questo spazio. Tuttavia, l'assioma delle parallele, nella forma enunciata da Euclide (cfr. cap. IV, § 3), era considerato un po' troppo complicato. Nessuno ne metteva realmente in dubbio la verità, ma tuttavia ad esso mancava la irresistibile evidenza degli altri assiomi. Apparentemente anche lo stesso Euclide non era soddisfatto della sua versione dell'assioma delle parallele, perché non vi fece ricorso se non dopo aver dimostrato tutti i teoremi che si potevano provare senza di esso.

Un problema connesso, che non preoccupò altrettante persone ma che finí per rivelarsi ugualmente fondamentale, è quello di stabilire se si possa assumere l'esistenza nello spazio fisico di rette infinite. Euclide aveva fatto attenzione a postulare soltanto che è possibile prolungare una retta (finita) fintanto che è necessario, cosicché anche la retta estesa continuava a essere finita. Anche la particolare formulazione da parte di Euclide dell'assioma delle parallele, e cioè che due rette si incontreranno dalla parte della trasversale in cui la somma degli angoli interni è minore di due angoli retti, era un modo per evitare l'affermazione esplicita che esistono coppie di rette che non s'incontrano mai, comunque vengano prolungate. Ciò nondimeno, quanto Euclide aveva postulato implicava l'esistenza di rette infinite perché, se fossero state finite, non avrebbero potuto essere prolungate tanto quanto fosse stato necessario in ogni contesto dato ed egli *dimostrò* l'esistenza di rette parallele.

*D 2L ! ! 1 ! { UUU

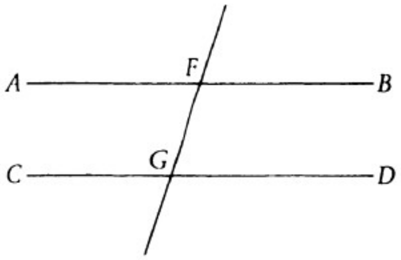

Figura 36.1.

La storia della geometria non euclidea comincia con gli sforzi per eliminare i dubbi intorno all'assioma euclideo delle parallele. A partire dall'epoca dei Greci fino all'inizio dell'Ottocento furono tentati due approcci. Il primo consisteva nel sostituire l'assioma delle parallele con un enunciato piú evidente. Il secondo consisteva nel tentare di dedurlo dagli altri nove assiomi di Euclide; se ciò fosse stato possibile, esso sarebbe diventato un teorema e tutti i dubbi sarebbero stati eliminati. Non faremo un resoconto dettagliato di tutte queste ricerche perché la loro storia è facilmente reperibile[2].

Il primo tentativo importante fu fatto da Tolomeo nel suo trattato sul postulato delle parallele. Egli tentò di dimostrarlo deducendolo dagli altri nove assiomi e dai teoremi 1-28 di Euclide che non dipendono dal postulato delle parallele. Tolomeo fece però l'assunzione inconscia che due rette non racchiudano una porzione di spazio e che, se *AB* e *CD* sono parallele (fig. 36.1), allora tutto ciò che vale per gli angoli interni da una delle parti di *FG* deve valere anche dall'altra.

Proclo, il commentatore del v secolo, fu molto esplicito nelle sue critiche al postulato delle parallele. Egli dice: «Questo postulato dovrebbe essere eliminato del tutto dai postulati perché esso è un teorema che implica molte difficoltà, che Tolomeo in un certo libro si propose di risolvere, e richiede per la sua dimostrazione un certo numero di definizioni e di teoremi; il suo inverso, inoltre, fu dimostrato come teorema da Euclide stesso». Proclo osserva che, mentre è necessario credere che due linee tendano l'una verso l'altra dalla parte della trasversale in cui la somma degli angoli interni è minore di due angoli retti, non è cosí chiaro che queste due rette si intersecheranno effettivamente in un punto finito. Questa conclusione è soltanto probabile. Infatti, continua, ci sono certe curve che si avvicinano l'una all'altra sempre di piú senza mai incontrarsi. Cosí, un'iperbole si avvicina al suo asintoto ma non l'incontra mai. Di conseguenza, non potrebbe ciò essere vero per le due rette del postulato di Euclide? Aggiunge poi che fino a un certo valore

---

[2] Si veda, ad esempio, il libro di Bonola citato nella bibliografia.

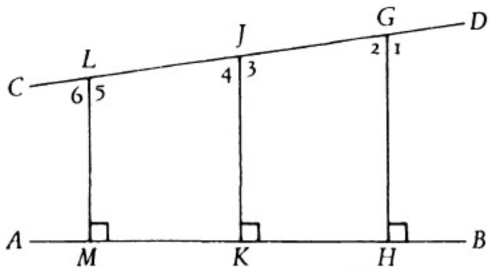

Figura 36.2.

della somma degli angoli interni da una delle parti della trasversale le due rette potrebbero effettivamente incontrarsi, mentre per un valore leggermente piú grande, ma ancora inferiore a due angoli retti, le rette potrebbero essere asintotiche.

Proclo basava la sua dimostrazione del postulato delle parallele su un assioma che Aristotele aveva usato per dimostrare che l'universo è finito. L'assioma dice: «Se da un punto si prolungano indefinitamente due rette formanti un certo angolo, le successive distanze fra le due rette finiranno per superare ogni grandezza finita». La dimostrazione di Proclo era sostanzialmente corretta, ma si limitava a sostituire un assioma discutibile con un altro altrettanto discutibile.

Nasîr-Eddin (1201-74), l'editore persiano di Euclide, diede anche lui una «dimostrazione» del postulato euclideo delle parallele assumendo che due rette non parallele si avvicinino l'una all'altra in una direzione e si allontanino nell'altra. Specificamente, se *AB* e *CD* (fig. 36.2) sono due rette tagliate da *GH*, *JK*, *LM*, ..., se queste ultime sono perpendicolari ad *AB* e se gli angoli 1, 3, 5, ... sono ottusi, mentre gli angoli 2, 4, 6, ... sono acuti, allora $GH > JK > LM$ ... Questo fatto, dice Nasîr-Eddin, lo si vede chiaramente.

Wallis fece nel 1663 alcune ricerche sull'assioma delle parallele, che pubblicò nel 1693[3]. Anzitutto riprodusse le ricerche di Nasîr-Eddin sull'assioma delle parallele che si era fatto tradurre da un professore di arabo di Oxford. Incidentalmente, fu cosí che il lavoro di Nasîr-Eddin divenne noto in Europa. Wallis criticò poi la dimostrazione di Nasîr-Eddin ed espose la sua dimostrazione dell'enunciato di Euclide. Essa si basa sull'assunzione esplicita che, per ogni triangolo, ne esiste uno simile i cui lati hanno un qualsiasi rapporto dato con i lati del triangolo di partenza. Wallis riteneva che questo assioma fosse piú evidente di quelli che si basano sulla possibilità di suddivisioni arbitrariamente piccole e di estensioni arbitrariamente grandi. In effetti, diceva, l'assioma di Euclide che afferma che si può costruire un cerchio di centro e raggio dati presuppone di avere a disposizione un raggio arbitrariamente grande. Si può perciò ben assumere che valga l'analogo per le figure rettilinee quali il triangolo.

---

[3] J. WALLIS, *Opera*, II, 669-78.

Il piú semplice degli assiomi sostitutivi fu proposto da Joseph Fenn nel 1769. Esso afferma che due rette che si intersecano non possono essere entrambe parallele a una terza. Questo assioma compare anche nel commento di Proclo alla proposizione 31 del libro I degli *Elementi* di Euclide. L'enunciato di Fenn è completamente equivalente all'assioma dato nel 1795 da John Playfair (1748-1819) e afferma che, per un dato punto *P* che non stia su una retta *l*, passa un'unica retta che giace nel piano di *P* ed *l* e che non incontra *l*. È questo l'assioma usato nei testi moderni (in cui per semplicità si dice di solito che passa «una e una sola retta...»)

Legendre lavorò sul problema del postulato delle parallele per un periodo di circa vent'anni. I suoi risultati furono pubblicati in libri e articoli, comprese le molte edizioni dei suoi *Eléments de géométrie*[4]. In uno dei suoi attacchi al problema dimostrò il postulato delle parallele assumendo l'esistenza di triangoli simili di dimensioni diverse; la sua dimostrazione era analitica, ma egli presuppose che l'unità di lunghezza non avesse alcuna influenza sulla dimostrazione. Diede poi una dimostrazione basata sull'assunzione che, dati tre punti non allineati, esiste un cerchio che passa per essi. In un altro approccio ancora si serví di tutti i postulati di Euclide ad eccezione di quello delle parallele e dimostrò che la somma degli angoli di un triangolo non può essere maggiore di due angoli retti. Osservò poi che, con queste stesse assunzioni, l'area è proporzionale al difetto, cioè alla differenza fra due angoli retti e la somma degli angoli. Cercò perciò di costruire un triangolo che avesse dimensione doppia di quella di un triangolo dato e quindi anche difetto doppio. Procedendo in questo modo sperava di ottenere dei triangoli con difetti sempre maggiori le cui somme degli angoli avrebbero perciò teso a zero. Questo risultato, pensava, sarebbe stato assurdo e perciò la somma degli angoli avrebbe dovuto essere uguale a 180°. Questo fatto avrebbe a sua volta implicato l'assioma euclideo delle parallele. Legendre trovò però che la costruzione si riduceva a dimostrare che, per un dato punto interno a un angolo minore di 60°, si può sempre tracciare una retta che incontri entrambi i lati dell'angolo e questo non era in grado di farlo senza il postulato delle parallele. In ciascuna delle dodici edizioni (l'ultima nel 1813) della sua versione degli *Elementi* di Euclide, Legendre aggiunse delle appendici che apparentemente davano delle dimostrazioni del postulato delle parallele, ma ciascuna era manchevole perché assumeva qualche cosa che non poteva esserlo o perché assumeva un assioma altrettanto discutibile di quello di Euclide.

---

[4] 1ª ed., 1794.

Nel corso delle sue ricerche Legendre[5], servendosi degli assiomi euclidei diversi da quello delle parallele, dimostrò i seguenti teoremi significativi: se la somma degli angoli di un triangolo è uguale a due angoli retti, lo stesso avviene per ogni triangolo. Analogamente, se la somma è minore di due angoli retti in un triangolo, lo stesso avviene per tutti. Egli dà poi la dimostrazione del fatto che, se la somma degli angoli di un triangolo è uguale a due angoli retti, allora vale il postulato euclideo delle parallele. Queste ricerche sulla somma degli angoli di un triangolo furono infruttuose anche perché Legendre non riuscí a dimostrare (senza l'aiuto dell'assioma delle parallele o di un assioma equivalente) che la somma degli angoli di un triangolo non può essere minore di due angoli retti.

Gli sforzi descritti finora erano soprattutto dei tentativi di trovare un sostituto dell'assioma euclideo delle parallele che fosse piú evidente, e molti degli assiomi proposti sembravano in effetti intuitivamente piú evidenti. Perciò i loro creatori erano soddisfatti e ritenevano di aver raggiunto il loro obiettivo. Tuttavia, un esame piú attento rivelava che questi assiomi sostitutivi non erano in realtà piú soddisfacenti. Alcuni di essi facevano delle affermazioni su ciò che accade infinitamente lontano nello spazio. Cosí, richiedere l'esistenza di un cerchio passante per tre qualsiasi punti non allineati implica l'esistenza di cerchi sempre piú grandi quando i tre punti tendono a essere allineati. D'altro lato, gli assiomi sostitutivi che non coinvolgevano direttamente l'«infinito», come ad esempio l'assioma che afferma che esistono due triangoli simili ma diversi, si rivelavano essere assunzioni abbastanza complesse e in nessun modo preferibili all'assioma euclideo delle parallele.

Il secondo gruppo di sforzi per risolvere il problema dell'assioma delle parallele fu rivolto a dedurre l'asserzione di Euclide dagli altri nove assiomi. La deduzione poteva essere diretta o indiretta. Tolomeo aveva tentato una dimostrazione diretta. Il metodo indiretto consiste nell'assumere una qualche asserzione che contraddice l'assioma euclideo e nel tentare di dedurre una contraddizione nel nuovo corpo di teoremi che ne conseguono. Ad esempio, poiché l'assioma euclideo delle parallele è equivalente all'assioma che dice che per un punto P che non sta su una retta l passa una e una sola retta parallela a l, esistono due alternative a questo assioma. Una consiste nell'affermare che non vi sono

---

[5] A.-M. LEGENDRE, in «Mém. de l'Acad. des Sci., Paris», XII (1833), 367-410.

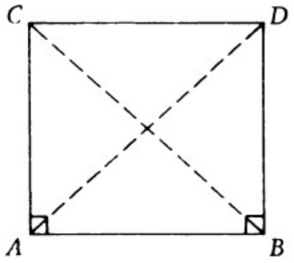

Figura 36.3.

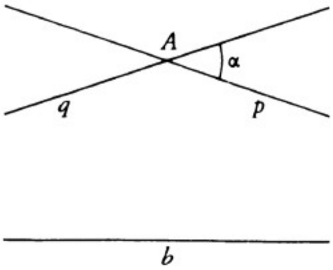

Figura 36.4.

parallele a l passanti per P, l'altra che ve ne sono piú di una. Se adottando ciascuna di queste alternative in luogo dell'assioma sull'«unica parallela» si potesse dimostrare che i nuovi insiemi di assiomi conducono a una contraddizione, allora entrambe dovrebbero essere respinte e l'asserzione sull'«unica parallela» risulterebbe *dimostrata*.

Lo sforzo piú significativo di questo tipo fu compiuto da Gerolamo Saccheri (1667-1733), un gesuita che fu professore all'università di Pavia. Egli studiò attentamente l'opera di Nasîr-Eddin e di Wallis e adottò poi il suo approccio personale. Saccheri partí con il quadrilatero $ABCD$ (fig. 36.3) in cui gli angoli in A e in B sono retti e $AC = BD$. È poi facile provare che $\sphericalangle C = \sphericalangle D$. Ora, l'assioma euclideo delle parallele è equivalente all'asserzione che gli angoli in C e in D sono retti. Saccheri prese perciò in considerazione le due alternative possibili: 1) ipotesi dell'angolo ottuso: $\sphericalangle C$ e $\sphericalangle D$ sono ottusi; 2) ipotesi dell'angolo acuto: $\sphericalangle C$ e $\sphericalangle D$ sono acuti. Sulla base della prima ipotesi (e degli altri nove assiomi di Euclide) Saccheri dimostrò che gli angoli in C e in D devono essere retti. L'ipotesi dell'angolo ottuso conduce perciò a una contraddizione.

Saccheri passò poi a considerare l'ipotesi dell'angolo acuto e dimostrò molti teoremi interessanti. Continuò fino a che giunse al seguente teorema: dati un punto A e una retta b (fig. 36.4), l'ipotesi dell'angolo acuto implica che nel fascio di rette per A esistano due rette p e q che lo dividono in due parti. La prima di esse è costituita dalle rette che intersecano b, la seconda è costituita dalle rette (comprese nell'angolo α) che posseggono una perpendicolare comune con b. Le rette p e q stesse sono asintotiche a b. Da questo risultato e da un lungo ragionamento successivo Saccheri dedusse che p e b dovrebbero avere una perpendicolare comune nel loro punto comune, che è all'infinito. Anche se non era giunto ad alcuna contraddizione, Saccheri trovò questa e altre conclusioni cosí ripugnanti che decise che l'ipotesi dell'angolo acuto doveva essere falsa.

Rimaneva soltanto l'ipotesi che gli angoli in C e in D della figura

36.3 fossero retti. Saccheri aveva dimostrato in precedenza che, quando questi angoli sono retti, la somma degli angoli di un qualsiasi triangolo è uguale a 180° e che questo fatto implica il postulato euclideo delle parallele. Si considerò perciò giustificato nel concludere che Euclide aveva ragione e pubblicò perciò l'*Euclides ab Omni Naevo Vindicatus* (1733). Tuttavia, poiché Saccheri non aveva ricavato una contraddizione dall'ipotesi dell'angolo acuto, il problema dell'assioma delle parallele rimaneva aperto.

Gli sforzi per trovare un sostituto accettabile per l'assioma euclideo delle parallele o per dimostrare che esso deve essere un teorema furono cosí numerosi e futili che nel 1759 d'Alembert chiamò il problema dell'assioma delle parallele «lo scandalo degli elementi di geometria».

4. *I primi presagi della geometria non euclidea.*

Nella sua dissertazione del 1763 Georg S. Klügel (1739-1812), professore di matematica all'università di Helmstädt, che conosceva il libro di Saccheri, fece la notevole osservazione che la certezza con cui veniva accettata la verità dell'assioma euclideo delle parallele era basata sull'esperienza. Questa osservazione introdusse per la prima volta l'idea che gli assiomi fossero convalidati dall'esperienza piuttosto che dall'evidenza. Klügel espresse dei dubbi circa il fatto che l'asserzione euclidea potesse essere provata. Egli si rendeva conto che Saccheri non era pervenuto a una contraddizione, ma soltanto a risultati che sembravano essere in disaccordo con l'esperienza.

Il lavoro di Klügel suggerí a Lambert delle ricerche sull'assioma delle parallele. Nella sua *Theorie der Parallellinien*, scritta nel 1766 e pubblicata nel 1786[6], Lambert, un po' come Saccheri, considerò un quadrilatero con tre angoli retti e prese in considerazione la possibilità che il quarto angolo fosse retto, ottuso o acuto. Tuttavia, a differenza di Saccheri, Lambert non concluse di aver ottenuto una contraddizione dall'ipotesi dell'angolo acuto.

Le conseguenze che Lambert dedusse rispettivamente dall'ipotesi dell'angolo ottuso e dell'angolo acuto, anche se la prima conduceva a una contraddizione, sono degne di nota. Il suo risultato piú notevole è che, in entrambe le ipotesi, l'area di un poligono con n lati è proporzionale alla differenza fra la somma degli angoli e $2n-4$ angoli retti (Saccheri aveva ottenuto questo risultato per il triangolo). Notò anche che l'ipotesi dell'angolo ottuso dava origine a teoremi simili a quelli che valgono per le figure tracciate sulla superficie di una sfera e fece la congettura che i teoremi che seguivano dall'ipotesi dell'angolo acuto si applicassero alle figure tracciate su una sfera di raggio immaginario. Questo lo indusse a scrivere un lavoro[7] sulle funzioni trigonometriche degli angoli immaginari, cioè della forma iA, dove A è un angolo reale e $i = \sqrt{-1}$, in cui in effetti introdusse le funzioni iperboliche (cfr. cap. XIX, § 2). Vedremo un po' piú chiaramente in seguito che cosa significano le affermazioni di Lambert.

---

[6] J. H. LAMBERT, in «Magazin für reine und angewandte Mathematik», 1786, 137-64, 325-58.

Le opinioni di Lambert sulla geometria erano molto avanzate. Egli si rendeva conto che ogni corpo di ipotesi che non conducessero a una contraddizione forniva una possibile geometria. Una tale geometria sarebbe stata una struttura logica valida anche se avesse avuto poco a che fare con le figure reali. Queste ultime potevano suggerire una particolare geometria, ma non controllavano la varietà di geometrie logicamente sviluppabili. Lambert non giunse alla conclusione piú radicale, che fu tratta un po' di tempo dopo da Gauss.

Un ulteriore passo avanti fu compiuto da Ferdinand Karl Schweikart (1780-1859), un professore di giurisprudenza che dedicava il tempo libero alla matematica. Egli lavorò sulla geometria non euclidea nel periodo in cui Gauss dedicò qualche pensiero all'argomento, ma Schweikart giunse alle sue conclusioni indipendentemente. Fu tuttavia influenzato dall'opera di Saccheri e di Lambert. In un promemoria del 1816 inviato a Gauss nel 1818 per l'approvazione, Schweikart distingueva due geometrie. C'è la geometria di Euclide e c'è una geometria basata sull'assunzione che la somma degli angoli di un triangolo non è uguale a due angoli retti. Egli chiamava quest'ultima geometria astrale perché potrebbe valere nello spazio stellare e i suoi teoremi erano quelli che Saccheri e Lambert avevano stabilito sulla base dell'ipotesi dell'angolo acuto.

Franz Adolph Taurinus (1794-1874), nipote di Schweikart, seguí il suggerimento dello zio di studiare la geometria astrale. Anche se stabilí nei suoi *Geometriae Prima Elementa* (1826) alcuni risultati nuovi, in particolare di geometria analitica, ne concluse che soltanto la geometria di Euclide poteva essere vera per lo spazio fisico, ma che la geometria astrale era *logicamente coerente*. Taurinus dimostrò anche che le formule che varrebbero su una sfera di raggio immaginario sono esattamente quelle che valgono nella sua geometria astrale.

Le ricerche di Lambert, Schweikart e Taurinus costituiscono dei progressi che meritano di essere ricapitolati. Tutti e tre, e insieme con loro altri matematici come Klügel e Abraham G. Kästner (1719-1800), un professore di Göttingen, erano convinti che l'assioma delle parallele non potesse essere dimostrato, cioè che fosse indipendente dagli altri assiomi di Euclide. Inoltre, Lambert, Schweikart e Taurinus erano convinti che fosse possibile adottare un assioma alternativo che contraddicesse quello di Euclide e costruire con esso una geometria logicamente coerente. Lambert non si pronunciò circa l'applicabilità di una tale geometria, Taurinus pensava che non fosse possibile applicarla allo spazio fisico, mentre Schweikart riteneva che essa potesse essere applicata allo spazio interstellare. Questi tre matematici notarono anche che la geometria su una sfera reale ha le stesse proprietà della geometria basata sull'ipotesi dell'angolo ottuso (lasciando da parte le contraddizioni che conseguono da quest'ultima) e che la geometria su una sfera con raggio immaginario ha le stesse proprietà della geometria basata sull'ipotesi dell'angolo acuto. Cosí, tutti e tre riconobbero l'esistenza di una geometria non euclidea, ma mancarono di cogliere un punto essenziale, e cioè che la geometria euclidea non è l'unica geometria che descrive le proprietà dello spazio fisico nei limiti della precisione che l'esperienza può garantire.

5. *La creazione della geometria non euclidea.*

Nessuna branca fondamentale della matematica né alcun importante risultato specifico sono opera di un solo uomo; al massimo, è possibile attribuire a un singolo un passo o una dimostrazione decisivi. Questo sviluppo collettivo della matematica si applica in particolare alla geometria non euclidea. Se si intende per creazione della geometria non euclidea il riconoscimento che esistono delle geometrie alternative a quelle di Euclide, allora il merito deve essere attribuito a Klügel e a Lambert. Se geometria non euclidea significa lo sviluppo tecnico delle conseguenze di un sistema di assiomi contenente un'alternativa all'assioma euclideo delle parallele, allora la maggior parte del merito deve essere attribuita a Saccheri, anche se beneficiò delle ricerche di molti matematici che avevano tentato di trovare un assioma piú accettabile che sostituisse quello di Euclide. Tuttavia, il fatto piú significativo concernente la geometria non euclidea è che essa può essere usata per descrivere le proprietà dello spazio fisico con altrettanta precisione della geometria euclidea. Quest'ultima non è la geometria necessaria dello spazio fisico e la sua verità fisica non può essere garantita su basi aprioristiche. Questa presa di coscienza, che non richiedeva nessuno sviluppo tecnico perché questi erano già stati ottenuti, fu conseguita per la prima volta da Gauss.

Carl Friedrich Gauss (1777-1855) era figlio di un muratore della città tedesca di Braunschweig e sembrava destinato al lavoro manuale. Il direttore della scuola in cui ricevette l'educazione elementare fu però colpito dalla sua intelligenza e richiamò su di lui l'attenzione del duca Carlo Guglielmo. Il duca mandò Gauss a una scuola superiore e poi, nel 1795, all'università di Göttingen. Qui Gauss incominciò a lavorare duramente sulle sue idee. A diciotto anni inventò il metodo dei minimi quadrati e a diciannove dimostrò che il poligono regolare di 17 lati è costruibile. Questi successi lo convinsero a passare dalla filologia alla matematica. Nel 1798 si trasferí all'università di Helmstädt dove fu notato da Johann Friedrich Pfaff, che diventò suo maestro e amico. Dopo aver ottenuto il dottorato, Gauss ritornò a Braunschweig, dove scrisse alcuni dei suoi lavori piú famosi, che gli fruttarono nel 1807 la nomina a professore di astronomia e a direttore dell'osservatorio di Göttingen. Se si eccettua un viaggio a Berlino per partecipare a un congresso scientifico, Gauss rimase a Göttingen per il resto della sua vita. Non amava insegnare e lo diceva. Gli piaceva tuttavia la vita di società, si sposò due volte ed ebbe dei bambini.

La prima opera importante di Gauss fu la sua tesi di dottorato, in cui dimostrò il teorema fondamentale dell'algebra. Nel 1801 pubblicò le classiche *Disquisitiones arithmeticae*. Il suo lavoro di geometria differenziale, le *Disquisitiones generales circa superficies curvas* (1827), che, incidentalmente, fu il risultato dei suoi interessi per la geodesia, la topografia e la cartografia, è una pietra miliare della matematica (cfr. cap. XXXVII, § 2). Portò molti altri contributi all'algebra, alla teoria delle funzioni complesse e alla teoria del potenziale. In lavori non pubblicati sono riportate le sue ricerche innovatrici sulla teoria delle funzioni ellittiche e sulla geometria non euclidea.

I suoi interessi per la fisica furono ugualmente ampi e ad essi dedicò la maggior parte delle sue energie. Quando Giuseppe Piazzi (1746-1826) scoprí nel 1801 il pianeta Cerere, Gauss si propose di determinarne l'orbita. Questo fu l'inizio delle sue ricerche astronomiche, l'attività che l'assorbí maggiormente e a cui dedicò circa vent'anni. Una delle sue grandi pubblicazioni in questo settore è la *Theoria Motus Corporum Coelestium* (1809). Gauss ottenne anche grande fama per le sue ricerche sul magnetismo teorico e sperimentale. Maxwell dice nell'*Electricity and Magnetism* che gli studi di Gauss sul magnetismo ricostruirono l'intera scienza, gli strumenti usati, i metodi di osservazione e il calcolo dei risultati. I lavori di Gauss sul magnetismo terrestre sono dei modelli di ricerche fisiche e fornirono il metodo migliore per misurare il campo magnetico terrestre. Le sue ricerche sull'astronomia e sul magnetismo aprirono un nuovo e brillante periodo di cooperazione fra la matematica e la fisica.

Anche se Gauss e Whilhelm Weber (1804-91) non inventarono il telegrafo, nel 1833 migliorarono le tecniche precedenti con un dispositivo pratico che faceva ruotare un ago a destra e a sinistra a seconda della direzione della corrente fatta passare in un filo. Gauss si occupò anche di ottica, che era stata trascurata dai tempi di Euclide, e le sue ricerche del 1838-41 diedero una base completamente nuova alla trattazione dei problemi ottici.

L'universalità delle attività di Gauss è tanto piú degna di nota in quanto i suoi contemporanei avevano incominciato a confinarsi in ricerche specialistiche. Sebbene sia considerato il piú grande matematico almeno dopo Newton, Gauss non fu tanto un innovatore quanto una figura di transizione fra il Settecento e l'Ottocento. Anche se elaborò delle idee nuove che occuparono in seguito molti altri matematici, egli fu orientato piú verso il passato che verso il futuro. Felix Klein descrive la posizione di Gauss con queste parole: «Potremmo avere un quadro dello sviluppo della matematica se immaginassimo una catena di alte montagne, rappresentanti i matematici del Settecento, che culmini con una cima imponente – Gauss – e poi un'ampia e ricca regione riempita da nuovi elementi di vita. I contemporanei di Gauss ne apprezzarono il genio e all'epoca della sua morte, avvenuta nel 1855, era universalmente venerato e chiamato il "principe dei matematici"».

Gauss pubblicò relativamente poco delle sue ricerche perché amava rifinire tutto ciò che faceva, in parte per conferirgli eleganza, in parte per dare alle sue dimostrazioni il massimo di concisione senza sacrificare il rigore (quello del suo tempo, almeno). Nel caso della geometria non euclidea non pubblicò nessun lavoro definitivo. In una lettera a Bessel del 27 gennaio 1829 dice che non avrebbe probabilmente mai pubblicato le sue scoperte in questo campo perché temeva «le strida dei Beoti». Può darsi che Gauss sia stato troppo cauto, ma bisogna ricordare che, anche se alcuni matematici avevano gradualmente raggiunto il vertice delle ricerche sulla geometria non euclidea, il mondo intellettuale in senso lato era ancora dominato dalle idee kantiane. Ciò che sappiamo delle ricerche gaussiane sulla geometria non euclidea è tratto dalle lettere agli amici, da due brevi recensioni apparse sulle «Göttingische gelehrte Anzeigen» del 1816 e del 1822 e da alcune note del 1831 trovate fra le sue carte dopo la morte[8].

---

[8] C. F. GAUSS, *Werke*, VIII, 157-268; contiene tutto ciò e anche la lettera discussa sotto.

Gauss era pienamente consapevole della vanità degli sforzi per stabilire il postulato euclideo delle parallele, perché questo era un fatto comunemente noto a Göttingen e tutta la storia di questi sforzi era pienamente nota al suo maestro Kästner. Gauss disse all'amico Schumacher che fin dal 1792 (quando aveva quindici anni) si era fatto l'idea che fosse possibile l'esistenza di una geometria logica in cui non fosse valido il postulato euclideo delle parallele. Con il 1794 Gauss aveva trovato che nel suo concetto di geometria non euclidea l'area di un quadrangolo deve essere proporzionale alla differenza fra 360° e la somma dei suoi angoli interni. In questo periodo, però, e fino al 1799, Gauss stava ancora tentando di dedurre il postulato euclideo delle parallele da altre assunzioni piú plausibili e riteneva ancora che la geometria euclidea fosse la geometria dello spazio fisico anche se poteva immaginare altre geometrie non euclidee logicamente corrette. Tuttavia, il 17 dicembre 1799 Gauss scrisse al matematico ungherese suo amico Wolfgang Farkas Bolyai (1775-1856):

> Quanto a me ho già fatto alcuni progressi nel mio lavoro. Tuttavia, il cammino che ho scelto non conduce affatto alla meta che cerchiamo [la deduzione dell'assioma delle parallele] e che tu mi assicuri di aver raggiunto. Essa sembra piuttosto obbligarmi a dubitare della verità della stessa geometria. È vero che sono giunto a qualche cosa che la maggior parte delle persone riterrebbe che costituisca una dimostrazione, ma ai miei occhi non prova un bel nulla. Ad esempio, se potessimo dimostrare la possibilità dell'esistenza di un triangolo rettilineo la cui area sia maggiore di ogni area data, allora sarei pronto a provare tutta la geometria [euclidea] in maniera assolutamente rigorosa.
>
> La maggior parte delle persone accetterebbero certamente questo fatto come assioma, ma io no! Potrebbe in effetti essere possibile che l'area rimanga sempre al di sotto di un certo limite, per quanto distanti siano presi i tre vertici del triangolo.

Questo passo dimostra che nel 1799 Gauss era abbastanza convinto che l'assioma delle parallele non potesse essere dedotto dagli altri assiomi euclidei e incominciava a prendere piú sul serio lo sviluppo di una nuova geometria suscettibile di applicazioni.

A partire dal 1813 circa Gauss sviluppò la sua nuova geometria che all'inizio chiamava geometria antieuclidea, poi geometria astrale e infine geometria non euclidea. Egli si convinse che essa era logicamente coerente ed era piuttosto sicuro che potesse essere applicata. Nelle recensioni del 1816 e del 1822 e nella lettera a Bessel del 1829 Gauss riaffermò che il postulato delle parallele non poteva essere dimostrato sulla base degli altri assiomi di Euclide. La lettera a Olbers scritta nel 1817[9] costituisce una pietra miliare. In essa Gauss dice: «Mi sto convincendo sempre di piú che la necessità fisica della nostra geometria [euclidea] non può essere dimostrata, almeno non dalla ragione umana né per ragioni umane. Forse in un'altra vita penetreremo la natura dello spazio, che è per ora irraggiungibile. Fino ad allora dovremo porre la geometria non nella stessa classe dell'aritmetica, che è puramente a priori, ma in quella della meccanica».

Per verificare l'applicabilità della geometria euclidea e della sua geometria non euclidea Gauss misurò effettivamente la somma degli angoli del triangolo formato dalle cime delle tre montagne Brocken, Hohehagen e Inselberg. I lati di questo triangolo erano rispettivamente lunghi 69, 85 e 197 chilometri. Gauss trovò[10] che la somma degli angoli superava i 180° di 14".85. L'esperimento non dimostrò niente perché l'errore sperimentale era molto piú grande dell'eccedenza trovata, cosicché la somma corretta avrebbe potuto benissimo essere uguale a 180° o anche meno. Come Gauss si rese conto, il triangolo era troppo piccolo e poiché nella geometria non euclidea il difetto è proporzionale all'area, soltanto un triangolo molto grande avrebbe potuto eventualmente rivelare una differenza significativa rispetto ai 180° nella somma degli angoli.

Non discuteremo i teoremi specifici di geometria non euclidea dovuti a Gauss. Egli non scrisse un'esposizione completamente deduttiva delle sue ricerche e i teoremi che provò sono in gran parte simili a quelli che incontreremo nell'opera di Lobatchevsky e di Bolyai, i due matematici a cui viene generalmente attribuita la creazione della geometria non euclidea. Che cosa debba loro essere attribuito lo discuteremo in seguito, ma essi pubblicarono delle presentazioni organiche di una geometria non euclidea su basi deduttive sintetiche rendendosi pienamente conto che questa nuova geometria era dal punto di vista logico altrettanto legittima di quella di Euclide.

Nikolai Ivanovich Lobatchevsky (1793-1856), russo, studiò all'università di Kazan di cui fu professore e rettore dal 1827 al 1846. Espose le sue vedute sui fondamenti della geometria in un lavoro letto di fronte al dipartimento di matematica e fisica dell'università nel 1826. Tuttavia, il lavoro non fu mai stampato e andò perduto. In seguito espose il suo approccio alla geometria non euclidea in una serie di lavori, i primi due dei quali furono pubblicati in riviste di Kazan e il terzo nel «Journal für Mathematik»[11]. Il primo era intitolato *Sui fondamenti della geometria* e apparve nel 1829-30. Il secondo, intitolato *Nuovi fondamenti della geometria con una teoria completa delle parallele* (1835-37), è una presentazione migliore delle idee di Lobatchevsky. Egli chiamava la sua nuova geometria «geometria immaginaria» per motivi che sono forse già chiari e che lo diventeranno di piú in seguito. Nel 1840 pubblicò un libro in tedesco, intitolato *Geometrische Untersuchungen zur Theorie der Parallellinien* (Ricerche geometriche sulla teoria delle parallele)[12]. In esso si lamenta per lo scarso interesse nei confronti dei suoi scritti. Pur essendo diventato cieco, dettò un'esposizione completamente nuova della sua geometria e la pubblicò nel 1855 con il titolo di *Pangéométrie*.

---

[9] *Ibid.*, 177.
[10] *Ibid.*, IV, 258.

János Bolyai (1802-60), figlio di Wolfgang Bolyai, era un ufficiale ungherese. Sulla geometria non euclidea, che chiamava geometria assoluta, scrisse un lavoro di ventisei pagine intitolato *La scienza dello spazio assoluto*[13], che fu pubblicato in appendice al libro del padre intitolato *Tentamen Juventutem Studiosam in Elementa Matheseos.* Anche se quest'opera in due volumi apparve nel 1832-33, e quindi dopo il primo lavoro di Lobatchevsky, sembra che Bolyai abbia elaborato le sue idee sulla geometria non euclidea prima del 1825 e che entro quel periodo si fosse convinto che la nuova geometria non era contraddittoria. In una lettera al padre datata 23 novembre 1823 János scrive: «Ho fatto delle scoperte cosí meravigliose che sono io stesso sconvolto per lo stupore». Le ricerche di Bolyai erano cosí simili a quelle di Lobatchevsky che quando Bolyai vide per la prima volta nel 1835 i lavori del russo pensò che li avesse copiati dalla sua pubblicazione del 1832-33. D'altro lato, Gauss lesse l'articolo di János Bolyai nel 1832 e scrisse a Wolfgang[14] che non poteva lodarlo perché, cosí facendo, avrebbe lodato le proprie ricerche.

6. *Il contenuto tecnico della geometria non euclidea.*

Gauss, Lobatchevsky e Bolyai si erano resi conto che l'assioma euclideo delle parallele non poteva essere dimostrato sulla base degli altri nove assiomi e che esso era necessario per fondare la geometria euclidea. Poiché l'assioma delle parallele era indipendente, doveva quindi

Figura 36.5.

essere possibile, almeno dal punto di vista logico, adottare un enunciato che lo contraddicesse e sviluppare le conseguenze del nuovo insieme di assiomi.

Per studiare il contenuto tecnico delle loro scoperte tanto vale prendere in considerazione l'opera di Lobatchevsky perché tutti e tre fecero praticamente le stesse cose. Lobatchevsky diede, come sappiamo, numerose versioni che differiscono soltanto nei dettagli. Come base per la nostra esposizione ci serviremo del lavoro del 1835-37.

Poiché, come negli *Elementi* di Euclide, si possono dimostrare molti teoremi che non dipendono affatto dall'assioma delle parallele, tali teoremi sono validi anche nella nuova geometria. Lobatchevsky dedica i primi sei capitoli del suo lavoro alla dimostrazione di questi teoremi fondamentali. Egli assume all'inizio che lo spazio sia infinito e può poi dimostrare che due rette non possono intersecarsi in piú di un punto e che due perpendicolari alla stessa retta non possono intersecarsi.

Nel settimo capitolo Lobatchevsky respinge bravamente l'assioma euclideo delle parallele e fa la seguente assunzione: dati una retta AB e un punto C (fig. 36.5), le rette per C si dividono in due classi rispetto ad AB, e cioè, la classe delle rette che incontrano AB e la classe delle rette che non la incontrano. A quest'ultima appartengono due rette p e q che costituiscono il confine fra le due classi. Queste due rette sono dette parallele. Piú precisamente, se C è un punto a distanza a dalla retta AB, allora esiste un angolo[15] $\pi(a)$ tale che tutte le rette per C che formano con la perpendicolare CD un angolo minore di $\pi(a)$ intersecheranno AB, mentre tutte le altre rette per C non intersecheranno AB[16]. Le due rette che formano l'angolo $\pi(a)$ con AB sono le parallele e $\pi(a)$ è detto angolo di parallelismo. Le rette per C diverse dalle parallele e che non incontrano AB sono dette linee non intersecanti, anche se nel senso di Euclide esse sono parallele ad AB, e perciò in questo senso la geometria di Lobatchevsky contiene un numero infinito di parallele passanti per C.

---

[15] Il simbolo $\pi(a)$ è standard e perciò viene usato qui. Va da sé che il π che compare in $\pi(a)$ non ha nulla a che fare con il numero π.

[16] L'idea che si possa associare un angolo specifico a ciascuna lunghezza è dovuta a Lambert.

Se $\pi(a) = \pi/2$ si ha l'assioma euclideo. In caso contrario, ne segue che $\pi(a)$ cresce e tende a $\pi/2$ quando a tende a 0, mentre $\pi(a)$ decresce e tende a 0 quando a diventa infinito. La somma degli angoli di un triangolo è sempre minore di π, decresce quando l'area del triangolo cresce e tende a π quando l'area tende a zero. Se due triangoli sono simili, allora sono congruenti.

Lobatchevsky affronta poi l'aspetto trigonometrico della sua geometria. Il primo passo è la determinazione di $\pi(a)$. Il risultato, se un angolo giro è uguale a 2π, è[17]:

$$\operatorname{tg} \frac{\pi(x)}{2} = e^{-x}, \tag{1}$$

da cui segue che $\pi(0) = \pi/2$ e $\pi(+\infty) = 0$. La relazione (1) è importante, in quanto a ogni lunghezza x associa un angolo definito $\pi(x)$. Se $x = 1$ si ha $\operatorname{tg} [\pi(1)/2] = e^{-1}$ e quindi $\pi(1) = 40° 24'$. L'unità di lunghezza è perciò quella lunghezza il cui angolo di parallelismo è uguale a 40° 24'. Questa unità di lunghezza non ha un significato fisico diretto. Dal punto di vista fisico può essere uguale a un centimetro o a un chilometro. Bisognerà scegliere l'interpretazione fisica che renda applicabile la geometria[18].

Lobatchevsky deduce poi le formule che legano fra loro i lati e gli angoli dei triangoli piani della sua geometria. In un lavoro del 1834 aveva definito cos x e sin x, per x reale, come le parti reale e immaginaria di e^{ix}. L'obiettivo di Lobatchevsky era quello di dare una fondazione puramente analitica alla trigonometria, in modo da renderla indipendente dalla geometria euclidea. Le principali formule trigonometriche della sua geometria sono le seguenti (fig. 36.6):

$$\begin{aligned} \operatorname{cotg} \pi(a) &= \operatorname{cotg} \pi(c) \sin A \\ \sin A &= \cos B \sin \pi(b) \\ \sin \pi(c) &= \sin \pi(a) \sin \pi(b). \end{aligned}$$

---

[17] Questa è una formulazione particolare. Nel lavoro del 1840 Lobatchevsky dà la formula che viene usata solitamente nei testi moderni e che è contenuta anche in Gauss, e cioè:

$$\operatorname{tg} \frac{1}{2} \pi(x) = e^{x/k}, \tag{a}$$

dove k è una costante che viene detta costante spaziale. Dal punto di vista teorico il valore di k è irrilevante. Anche Bolyai dà la formula (*a*).

[18] Nel caso della relazione $\operatorname{tg} [\pi(x)/2] = e^{-x/k}$, la scelta del valore di x che corrisponde, ad esempio, a 40° 24' determina k.

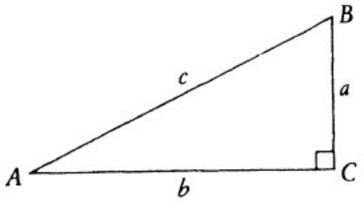

Figura 36.6.

Queste formule sono valide nella trigonometria sferica ordinaria purché i lati abbiano lunghezze immaginarie. In altri termini, se si sostituiscono a, b e c nelle formule usuali della trigonometria sferica con ia, ib e ic si ottengono le formule di Lobatchevsky. Poiché le funzioni trigonometriche degli angoli immaginari possono essere sostituite dalle funzioni iperboliche, ci si potrebbe aspettare di veder comparire queste ultime funzioni nelle formule di Lobatchevsky. Esse possono essere introdotte servendosi della relazione $\operatorname{tg} [\pi(x)/2] = e^{-x/k}$. In questo modo la prima delle formule precedenti diventa:

$$\sinh \frac{a}{k} = \sinh \frac{c}{k} \sin A.$$

Inoltre, mentre nella geometria sferica usuale l'area di un triangolo di angoli A, B e C è uguale a $r^2(A + B + C - \pi)$, nella geometria non euclidea essa è uguale a $r^2[\pi - (A + B + C)]$, il che equivale a sostituire il raggio r della sfera con ir nella formula usuale.

Servendosi di un triangolo infinitesimo, Lobatchevsky aveva derivato nel suo primo lavoro (1829-30) la formula

$$ds = \sqrt{(dy)^2 + \frac{(dx)^2}{\sin^2 \pi(x)}}$$

per l'elemento d'arco di una curva di equazione $y = f(x)$ nel punto (x, y). Servendosi di essa si può calcolare la lunghezza della circonferenza di un cerchio di raggio r, che risulta essere uguale a

$$C = \pi(e^r - e^{-r}).$$

Analogamente, il valore dell'area del cerchio risulta essere uguale a

$$A = \pi(e^{r/2} - e^{-r/2})^2.$$

Egli dà anche dei teoremi sulle aree di regioni piane e curve e sui volumi dei solidi.

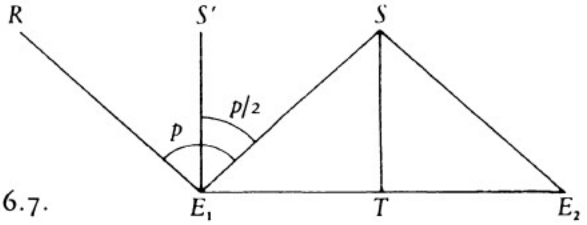

Figura 36.7.

Le formule della geometria euclidea seguono da quelle non euclidee quando le grandezze in gioco sono piccole. Cosí, se si usa il fatto che

$$e^r = 1 + r + \frac{r^2}{2!} + \dots$$

e si trascurano, per r piccolo, tutti i termini tranne i primi due, si ottiene ad esempio

$$C = \pi(e^r - e^{-r}) \sim \pi\{1 + r - (1 - r)\} = 2\pi r.$$

Nel primo lavoro (1829-30) Lobatchevsky prese anche in esame le possibilità di applicazione della sua geometria allo spazio fisico. L'essenza del suo ragionamento si basa sulla parallasse delle stelle. Supponiamo che E_1 ed E_2 (fig. 36.7) siano le posizioni della Terra a distanza di sei mesi e che S sia una stella. La parallasse p di S è la differenza fra le direzioni di E_1S e di E_2S misurata, ad esempio, a partire dalla perpendicolare E_1S'. Se E_1R è la parallela euclidea a E_2S, allora, poiché E_1SE_2 è un triangolo isoscele, $\pi/2 - \sphericalangle SE_1E_2$ è la metà del cambiamento di direzione della stella, cioè è uguale a $p/2$. Questo angolo è uguale a $1''.24$ per la stella Sirio (valore dato da Lobatchevsky). Fintanto che questo angolo non è uguale a zero, la retta da E_1 alla stella non può essere parallela a TS perché essa taglia TS. Se invece ci fosse un estremo inferiore per le varie parallassi di tutte le stelle, allora ogni retta uscente da E_1 e formante con E_1S' un angolo minore di questo estremo inferiore potrebbe essere considerata una parallela a TS passante per E_1 e questa geometria sarebbe ugualmente utile fintanto che si abbia a che fare con le misure stellari. Tuttavia, Lobatchevsky dimostra che l'unità di lunghezza di questa geometria dovrebbe essere uguale a piú di mezzo milione di volte il raggio dell'orbita terrestre. In altre parole, le geometria di Lobatchevsky potrebbe essere applicata soltanto in un triangolo enormemente grande.

7. *Le rivendicazioni di priorità di Lobatchevsky e di Bolyai.*

La geometria non euclidea viene spesso usata come esempio del come la stessa idea possa venire nello stesso momento, ma indipendentemente, a piú persone. Talvolta ciò viene considerato come una pura coincidenza e talvolta come una prova del fatto che lo spirito dei tempi esercita la sua influenza in direzioni molto distanti fra loro. La creazione della geometria non euclidea da parte di Gauss, Lobatchevsky e Bolyai non è un esempio di creazione simultanea né è giustificato il grande merito attribuito a Lobatchevsky e a Bolyai. È vero, come abbiamo già notato, che essi furono i primi a pubblicare una geometria dichiaratamente non euclidea e con questo atto diedero prova di un coraggio maggiore di quello di Gauss. Tuttavia, la creazione della geometria non euclidea può difficilmente esser loro attribuita. Abbiamo già osservato che anche Gauss era stato preceduto da Lambert, che Schweikart e Taurinus furono dei creatori indipendenti, che Lambert e Taurinus pubblicarono le loro ricerche e, inoltre, che fu Gauss a rendersi conto per primo che la nuova geometria può essere applicata allo spazio fisico.

Sia Lobatchevsky che Bolyai devono molto a Gauss. Il maestro di Lobatchevsky a Kazan fu Johann Martin Bartels (1769-1836), un buon amico di Gauss. In effetti, essi passarono insieme a Braunschweig gli anni che vanno dal 1805 al 1807. Successivamente Gauss e Bartels rimasero in contatto fra di loro. È estremamente improbabile che Bartels non abbia comunicato a Lobatchevsky, che rimase a Kazan come suo collega, i progressi di Gauss nella geometria non euclidea. In particolare, Bartels deve essere stato al corrente dei dubbi di Gauss circa la verità della geometria euclidea.

Quanto a János Bolyai, il padre Wolfgang era anch'esso un intimo amico di Gauss, di cui era stato compagno a Göttingen dal 1796 al 1798. Wolfgang Bolyai e Gauss non soltanto continuarono a rimanere in comunicazione, ma discussero anche l'argomento dell'assioma delle parallele, come indica una delle citazioni precedenti. Wolfgang Bolyai continuò a lavorare intensamente sul problema dell'assioma delle parallele e mandò a Gauss nel 1804 quella che riteneva essere una dimostrazione, ma Gauss gli dimostrò che era sbagliata. Entro il 1817 Gauss era sicuro non soltanto che l'assioma non poteva essere dimostrato, ma anche che era possibile costruire una geometria non euclidea logicamente coerente e applicabile fisicamente. Oltre alla sua comunicazione in tal senso del 1799, Gauss trasmise liberamente le sue idee successive all'amico, il quale continuò a occuparsi del problema fino a quando pubblicò il

Claude Bachet de Méziriac (1581–1638) preferred to write $x^3 + 13x^2 + 5x + 2$ as $1C + 13Q + 5N + 2$. Vieta used the same notation for equations with numerical coefficients.

Descartes made rather systematic use of positive integral exponents. He expressed

$$1 + 3x + 6x^2 + x^3 \quad \text{as} \quad 1 + 3x + 6xx + x^3.$$

Occasionally he and others used x^2 also. For higher powers he used x^4, $x^5, \ldots$ but not x^n. Newton used positive, negative, integral, and fractional exponents, as in $x^{5/3}$ and x^{-3}. When, in 1801, Gauss adopted x^2 for xx, the former became standard.

The most significant change in the character of algebra was introduced in connection with symbolism by François Vieta. Trained as a lawyer, he served in that capacity for the parliament in Brittany; he was later privy councillor to Henry of Navarre. When he was out of office from 1584 to 1589, as a result of political opposition, he devoted himself entirely to mathematics. Generally, he pursued mathematics as a hobby and printed and circulated his work at his own expense—a guarantee, as one writer put it, of oblivion.

Vieta was a humanist in spirit and intention; he wished to be the preserver, rediscoverer, and continuator of ancient mathematics. Innovation was for him renovation. He describes his *In Artem Analyticam Isagoge*[6] as the "work of the restored mathematical analysis." For this book he drew on the seventh book of Pappus' *Mathematical Collection* and on Diophantus' *Arithmetica*. He believed that the ancients had used a general algebraic type of calculation, which he reintroduced in his algebra, thus merely reactivating an art known and approved of in antiquity.

During the hiatus in his political career Vieta studied the works of Cardan, Tartaglia, Bombelli, Stevin, and Diophantus. From them and particularly from Diophantus he got the idea of using letters. Though a number of men, including Euclid and Aristotle, had used letters in place of specific numbers, these uses were infrequent, sporadic, and incidental. Vieta was the first to use letters purposefully and systematically, not just to represent an unknown or powers of the unknown but as general coefficients. Usually he used consonants for the known quantities and vowels for the unknown quantities. He called his symbolic algebra *logistica speciosa*, as opposed to *logistica numerosa*. Vieta was fully aware that when he studied the general quadratic equation $ax^2 + bx + c = 0$ (in our notation), he was studying an entire class of expressions. In making the distinction between *logistica numerosa* and *logistica speciosa* in his *Isagoge*, Vieta drew the line between arithmetic and algebra. Algebra, the *logistica speciosa*, he said, was a method of operating on species or forms of things. Arithmetic, the *numerosa*,

$\phi = \pi$. The notation $\Delta(k, \phi)$ for $\sqrt{1 - k^2 \sin^2 \phi}$ was also introduced by Legendre.

These forms can be converted, by the change of variable $x = \sin \phi$, to the Jacobi forms

$$F(k, x) = \int_0^x \frac{dx}{\sqrt{1 - x^2}\sqrt{1 - k^2x^2}} \tag{42}$$

$$E(k, x) = \int_0^x \sqrt{\frac{1 - k^2x^2}{1 - x^2}}\, dx \tag{43}$$

$$\pi(n, k, x) = \int_0^x \frac{dx}{(1 + nx^2)\sqrt{(1 - x^2)(1 - k^2x^2)}}. \tag{44}$$

The quantity k is called the modulus of each elliptic integral. If the limits of integration are $\phi = \pi/2$ or $x = 1$, then the integrals are called complete; otherwise, incomplete.

There was much merit in Legendre's work on elliptic integrals. He drew many inferences, previously unstated, from the work of his predecessors and organized the mathematical subject; but he did not add any basic ideas, nor did he attain the new insight of Abel and Jacobi (Chap. 27, sec. 6) who inverted these integrals and so conceived of the elliptic *functions*. Legendre did get to know the work of Abel and Jacobi and praised them, with much humility and, probably, some bitterness. In devoting the supplements to his 1825 work to their new ideas, he understood very well that this material threw into the shade all he had done on the subject. He had overlooked one of the great discoveries of his epoch.

5. *Further Special Functions*

The elliptic indefinite integrals are new transcendental functions. As the analytical work of the eighteenth century developed, more transcendental functions were obtained. Of these the most important is the gamma function, which arose from work on two problems, interpolation theory and antidifferentiation. The problem of interpolation had been considered by James Stirling (1692–1770), Daniel Bernoulli, and Christian Goldbach (1690–1764). It was posed to Euler and he announced his solution in a letter of October 13, 1729, to Goldbach.[33] A second letter, of January 8, 1730, brought in the integration problem.[34] In 1731 Euler published results on both in a paper, "De Progressionibus. . . ."[35]

[33] Fuss, *Correspondance*, 1, 3–7.

[34] Fuss, *Correspondance*, 1, 11–18.

[35] *Comm. Acad. Sci. Petrop.*, 5, 1730/1, 36–57, pub. 1738 = *Opera*, (1), 14, 1–24.

The interpolation problem was to give meaning to $n!$ for nonintegral values of n. Euler noted that

$$(45)\qquad \begin{aligned} n! &= \left[\left(\frac{2}{1}\right)^n \frac{1}{n+1}\right]\left[\left(\frac{3}{2}\right)^n \frac{2}{n+2}\right]\left[\left(\frac{4}{3}\right)^n \frac{3}{n+3}\right]\cdots \\ &= \prod_{k=1}^{\infty} \left(\frac{k+1}{k}\right)^n \frac{k}{k+n}. \end{aligned}$$

The equation is seen to be formally correct if one cancels common factors in the infinite product. However, this analytic expression for $n!$, unlike the basic definition $n(n-1)\cdots 2\cdot 1$, has a meaning for all n except negative integral values. Euler noticed that for $n = 1/2$ the right side yields, after a bit of manipulation, the infinite product of Wallis

$$(46)\qquad \frac{\pi}{2} = \left(\frac{2\cdot 2}{1\cdot 3}\right)\left(\frac{4\cdot 4}{3\cdot 5}\right)\left(\frac{6\cdot 6}{5\cdot 7}\right)\left(\frac{8\cdot 8}{7\cdot 9}\right)\cdots.$$

In the notation $\Gamma(n+1) = n!$, introduced later by Legendre, Euler also showed that $\Gamma(n+1) = n\Gamma(n)$ and so obtained $\Gamma(3/2)$, $\Gamma(5/2)$, and so forth.

Euler could have used (45) as his generalization of the factorial concept. In fact, it is often introduced today in the equivalent form, which Euler also gave, namely,

$$(47)\qquad \lim_{m\to\infty} \frac{m!\,(m+1)^n}{(n+1)(n+2)\cdots(n+m)}.$$

But the connection with Wallis's result led Euler to take up an integral already considered by Wallis, namely,

$$(48)\qquad \int_0^1 x^e(1-x)^n\,dx$$

wherein for Euler e and n are now arbitrary. Euler evaluated this integral by expanding $(1-x)^n$ by the binomial theorem and obtained

$$(49)\qquad \begin{aligned} &\int_0^1 x^e(1-x)^n\,dx \\ &\quad = \frac{1}{e+1} - \frac{n}{1(e+2)} + \frac{n(n-1)}{1\cdot 2(e+3)} - \frac{n(n-1)(n-2)}{1\cdot 2\cdot 3(e+4)} + \cdots. \end{aligned}$$

For $n = 0, 1, 2, 3, \ldots$ the sums on the right side are respectively

$$(50)\qquad \frac{1}{e+1}, \frac{1}{(e+1)(e+2)}, \frac{1\cdot 2}{(e+1)(e+2)(e+3)}, \frac{1\cdot 2\cdot 3}{(e+1)(e+2)(e+3)(e+4)}, \ldots.$$

Hence for positive integral n Euler found that

$$\int_0^1 x^e(1-x)^n\,dx = \frac{n!}{(e+1)(e+2)\cdots(e+n+1)}. \tag{51}$$

Euler now sought an expression for $n!$ with n arbitrary. By a series of transformations that would not be wholly acceptable to us today, Euler arrived at

$$n! = \int_0^1 (-\log x)^n\,dx. \tag{52}$$

This integral has meaning for almost all arbitrary n. It is called the second Eulerian integral, or, as Legendre later called it, the gamma function, and is denoted by $\Gamma(n+1)$. [Gauss let $\pi(n) = \Gamma(n+1)$]. Later, in 1781 (pub. 1794), Euler gave the modern form, which is obtained from (52) by letting $t = -\log x$,

$$\Gamma(n+1) = \int_0^\infty x^n e^{-x}\,dx. \tag{53}$$

The integral (48), which Legendre called the first Eulerian integral, became standardized as the beta function,

$$B(m,n) = \int_0^1 x^{m-1}(1-x)^{n-1}\,dx. \tag{54}$$

Euler discovered the relation between the two integrals,[36] namely,

$$B(m,n) = \frac{\Gamma(m)\Gamma(n)}{\Gamma(m+n)}.$$

In his *Exercices de calcul intégral*, Legendre made a profound study of the Eulerian integrals and arrived at the duplication formula

$$\Gamma(2x) = (2\pi)^{-1/2}\,2^{2x-(1/2)}\Gamma(x)\Gamma\left(x+\frac{1}{2}\right). \tag{55}$$

Gauss studied the gamma function in his work on the hypergeometric function[37] and extended Legendre's result to what is called the multiplication formula:

$$\Gamma(nx) = (2\pi)^{(1-n)/2}\,n^{nx-(1/2)}\Gamma(x)\Gamma\left(x+\frac{1}{n}\right)\Gamma\left(x+\frac{2}{n}\right)\cdots\Gamma\left(x+\frac{n-1}{n}\right). \tag{56}$$

out that complex roots occur in conjugate pairs, so that the product of $x - (a + b\sqrt{-1})$ and $x - (a - b\sqrt{-1})$, wherein $a + b\sqrt{-1}$ and $a - b\sqrt{-1}$ are a conjugate pair, gives a quadratic expression with real coefficients. Euler then showed that this was true for Bernoulli's example. But Goldbach, too, rejected the idea that every polynomial with real coefficients can be factored into real factors and gave the example $x^4 + 72x - 20$. Euler then showed Goldbach that the latter had made a mistake and that he (Euler) had proved his theorem for polynomials up to the sixth degree. However, Goldbach was not convinced, because Euler did not succeed in giving a general proof of his assertion.

The kernel of the problem of factoring a real polynomial into linear and quadratic factors with real coefficients was to prove that every such polynomial had at least one real or complex root. The proof of this fact, called the fundamental theorem of algebra, became a major goal.

Proofs offered by d'Alembert and Euler were incomplete. In 1772[1] Lagrange, in a long and detailed argument, "completed" Euler's proof. But Lagrange, like Euler and his contemporaries, applied freely the ordinary properties of numbers to what were supposedly the roots without establishing that the roots must at worst be complex numbers. Since the nature of the roots was unknown, the proof was actually incomplete.

The first substantial proof of the fundamental theorem, though not rigorous by modern standards, was given by Gauss in his doctoral thesis of 1799 at Helmstädt.[2] He criticized the work of d'Alembert, Euler, and Lagrange and then gave his own proof. Gauss's method was not to calculate a root but to demonstrate its existence. He points out that the complex roots $a + ib$ of $P(x + iy) = 0$ correspond to points (a, b) of the plane, and if $P(x + iy) = u(x, y) + iv(x, y)$ then (a, b) must be an intersection of the curves $u = 0$ and $v = 0$. By a qualitative study of the curves he shows that a continuous arc of one joins the points of two distinct regions separated by the other. Then the curve $u = 0$ must cut the curve $v = 0$. The argument was highly original. However, he depended on the graphs of these curves, which were somewhat complicated, to show that they must cross In this same paper Gauss proved that the nth degree polynomial can be expressed as a product of linear and quadratic factors with real coefficients.

Gauss gave three more proofs of the theorem. In the second proof[3] he dispensed with geometrical arguments. In this proof he also showed that the product of the differences of each two roots (which we, following Sylvester, call the discriminant) can be expressed as a linear combination of the polynomial and its derivative, so that a necessary and sufficient condition that the polynomial and its derivative have a common root is that the discriminant vanish. However, this second proof assumed that a polynomial cannot change signs at two different values of x without vanishing in between. The proof of this fact lay beyond the rigor of the time.

---

[3] *Comm. Soc. Gott.*, 3, 1814/15, 107–42 = *Werke*, 3, 33–56.

The third proof[4] used in effect what we now call the Cauchy integral theorem (Chap. 27, sec. 4).[5] The fourth proof[6] is a variation of the first as far as method is concerned. However, in this proof Gauss uses complex numbers more freely because, he says, they are now common knowledge. It is worth noting that the theorem was, in many proofs, not proved in all generality. Gauss's first three proofs and later proofs by Cauchy, Jacobi, and Abel assumed that the (literal) coefficients represented real numbers, whereas the full theorem includes the case of complex coefficients. Gauss's fourth proof did allow the coefficients of the polynomial to be complex numbers.

Gauss's approach to the fundamental theorem of algebra inaugurated a new approach to the entire question of mathematical existence. The Greeks had wisely recognized that the existence of mathematical entities must be established before theorems about them can be entertained. Their criterion of existence was constructibility. In the more explicit formal work of the succeeding centuries, existence was established by actually obtaining or exhibiting the quantity in question. For example, the existence of the solutions of a quadratic equation is established by exhibiting quantities that satisfy the equation. But in the case of equations of degree higher than four, this method is not available. Of course a proof of existence such as Gauss's may be of no help at all in computing the object whose existence is being established.

While the work that ultimately showed that every polynomial equation with real coefficients has at least one root was under way, the mathematicians also pushed hard to solve equations of degree higher than four by algebraic processes. Leibniz and his friend Tschirnhausen were the first to make serious efforts. Leibniz[7] reconsidered the irreducible case of the third degree equation and convinced himself that one could not avoid the use of complex numbers to solve this type. He then tackled the solution of the fifth degree equation but without success. Tschirnhausen[8] thought he had solved this problem by transforming the given equation into a new one by means of a transform $y = P(x)$, where $P(x)$ is a suitable fourth degree polynomial.

---

[8] *Acta Erud.*, 2, 1683, 204–07.

This transformation eliminated all but the x^5 and constant terms of the equation. But Leibniz showed that to determine the coefficients of $P(x)$ one had to solve equations of degree higher than five, and so the method was useless.

For a while the problem of solving the nth degree equation centered on the special case $x^n - 1 = 0$, called the binomial equation. Cotes and De Moivre showed, through the use of complex numbers, that the solution of this problem amounts to the division of the circumference of a circle into n equal parts. To obtain the roots by radicals (trigonometric solutions are not necessarily algebraic) it is sufficient to consider the case of n an odd prime, because if $n = pm$, where p is a prime, then one can consider $(x^m)^p - 1 = 0$. If this equation can be solved for x^m, then $x^m - A$ can be considered where A is any of the roots of the preceding equation. Alexandre-Théophile Vandermonde (1735–96) affirmed in a paper of 1771[9] that every equation of the form $x^n - 1 = 0$, where n is a prime, is solvable by radicals. However, Vandermonde merely verified that this is so for values of n up to 11. The decisive work on binomial equations was done by Gauss (Chap. 31, sec. 2).

The major effort toward solving equations of degree higher than four concentrated on the general equation, and toward this end some subsidiary work on symmetric functions proved important. The expression $x_1x_2 + x_2x_3 + x_3x_1$ is a symmetric function of x_1, x_2, and x_3 because replacement throughout of any x_i by an x_j and x_j by x_i leaves the entire expression unaltered. The interest in symmetric functions arose when the seventeenth-century algebraists noted and Newton proved that the various sums of the products of the roots of a polynomial equation can be expressed in terms of the coefficients. For example, for $n = 3$, the sum of the products taken two at a time,

$$a_1a_2 + a_2a_3 + a_3a_1$$

is an elementary symmetric function; and if the equation is written as

$$x^3 - c_1x^2 + c_2x - c_3 = 0,$$

the sum equals c_2. The progress made by Vandermonde in the 1771 paper was to show that any symmetric function of the roots can be expressed in terms of the coefficients of the equation.

The outstanding work of the eighteenth century on the problem of the solution of equations by radicals, after efforts by many men including Euler,[10] was by Vandermonde in the 1771 paper and Lagrange, in his massive paper "Réflexions sur la résolution algébrique des équations."[11] Vandermonde's

Elimination theory was also applied to two equations, $f(x, y) = 0$ and $g(x, y) = 0$, of degree higher than 1. The motivation was to establish the number of common solutions of the two equations or, geometrically, to find the number of intersections of the curves corresponding to the equations. The outstanding method for eliminating one unknown from $f(x, y) = 0$ and $g(x, y) = 0$, sketched first by Bezout in a paper of 1764, was presented by him in his *Théorie générale des équations algébriques* (1779). Bezout's idea was that by multiplying $f(x, y)$ and $g(x, y)$ by suitable polynomials, $F(x)$ and $G(x)$ respectively, he could form

$$R(y) = F(x)f(x, y) + G(x)g(x, y). \tag{11}$$

Moreover he sought an F and G such that the degree of $R(y)$ would be as small as possible.

The question of the degree of the eliminant was also answered by Bezout in his *Théorie* (and independently by Euler in the 1764 paper). Both gave the answer as mn, the product of the two degrees of f and g, and both proved this theorem by reducing the problem to one of elimination from an auxiliary set of linear equations. This product is the number of points of intersection of the two algebraic curves. Jacobi[22] and Minding[23] also gave Bezout's method of elimination for the two equations, but neither mentions Bezout. It could be that Bezout's work was not known to them.

4. *The Theory of Numbers*

The theory of numbers in the eighteenth century remained a series of disconnected results. The most important works in the subject were Euler's *Anleitung zur Algebra* (German edition, 1770) and Legendre's *Essai sur la théorie des nombres* (1798). The second edition appeared in 1808 under the title *Théorie des nombres*, and an expanded third edition in two volumes appeared in 1830. The problems and results to be described are a small sample of what was done.

In 1736 Euler established[24] the minor theorem of Fermat, namely, if p is a prime and a any positive integer, $a^p - a$ is divisible by p. Many proofs of this same theorem were given by other men in the eighteenth and nineteenth centuries. In 1760 Euler generalized this theorem[25] by introducing the ϕ function or totient of n; $\phi(n)$ is the number of integers $< n$ and prime to n so that if n is a prime, $\phi(n)$ is $n - 1$. [The notation $\phi(n)$ was introduced by Gauss.] Then Euler proved that if a is relatively prime to n,

$$a^{\phi(n)} - 1$$

is divisible by n.

As for the famous Fermat conjecture on $x^n + y^n = z^n$, Euler proved[26] this was correct for $n = 3$ and $n = 4$; the case $n = 4$ had been proven by Frénicle de Bessy. This work of Euler had to be completed by Lagrange, Legendre, and Gauss. Legendre then proved[27] the conjecture for $n = 5$. As we shall see, the history of the efforts to prove Fermat's conjecture is extensive.

Fermat had also conjectured (Chap. 13, sec. 7) that the formula

$$2^{2^n} + 1$$

yielded primes for an unspecified set of values of n. This is true for $n = 0$, 1, 2, 3, and 4. Fermat did not claim it was always true, and Euler showed in 1732[28] that 641 was a factor when $n = 5$. In fact the formula is now known not to yield primes for many other values of n, whereas no other value beyond 4 has been found for which the formula does yield primes. However, the formula is of interest in that it reappears in the work of Gauss on the constructibility of regular polygons (Chap. 31, sec. 2).

A topic with many subdivisions concerns the decomposition of integers of various types into other classes of integers. Fermat had affirmed that each positive integer is the sum of at most four squares (repetition of a square as in $8 = 4 + 4$ is permitted if it is counted the number of times it appears). Over a period of forty years, Euler kept trying to prove this theorem and gave partial results.[29] Using some of Euler's work, Lagrange[30] proved the theorem. Neither Euler nor Lagrange obtained the number of representations.

Euler, in the 1754/5 paper just referred to and in another paper in the same journal[31] proved Fermat's assertion that every prime of the form $4n + 1$ is decomposable uniquely into a sum of two squares. However, Euler's proof did not follow the method of descent that Fermat had sketched for this theorem. In another paper[32] Euler also proved that every divisor of the sum of two relatively prime squares is the sum of two squares.

Edward Waring (1734–98) stated, in his *Meditationes Algebraicae* (1770), the theorem known now as "Waring's theorem," that every integer is either a cube or the sum of at most nine cubes; also every integer is either a fourth power or the sum of at most 19 fourth powers. He conjectured also that every positive integer can be expressed as the sum of at most r kth powers, the r depending upon k. These theorems were not proven by him.[33]

[33] The general theorem was proven by David Hilbert (*Math. Ann.*, 67, 1909, 281–300).

In a letter to Euler of June 7, 1742, Christian Goldbach, a Prussian envoy to Russia, stated without proof that every even integer is the sum of two primes and every odd integer is either a prime or a sum of three primes. The first part of the assertion is now known as Goldbach's conjecture and is still an unsolved problem. The second assertion actually follows from the first, because if n is odd substract any prime p from it. Then $n - p$ is even.

Among somewhat more specialized results dealing with the decomposition of numbers is Euler's proof that $x^4 - y^4$ and $x^4 + y^4$ cannot be squares.[34] Euler and Lagrange proved many of Fermat's assertions to the effect that certain primes can be expressed in particular ways. For example Euler proved[35] that a prime of the form $3n + 1$ can be expressed uniquely in the form $x^2 + 3y^2$.

Amicable and perfect numbers continued to interest the mathematicians. Euler[36] gave 62 pairs of amicable numbers, including the three pairs already known. Two of his pairs were incorrect. He also proved in a posthumously published paper[37] the converse of Euclid's theorem: Every even perfect number is of the form $2^{p-1}(2^p - 1)$ where the second factor is prime.

John Wilson (1741–93), who had been a prize student of mathematics at Cambridge but became a lawyer and judge, stated a theorem still named after him: For every prime p, the quantity $(p - 1)! + 1$ is divisible by p; in addition, if the quantity is divisible by p, then p is a prime. Waring published the statement in his *Meditationes Algebraicae* and Lagrange proved it in 1773.[38]

The problem of solving the equation $x^2 - Ay^2 = 1$ in integers has already been discussed (Chap. 13, sec. 7). Euler, in a paper of 1732/33, erroneously called it Pell's equation, and the name has stuck. He became interested in this equation because he needed its solutions to solve $ax^2 + bx + c = y^2$ in integers; he wrote several papers on this last theme. In 1759 Euler gave a method of solving the Pellian equation by expressing $\sqrt{A}$ as a continued fraction.[39] Euler's idea was that the values x and y which satisfy the equation are such that the ratios x/y are convergents (in the sense of continued fractions) to $\sqrt{A}$. He failed to prove that his method always gives solutions and that all its solutions are given by the continued fraction development of $\sqrt{A}$. The existence of solutions of Pell's equation was shown in 1766 by Lagrange[40] and then more simply in later papers.[41]

Fermat had asserted that he could determine when the more general equation $x^2 - Ay^2 = B$ was solvable in integers and that he could solve it when solvable. The equation was solved by Lagrange in the two papers just mentioned.

The problem of giving all integral solutions of the general equation

$$ax^2 + 2bxy + cy^2 + 2dx + 2ey + f = 0,$$

where the coefficients are integers, was also tackled. Euler gave incomplete classes of solutions; then Lagrange[42] gave the complete solution. In the next volume of the *Mémoires*[43] he gave a simpler proof.

The most original and perhaps the most consequential discovery of the eighteenth century in the theory of numbers is the law of quadratic reciprocity. It uses the notion of quadratic remainders or residues. In the language introduced by Euler in the 1754/55 paper and adopted by Gauss, if there exists an x such that $x^2 - p$ is divisible by q, then p is said to be a quadratic residue of q; if there is no such x, p is said to be a quadratic nonresidue of q. Legendre (1808) invented a symbol that is now used to represent either state of affairs. The symbol is (p/q) and means the following: For any number p and any prime q,

$$(p/q) = \begin{cases} 1 & \text{if } p \text{ is a quadratic residue of } q \\ -1 & \text{if } p \text{ is a quadratic nonresidue of } q. \end{cases}$$

It is also understood that $(p/q) = 0$ if p divides evenly into q.

The law of quadratic reciprocity, in symbolic form, states that if p and q are distinct odd primes, then

$$(p/q)(q/p) = (-1)^{(p-1)(q-1)/4}.$$

This means that if the exponent of (-1) is even, p is a quadratic residue of q and q is a quadratic residue of p or neither is a quadratic residue of the other. When the exponent is odd, which occurs when p and q are of the form $4k + 3$, one prime will be a quadratic residue of the other but not the second of the first.

The history of this law is detailed. Euler in a paper of 1783[44] gave four theorems and a fifth summarizing theorem that states the law of quadratic reciprocity very clearly. However, he did not prove these theorems. The work on this paper dates from 1772 and incorporates even earlier work. Kronecker observed in 1875[45] that the statement of the law is actually contained in a much earlier paper by Euler.[46] However, Euler's "proof" was based on calculations. In 1785 Legendre announced the law independently, though he cites another paper by Euler, in the same volume of the *Opuscula*, in his own paper on the subject. His proof[47] was incomplete. In his *Théorie des nombres*[48] he again stated the law and gave another proof. However, this one, too, was incomplete, because he assumed that there are an infinite number of primes in certain arithmetic progressions. The desire to find what is behind the law and to derive its many implications has been a key theme in investigations since 1800 and has led to important discoveries, some of which we shall consider in a later chapter.

The eighteenth-century work on the theory of numbers closes with Legendre's classic *Théorie* of 1798. Though it contains a number of interesting results, in this domain as in others (such as the subject of elliptic integrals), Legendre made no great innovations. One could reproach him for presenting a collection of propositions from which general conceptions could have been extracted but were not. This was done by his successors.

Galois Theory

> Unfortunately what is little recognized is that the most worthwhile scientific books are those in which the author clearly indicates what he does not know; for an author most hurts his readers by concealing difficulties. EVARISTE GALOIS

1. *Introduction*

The basic problem of algebra, the solution of polynomial equations, continued to occupy the center of the stage in the algebra of the early nineteenth century. In this period, the broad question of which equations are solvable by algebraic operations was definitely and comprehensively answered by Galois. Moreover, he not only created the first significant coherent body of algebraic theory but he introduced new notions which were to be developed into still other broadly applicable theories of algebra. In particular the concepts of a group and a field emerged from his work and Abel's.

2. *Binomial Equations*

We have already discussed (Chap. 25, sec. 2) the fruitless efforts of Euler, Vandermonde, Lagrange, and Ruffini to solve algebraically equations of degree greater than 4 and the binomial equation $x^n - 1 = 0$. A major success was achieved by Gauss. In the last section of his *Disquisitiones Arithmeticae*[1] Gauss considered the equation

$$(1) \qquad x^p - 1 = 0,$$

where p is a prime.[2] This equation is often called the cyclotomic equation or the equation for the division of a circle. The latter term refers to the fact that the roots of this equation are, by de Moivre's theorem,

$$(2) \qquad x_j = \cos\frac{k2\pi\theta}{p} + i\sin\frac{k2\pi\theta}{p}, \qquad k = 1, 2, \ldots, p,$$

---

[1] 1801, *Werke*, I.

[2] The case of p prime takes care of $x^n - 1 = 0$ for if $n = pq$, let $y = x^q$. But $y^p - 1 = 0$ is solvable. Hence x^q = const. can be solved if q is a prime and if not q can be decomposed in the same manner that n is.

and the complex numbers x_j when plotted geometrically are the vertices of a p-sided regular polygon that lie on the unit circle.

Gauss showed that the roots of this equation may be rationally expressed in terms of the roots of a sequence of equations

$$Z_1 = 0, Z_2 = 0, \cdots, \tag{3}$$

whose coefficients are rational in the roots of the preceding equations of the sequence. The degrees of the equations (3) are precisely the prime factors of $p - 1$. There is a Z_i for each factor even if repeated. Moreover, each of the $Z_i = 0$ can be solved by radicals and so equation (1) can also be so solved.

This result is of course of great significance for the problem of solving the general nth-degree equation algebraically. It shows that some equations of high degree can be solved by radicals, for example a fifth degree equation if 5 is a factor of $p - 1$ or a seventh degree equation if 7 is a factor.

The result is of major importance also for the geometric problem of constructing regular polygons of p sides. If $p - 1$ contains no factors other than 2, then the polygon is constructible with straightedge and compass because the degrees of the equations (3) are each 2 and each of its roots is constructible in terms of its coefficients. Thus we are able to construct all polygons of a prime number of sides p if $p - 1$ is a power of 2. Such primes are 3, 5, 17, 257, 65537, ... Alternatively, a regular polygon can be constructed if p is a prime of the form $2^{2^h} + 1$.[3] Gauss remarks (Art. 365) that although the geometric construction of regular polygons of 3, 5, and 15 sides and those immediately derivable from them—for example, 2^n, $2^n \cdot 3$, $2^n \cdot 5$, $2^n \cdot 15$, wherein n is a positive integer—was known in Euclid's time, in an interval of 2000 years no new constructible polygons had been discovered and geometers had been unanimous in declaring that no others could be constructed.

Gauss thought that his result might lead to all sorts of attempts to find new constructible polygons of a prime number of sides. He warns then: "As often as $p - 1$ contains other prime factors besides 2, we arrive at higher equations, namely, to one or more cubic equations if 3 enters once or oftener as a factor of $p - 1$, to equations of the fifth degree if $p - 1$ is divisible by 5, etc. And we can prove with all rigor that these higher equations cannot be avoided or made to depend upon equations of lower degree; and although the limits of this work do not permit us to give the demonstration here, we still thought it necessary to note this fact in order that one should not seek to construct other polygons [of prime number of sides] than those given by our theory, as for example, polygons of 7, 11, 13, 19 sides, and so employ his time in vain."

Gauss then considers (Art. 366) polygons of any number of sides n and asserts that a regular polygon of n sides is constructible if and only if

---

[3] In a prime of the form $2^{\mu} + 1$, μ is necessarily of the form 2^h, but $2^{2^h} + 1$ is not necessarily prime.

$n = 2^l p_1 \cdot p_2 \cdots p_n$, where $p_1, p_2, \ldots, p_n$ are distinct primes of the form $2^{2^h} + 1$ and where l is any positive integer or 0. The sufficiency of this condition does follow readily from Gauss's work on polygons of a prime number of sides but the necessity is not at all obvious and was not proven by Gauss.[4]

The construction of regular polygons had interested Gauss since 1796 when he conceived the first proof that the 17-sided polygon is constructible. There is a story about this discovery which may bear repeating. This construction problem was already famous. One day Gauss approached his professor A. G. Kästner at the University of Göttingen with the proof that this polygon is constructible. Kästner was incredulous and sought to dismiss Gauss, much as university teachers today dismiss angle-trisectors. Rather than take the time to examine Gauss's proof and find the supposed error in it, Kästner told Gauss the construction was unimportant because practical constructions were known. Of course Kästner knew that the existence of practical or approximate constructions was irrelevant for the theoretical problem. To interest Kästner in his proof Gauss pointed out that he had solved a seventeenth degree algebraic equation. Kästner replied that the solution was impossible. But Gauss rejoined that he had reduced the problem to solving an equation of lower degree. "Oh well," scoffed Kästner, "I have already done this." Later Gauss repaid Kästner, who also prided himself on his poetry, by lauding Kästner as the best poet among mathematicians and the best mathematician among poets.

3. *Abel's Work on the Solution of Equations by Radicals*

Abel read Lagrange's and Gauss's work on the theory of equations and while still a student in high school tackled the problem of the solvability of higher degree equations by following Gauss's treatment of the binomial equation. At first Abel thought he had solved the general fifth degree equation by radicals. But soon convinced of his error he tried to prove that such a solution was not possible (1824–26). First he succeeded in proving the theorem: The roots of an equation solvable by radicals can be given such a form that each of the radicals occurring in the expressions for the roots is expressible as a rational function of the roots of the equation and certain roots of unity. Abel then used this theorem to prove[5] the impossibility of solving by radicals the general equation of degree greater than four.

Abel's proof, done in ignorance of Ruffini's work (Chap. 25, sec. 2), is

The Theory of Numbers in the Nineteenth Century

> It is true that Fourier had the opinion that the principal object of mathematics was public use and the explanation of natural phenomena; but a philosopher like him ought to know that the sole object of the science is the honor of the human spirit and that under this view a problem of [the theory of] numbers is worth as much as a problem on the system of the world.
>
> C. G. J. JACOBI

1. *Introduction*

Up to the nineteenth century the theory of numbers was a series of isolated though often brilliant results. A new era began with Gauss's *Disquisitiones Arithmeticae*[1] which he composed at the age of twenty. This great work had been sent to the French Academy in 1800 and was rejected but Gauss published it on his own. In this book he standardized the notation; he systematized the existing theory and extended it; and he classified the problems to be studied and the known methods of attack and introduced new methods. In Gauss's work on the theory of numbers there are three main ideas: the theory of congruences, the introduction of algebraic numbers, and the theory of forms as the leading idea in Diophantine analysis. This work not only began the modern theory of numbers but determined the directions of work in the subject up to the present time. The *Disquisitiones* is difficult to read but Dirichlet expounded it.

Another major nineteenth-century development is analytic number theory, which uses analysis in addition to algebra to treat problems involving the integers. The leaders in this innovation were Dirichlet and Riemann.

2. *The Theory of Congruences*

Though the notion of congruence did not originate with Gauss—it appears in the work of Euler, Lagrange, and Legendre—Gauss introduced the notation in the first section of *Disquisitiones* and used it systematically thereafter. The basic idea is simple. The number 27 is congruent to 3 modulo 4,

---

[1] Published 1801 = *Werke*, 1.

$$27 \equiv 3 \text{ modulo } 4,$$

because $27 - 3$ is exactly divisible by 4. (The word modulo is often abbreviated to mod.) In general, if a, b, and m are integers

$$a \equiv b \text{ modulo } m$$

if $a - b$ is (exactly) divisible by m or if a and b have the same remainders on division by m. Then b is said to be a residue of a modulo m and a is a residue of b modulo m. As Gauss shows, all the residues of a modulo m, for fixed a and m, are given by $a + km$ where $k = 0, \pm 1, \pm 2, \ldots$.

Congruences with respect to the same modulus can be treated to some extent like equations. Such congruences can be added, subtracted, and multiplied. One can also ask for the solution of congruences involving unknowns. Thus, what values of x satisfy

$$2x \equiv 25 \text{ modulo } 12?$$

This equation has no solutions because $2x$ is even and $2x - 25$ is odd. Hence $2x - 25$ cannot be a multiple of 12. The basic theorem on polynomial congruences, which Gauss re-proves in the second section, had already been established by Lagrange.[2] A congruence of the nth degree

$$Ax^n + Bx^{n-1} + \cdots + Mx + N \equiv 0 \text{ modulo } p$$

whose modulus is a prime number p which does not divide A cannot have more than n noncongruent roots.

In the third section Gauss takes up residues of powers. Here he gives a proof in terms of congruences of Fermat's minor theorem, which, stated in terms of congruences, reads: If p is a prime and a is not a multiple of p then

$$a^{p-1} \equiv 1 \text{ modulo } p.$$

The theorem follows from his study of congruences of higher degree, namely,

$$x^n \equiv a \text{ modulo } m$$

where a and m are relatively prime. This subject was continued by many men after Gauss.

The fourth section of *Disquisitiones* treats quadratic residues. If p is a prime and a is not a multiple of p and if there exists an x such that $x^2 \equiv a$ mod p, then a is a quadratic residue of p; otherwise a is a quadratic nonresidue of p. After proving some subordinate theorems on quadratic residues Gauss gave the first rigorous proof of the law of quadratic reciprocity (Chap.

---

[2] *Hist. de l'Acad. de Berlin*, 24, 1768, 192 ff., pub. 1770 = *Œuvres*, 2, 655–726.

25, sec. 4). Euler had given a complete statement much like Gauss's in one paper of his *Opuscula Analytica* of 1783 (Chap. 25, sec. 4). Nevertheless in article 151 of his *Disquisitiones* Gauss says that no one had presented the theorem in as simple a form as he had. He refers to other work of Euler including another paper in the *Opuscula* and to Legendre's work of 1785. Of these papers Gauss says rightly that the proofs were incomplete.

Gauss is supposed to have discovered a proof of the law in 1796 when he was nineteen. He gave another proof in the *Disquisitiones* and later published four others. Among his unpublished papers two more were found. Gauss says that he sought many proofs because he wished to find one that could be used to establish the biquadratic reciprocity theorem (see below). The law of quadratic reciprocity, which Gauss called the gem of arithmetic, is a basic result on congruences. After Gauss gave his proofs, more than fifty others were given by later mathematicians.

Gauss also treated congruences of polynomials. If A and B are two polynomials in x with, say, real coefficients then one knows that one can find unique polynomials Q and R such that

$$A = B \cdot Q + R,$$

where the degree of R is less than the degree of B. One can then say that two polynomials A_1 and A_2 are congruent modulo a third polynomial P if they have the same remainder R on division by P.

Cauchy used this idea[3] to define complex numbers by polynomial congruences. Thus if $f(x)$ is a polynomial with real coefficients then under division by $x^2 + 1$

$$f(x) \equiv a + bx \bmod x^2 + 1$$

because the remainder is of lower degree than the divisor. Here a and b are necessarily real by virtue of the division process. If $g(x)$ is another such polynomial then

$$g(x) \equiv c + dx \bmod x^2 + 1.$$

Cauchy now points out that if A_1, A_2, and B are any polynomials and if

$$A_1 = BQ_1 + R_1 \quad \text{and} \quad A_2 = BQ_2 + R_2,$$

then

$$A_1 + A_2 \equiv R_1 + R_2 \bmod B, \quad \text{and} \quad A_1A_2 \equiv R_1R_2 \bmod B.$$

We can now see readily that

$$f(x) + g(x) \equiv (a + c) + (b + d)x \bmod x^2 + 1$$

---

[3] *Exercices d'analyse et de physique mathématique*, 4, 1847, 84 ff. = *Œuvres*, (1), 10, 312–23 and (2), 14, 93–120.

and since $x^2 \equiv -1 \bmod x^2 + 1$ that

$$f(x)g(x) \equiv (ac - bd) + (ad + bc)x \bmod x^2 + 1.$$

Thus the numbers $a + bx$ and $c + dx$ combine like complex numbers; that is, they have the formal properties of complex numbers, x taking the place of i. Cauchy also proved that every polynomial $g(x)$ not congruent to 0 modulo $x^2 + 1$ has an inverse, that is, a polynomial $h(x)$ such that $h(x)g(x)$ is congruent to 1 modulo $x^2 + 1$.

Cauchy did introduce i for x, i being for him a real indeterminate quantity. He then showed that for any

$$f(i) = a_0 + a_1 i + a_2 i^2 + \cdots$$

that

$$f(i) \equiv a_0 - a_2 + a_4 - \cdots + (a_1 - a_3 + a_5 - \cdots)i \text{ modulo } i^2 + 1.$$

Hence any expression involving complex numbers behaves as one of the form $c + di$ and one has all the apparatus needed to work with complex expressions. For Cauchy, then, the polynomials in i, with his understanding about i, take the place of complex numbers and one can put into one class all those polynomials having the same residue modulo $i^2 + 1$. These classes are the complex numbers.

It is interesting that in 1847 Cauchy still had misgivings about $\sqrt{-1}$. He says, "In the theory of algebraic equivalences substituted for the theory of imaginary numbers the letter i ceases to represent the symbolic sign $\sqrt{-1}$, which we repudiate completely and which we can abandon without regret since one does not know what this supposed sign signifies nor what sense to attribute to it. On the contrary we represent by the letter i a real quantity but indeterminate and in substituting the sign $\equiv$ for $=$ we transform what has been called an imaginary equation into an algebraic equivalence relative to the variable i and to the divisor $i^2 + 1$. Since this divisor remains the same in all the formulas one can dispense with writing it."

In the second decade of the century Gauss proceeded to search for reciprocity laws applicable to congruences of higher degree. These laws again involve residues of congruences. Thus for the congruence

$$x^4 \equiv q \bmod p$$

one can define q as a biquadratic residue of p if there is an integral value of x satisfying the equation. He did arrive at a law of biquadratic reciprocity (see below) and a law of cubic reciprocity. Much of this work appeared in papers from 1808 to 1817 and the theorem proper on biquadratic residues was given in papers of 1828 and 1832.[4]

---

[4] *Comm. Soc. Gott.*, 6, 1828, and 7, 1832 = *Werke*, 2, 65–92 and 93–148; also pp. 165–78.

To attain elegance and simplicity in his theory of cubic and biquadratic residues Gauss made use of complex integers, that is, numbers of the form $a + bi$ with a and b integral or 0. In Gauss's work on biquadratic residues it was necessary to consider the case where the modulus p is a prime of the form $4n + 1$ and Gauss needed the complex factors into which prime numbers of the form $4n + 1$ can be decomposed. To obtain these Gauss realized that one must go beyond the domain of the ordinary integers to introduce the complex integers. Though Euler and Lagrange had introduced such integers into the theory of numbers it was Gauss who established their importance.

Whereas in the ordinary theory of integers the units are $+1$ and -1 in Gauss's theory of complex integers the units are ± 1 and $\pm i$. A complex integer is called composite if it is the product of two such integers neither of which is a unit. If such a decomposition is not possible the integer is called a prime. Thus $5 = (1 + 2i)(1 - 2i)$ and so is composite, whereas 3 is a complex prime.

Gauss showed that complex integers have essentially the same properties as ordinary integers. Euclid had proved (Chap. 4, sec. 7) that every integer is uniquely decomposable into a product of primes. Gauss proved that this unique decomposition, which is often referred to as the fundamental theorem of arithmetic, holds also for complex integers provided we do not regard the four unit numbers as different factors. That is, if $a = bc = (ib)(-ic)$, the two decompositions are the same. Gauss also showed that Euclid's process for finding the greatest common divisor of two integers is applicable to the complex integers.

Many theorems for ordinary primes carry over to the complex primes. Thus Fermat's theorem carries over in the form: If p be a complex prime $a + bi$ and k any complex integer not divisible by p then

$$k^{Np-1} \equiv 1 \text{ modulo } p$$

where Np is the norm $(a^2 + b^2)$ of p. There is also a law of quadratic reciprocity for complex integers, which was stated by Gauss in his 1828 paper.

In terms of complex integers Gauss was able to state the law of biquadratic reciprocity rather simply. One defines an uneven integer as one not divisible by $1 + i$. A primary uneven integer is an uneven integer $a + bi$ such that b is even and $a + b - 1$ is even. Thus -7 and $-5 + 2i$ are primary uneven numbers. The law of reciprocity for biquadratic residues states that if α and β are two primary uneven primes and A and B are their norms, then

$$\left(\frac{\alpha}{\beta}\right)_4 = (-1)^{(1/4)(A-1)(1/4)(B-1)}\left(\frac{\beta}{\alpha}\right)_4.$$

The symbol $(\alpha/\beta)_4$ has the following meaning: If p is any complex prime and k is any biquadratic residue not divisible by p, then $(k/p)_4$ is the power i^e of i which satisfies the congruence

$$k^{(Np-1)/4} \equiv 1 \text{ modulo } p$$

wherein Np stands for the norm of p. This law is equivalent to the statement: The biquadratic characters of two primary uneven prime numbers with respect to one another are identical, that is, $(\alpha/\beta)_4 = (\beta/\alpha)_4$, if either of the primes is congruent to 1 modulo 4; but if neither of the primes satisfies the congruence, then the two biquadratic characters are opposite, that is, $(\alpha/\beta)_4 = -(\beta/\alpha)_4$.

Gauss stated this reciprocity theorem but did not publish his proof. This was given by Jacobi in his lectures at Königsberg in 1836–37. Ferdinand Gotthold Eisenstein (1823–52), a pupil of Gauss, published five proofs of the law, of which the first two appeared in 1844.[5]

For cubic reciprocity Gauss found that he could obtain a law by using the "integers" $a + b\rho$ where ρ is a root of $x^2 + x + 1 = 0$ and a and b are ordinary (rational) integers but Gauss did not publish this result. It was found in his papers after his death. The law of cubic reciprocity was first stated by Jacobi[6] and proved by him in his lectures at Königsberg. The first published proof is due to Eisenstein.[7] Upon noting this proof Jacobi claimed[8] that it was precisely the one given in his lectures but Eisenstein indignantly denied any plagiarism.[9] There are also reciprocity laws for congruences of degree greater than four.

3. *Algebraic Numbers*

The theory of complex integers is a step in the direction of a vast subject, the theory of algebraic numbers. Neither Euler nor Lagrange envisioned the rich possibilities which their work on complex integers opened up. Neither did Gauss.

The theory grew out of the attempts to prove Fermat's assertion about $x^n + y^n = z^n$. The cases $n = 3$, 4, and 5 have already been discussed (Chap. 25, sec. 4). Gauss tried to prove the assertion for $n = 7$ but failed. Perhaps because he was disgusted with his failure, he said in a letter of 1816 to Heinrich W. M. Olbers (1758–1840), "I confess indeed that Fermat's theorem as an isolated proposition has little interest for me, since a multitude of such propositions, which one can neither prove nor refute, can easily be formulated." This particular case of $n = 7$ was disposed of by Lamé in 1839,[10] and Dirichlet established the assertion for $n = 14$.[11] However, the general proposition was unproven.

[9] *Jour. für Math.*, 35, 1847, 135–274 (p. 273).

It was taken up by Ernst Eduard Kummer (1810–93), who turned from theology to mathematics, became a pupil of Gauss and Dirichlet, and later served as a professor at Breslau and Berlin. Though Kummer's major work was in the theory of numbers, he made beautiful discoveries in geometry which had their origin in optical problems; he also made important contributions to the study of refraction of light by the atmosphere.

Kummer took $x^p + y^p$ where p is prime, and factored it into

$$(x + y)(x + \alpha y)\cdots(x + \alpha^{p-1}y),$$

where α is an imaginary pth root of unity. That is, α is a root of

$$(1) \qquad \alpha^{p-1} + \alpha^{p-2} + \cdots + \alpha + 1 = 0.$$

This led him to extend Gauss's theory of complex integers to algebraic numbers insofar as they are introduced by equations such as (1), that is, numbers of the form

$$f(\alpha) = a_0 + a_1\alpha + \cdots + a_{p-2}\alpha^{p-2},$$

where each a_i is an ordinary (rational) integer. (Since α satisfies (1), terms in α^{p-1} can be replaced by terms of lower power.) Kummer called the numbers $f(\alpha)$ complex integers.

By 1843 Kummer made appropriate definitions of integer, prime integer, divisibility, and the like (we shall give the standard definitions in a moment) and then made the mistake of assuming that unique factorization holds in the class of algebraic numbers that he had introduced. He pointed out while transmitting his manuscript to Dirichlet in 1843 that this assumption was necessary to prove Fermat's theorem. Dirichlet informed him that unique factorization holds only for certain primes p. Incidentally, Cauchy and Lamé made the same mistake of assuming unique factorization for algebraic numbers. In 1844 Kummer[12] recognized the correctness of Dirichlet's criticism.

To restore unique factorization Kummer created a theory of ideal numbers in a series of papers starting in 1844.[13] To understand his idea let us consider the domain of $a + b\sqrt{-5}$, where a and b are integers. In this domain

$$6 = 2\cdot 3 = (1 + \sqrt{-5})(1 - \sqrt{-5})$$

---

[10] *Jour. de Math.*, 5, 1840, 195–211.

[11] *Jour. für Math.*, 9, 1832, 390–93 = *Werke*, 1, 189–94.

[12] *Jour. de Math.*, 12, 1847, 185–212.

[13] *Jour. für Math.*, 35, 1847, 319–26, 327–67.

and all four factors can readily be shown to be prime integers. Then unique decomposition does not hold. Let us introduce, for this domain, the ideal numbers $\alpha = \sqrt{2}$, $\beta_1 = (1 + \sqrt{-5})/\sqrt{2}$, $\beta_2 = (1 - \sqrt{-5})/\sqrt{2}$. We see that $6 = \alpha^2\beta_1\beta_2$. Thus 6 is now uniquely expressed as the product of four factors, all ideal numbers as far as the domain $a + b\sqrt{-5}$ is concerned.[14] In terms of these ideals and other primes factorization in the domain is unique (apart from factors consisting of units). With ideal numbers one can prove some of the results of ordinary number theory in all domains that previously lacked unique factorization.

Kummer's ideal numbers, though ordinary numbers, do not belong to the class of algebraic numbers he had introduced. Moreover, the ideal numbers were not defined in any general way. As far as Fermat's theorem is concerned, with his ideal numbers Kummer did succeed in showing that it was correct for a number of prime numbers. In the first hundred integers only 37, 59, and 67 were not covered by Kummer's demonstration. Then Kummer in a paper of 1857[15] extended his results to these exceptional primes. These results were further extended by Dimitry Mirimanoff (1861–1945), a professor at the University of Geneva, by perfecting Kummer's method.[16] Mirimanoff proved that Fermat's theorem is correct for each n up to 256 if x, y, and z are prime to that exponent n.

Whereas Kummer worked with algebraic numbers formed out of the roots of unity, Richard Dedekind (1831–1916), a pupil of Gauss, who spent fifty years of his life as a teacher at a technical high school in Germany, approached the problem of unique factorization in an entirely new and fresh manner. Dedekind published his results in supplement 10 to the second edition of Dirichlet's *Zahlentheorie* (1871) which Dedekind edited. He extended these results in the supplements to the third and fourth editions of the same book.[17] Therein he created the modern theory of algebraic numbers.

Dedekind's theory of algebraic numbers is a generalization of Gauss's complex integers and Kummer's algebraic numbers but the generalization is somewhat at variance with Gauss's complex integers. A number r that is a root of

$$(2) \qquad a_0x^n + a_1x^{n-1} + \cdots + a_{n-1}x + a_n = 0,$$

where the a_i's are ordinary integers (positive or negative), and that is not a root of such an equation of degree less than n is called an algebraic number of degree n. If the coefficient of the highest power of x in (2) is 1, the solutions are called algebraic integers of degree n. The sum, difference, and product of algebraic integers are algebraic integers, and if an algebraic integer is a rational number it is an ordinary integer.

---

[14] With the introduction of the ideal numbers, 2 and 3 are no longer indecomposable, for $2 = \alpha^2$ and $3 = \beta_1\beta_2$.

[15] *Abh. König. Akad. der Wiss. Berlin*, 1858, 41–74.

[16] *Jour. für Math.*, 128, 1905, 45–68.

[17] 4th ed., 1894 = *Werke*, 3, 2–222.

We should note that under the new definitions an algebraic integer can contain ordinary fractions. Thus $(-13 + \sqrt{-115})/2$ is an algebraic integer of the second degree because it is a root of $x^2 + 13x + 71 = 0$. On the other hand $(1 - \sqrt{-5})/2$ is an algebraic number of degree 2 but not an algebraic integer because it is a root of $2x^2 - 2x + 3 = 0$.

Dedekind introduced next the concept of a number field. This is a collection F of real or complex numbers such that if α and β belong to F then so do $\alpha + \beta$, $\alpha - \beta$, $\alpha\beta$ and, if $\beta \neq 0$, α/β. Every number field contains the rational numbers because if α belongs then so does α/α or 1 and consequently $1 + 1$, $1 + 2$, and so forth. It is not difficult to show that the set of all algebraic numbers forms a field.

If one starts with the rational number field and θ is an algebraic number of degree n then the set formed by combining θ with itself and the rational numbers under the four operations is also a field of degree n. This field may be described alternatively as the smallest field containing the rational numbers and θ. It is also called an extension field of the rational numbers. Such a field does not consist of all algebraic numbers and is a specific algebraic number field. The notation $R(\theta)$ is now common. Though one might expect that the members of $R(\theta)$ are the quotients $f(\theta)/g(\theta)$ where $f(x)$ and $g(x)$ are any polynomials with rational coefficients, one can prove that if θ is of degree n, then any member α of $R(\theta)$ can be expressed in the form

$$\alpha = a_0\theta^{n-1} + a_1\theta^{n-2} + \cdots + a_{n-1},$$

where the a_i are ordinary rational numbers. Moreover, there exist algebraic integers $\theta_1, \theta_2, \ldots, \theta_n$ of this field such that all the algebraic integers of the field are of the form

$$A_1\theta_1 + A_2\theta_2 + \cdots + A_n\theta_n,$$

where the A_i are ordinary positive and negative integers.

A ring, a concept introduced by Dedekind, is essentially any collection of numbers such that if α and β belong, so do $\alpha + \beta$, $\alpha - \beta$, and $\alpha\beta$. The set of all algebraic integers forms a ring as does the set of all algebraic integers of any specific algebraic number field.

The algebraic integer α is said to be divisible by the algebraic integer β if there is an algebraic integer γ such that $\alpha = \beta\gamma$. If j is an algebraic integer which divides every other integer of a field of algebraic numbers then j is called a unit in that field. These units, which include $+1$ and -1, are a generalization of the units $+1$ and -1 of ordinary number theory. The algebraic integer α is a prime if it is not zero or a unit and if any factorization of α into $\beta\gamma$, where β and γ belong to the same algebraic number field, implies that β or γ is a unit in that field.

Now let us see to what extent the fundamental theorem of arithmetic holds. In the ring of *all* algebraic integers there are no primes. Let us consider the ring of integers in a specific algebraic number field $R(\theta)$, say the field $a + b\sqrt{-5}$, where a and b are ordinary rational numbers. In this field unique factorization does not hold. For example,

$$21 = 3 \cdot 7 = (4 + \sqrt{-5})(4 - \sqrt{-5}) = (1 + 2\sqrt{-5})(1 - 2\sqrt{-5}).$$

Each of these last four factors is prime in the sense that it cannot be expressed as a product of the form $(c + d\sqrt{-5})(e + f\sqrt{-5})$ with c, d, e, and f integral.

On the other hand let us consider the field $a + b\sqrt{6}$ where a and b are ordinary rational numbers. If one applies the four algebraic operations to these numbers one gets such numbers. If a and b are restricted to integers one gets the algebraic integers (of degree 2) of this domain. In this domain we can take as an equivalent definition of unit that the algebraic integer M is a unit if $1/M$ is also an algebraic integer. Thus 1, -1, $5 - 2\sqrt{6}$, and $5 + 2\sqrt{6}$ are units. Every integer is divisible by any one of the units. Further, an algebraic integer of the domain is prime if it is divisible only by itself and the units. Now

$$6 = 2 \cdot 3 = \sqrt{6} \cdot \sqrt{6}.$$

It would seem as though there is no unique decomposition into primes. But the factors shown are not primes. In fact

$$6 = 2 \cdot 3 = \sqrt{6} \cdot \sqrt{6} = (2 + \sqrt{6})(-2 + \sqrt{6})(3 + \sqrt{6})(3 - \sqrt{6}).$$

Each of the last four factors is a prime in the domain and unique decomposition does hold in this domain.

In the ring of integers of a specific algebraic number field factorization of the algebraic integers into primes is always possible but *unique* factorization does not generally hold. In fact for domains of the form $a + b\sqrt{-D}$, where D may have any positive integral value not divisible by a square, the unique factorization theorem is valid only when $D = 1, 2, 3, 7, 11, 19, 43, 67$, and 163, at least for D's up to 10^9.[18] Thus the algebraic numbers themselves do not possess the property of unique factorization.

4. *The Ideals of Dedekind*

Having generalized the notion of algebraic number, Dedekind now undertook to restore unique factorization in algebraic number fields by a scheme quite different from Kummer's. In place of ideal numbers he introduced

---

[18] H. M. Stark has shown that the above values of D are the only ones possible. See his "On the Problem of Unique Factorization in Complex Quadratic Fields," *Proceedings of Symposia in Pure Mathematics*, XII, 41–56, Amer. Math. Soc., 1969.

does. The latter is not the necessary geometry of physical space; its physical truth cannot be guaranteed on any a priori grounds. This realization, which did not call for any technical mathematical development because this had already been done, was first achieved by Gauss.

Carl Friedrich Gauss (1777–1855) was the son of a mason in the German city of Brunswick and seemed destined for manual work. But the director of the school at which he received his elementary education was struck by Gauss's intelligence and called him to the attention of Duke Karl Wilhelm. The Duke sent Gauss to a higher school and then in 1795 to the University of Göttingen. Gauss now began to work hard on his ideas. At eighteen he invented the method of least squares and at nineteen he showed that the 17-sided regular polygon is constructible. These successes convinced him that he should turn from philology to mathematics. In 1798 he transferred to the University of Helmstädt and there he was noticed by Johann Friedrich Pfaff who became his teacher and friend. After finishing his doctor's degree Gauss returned to Brunswick where he wrote some of his most famous papers. This work earned for him in 1807 the appointment as professor of astronomy and director of the observatory at Göttingen. Except for one visit to Berlin to attend a scientific meeting he remained at Gottingen for the rest of his life. He did not like to teach and said so. However, he did enjoy social life, was married twice, and raised a family.

Gauss's first major work was his doctoral thesis in which he proved the fundamental theorem of algebra. In 1801 he published the classic *Disquisitiones Arithmeticae*. His mathematical work in differential geometry, the "Disquisitiones Generales circa Superficies Curvas" (General Investigations of Curved Surfaces, 1827), which, incidentally, was the outcome of his interest in surveying, geodesy, and map-making, is a mathematical landmark (Chap. 37, sec. 2). He made many other contributions to algebra, complex functions, and potential theory. In unpublished papers he recorded his innovative work in two major fields: the elliptic functions and non-Euclidean geometry.

His interests in physics were equally broad and he devoted most of his energy to them. When Giuseppe Piazzi (1746–1826) discovered the planet Ceres in 1801 Gauss undertook to determine its path. This was the beginning of his work in astronomy, the activity that absorbed him most and to which he devoted about twenty years. One of his great publications in this area is his *Theoria Motus Corporum Coelestium* (Theory of Motion of the Heavenly Bodies, 1809). Gauss also earned great distinction in his physical research on theoretical and experimental magnetism. Maxwell says in his *Electricity and Magnetism* that Gauss's studies of magnetism reconstructed the whole science, the instruments used, the methods of observation, and the calculation of results. Gauss's papers on terrestrial magnetism are models of physical research and supplied the best method of measuring the earth's magnetic

of surfaces, from the (modern) definition of a surface to Gauss's *Theorema Egregium*. Chapter 5 studies geodesics on a surface, up to the proof of their existence and local uniqueness.

The remaining chapters (and some of the chapters' supplementary material; see below) are devoted instead to global properties. Chapter 2 discusses some fundamental results in the global theory of plane curves, including the *Jordan curve theorem*, which is a good example of the relatively belated development of the interest in global properties of curves: the statement of the Jordan curve theorem seems obvious until you try to actually prove it — and then it turns out to be surprisingly difficult, and far deeper than expected.

Chapter 6 is devoted to the Gauss-Bonnet theorem, with a complete proof is given, and to some of its innumerable applications. Finally, in Chapter 7, we discuss a few important results about the global theory of surfaces (one of them, the Hartman-Nirenberg theorem, proved only in 1959), mainly focusing on the connections between the sign of Gaussian curvature and the global (topological and differential) structure of surfaces. We shall confine ourselves to curves and surfaces in the plane and in space; but the language and the methods we shall introduce are compatible with those used in differential geometry of manifolds of any dimension, and so this book can be useful as a training field before attacking n-dimensional manifolds.

We have attempted to provide several possible paths for using this book as a textbook. A minimal path consists in just dealing with local theory: Chapters 1, 3, and 4 can be read independently of the remaining ones, and can be used to offer, in a two-month course, a complete route from initial definitions to Gauss's Theorema Egregium; if time permits, the first two sections of Chapter 5 can be added, describing the main properties of geodesics. Such a course is suitable and useful both for Mathematics (of course) and Physics students, from the second year on, and for Engineering and Computer Science students (possibly for a Master degree) who need (or are interested in) more advanced mathematical techniques than those learnt in a first-level degree.

In a one-semester course, on the other hand, it is possible to adequately cover the global theory too, introducing Chapter 2 about curves, the final section of Chapter 5 about vector fields, and, at the professor's discretion, Chapter 6 about the Gauss-Bonnet theorem or Chapter 7 about the classification of closed surfaces with constant Gaussian curvature. In our experience, in a one-semester course given to beginning or intermediate undergraduate Mathematics or Physics students, it is difficult to find time to cover both topics, so the two chapters are completely independent; but in the case of an one-year course, or in an one-semester course for advanced students, it might be possible to do so, possibly even touching upon some of the supplementary material (see below).

Each chapter comes with several guided problems, that is, solved exercises, both computational (one of the nice features of local differential geometry of curves and surfaces is that almost everything can be explicitly computed — well, with the exception of geodesics) and of a more theoretical character,

6.2 The Gauss Map

In Section 2.2, given any closed, simple, regular curve $\gamma : I \to \mathbb{R}^2$ in the plane, we defined the tangential indicatrix to be the curve given by $\vec{T} : I \to \mathbb{R}^2$, the unit tangent vector of $\gamma(t)$. The image of $\vec{T}$ lies on the unit circle, and though $\vec{T}$ is a closed curve, it need not be regular as its locus may stop and double back. Regardless of the parametrization, the tangential indicatrix is well defined up to a change in sign.

On any regular surface S in $\mathbb{R}^3$, the tangent plane T_pS at a point $p \in S$ is a two-dimensional subspace of $\mathbb{R}^2$, and hence the vectors that are normal to S at p form a one-dimensional subspace. Thus, there exist exactly two possible choices for a unit normal vector. Proposition 5.5.4 implies that if the surface is orientable, we can specify its orientation by a continuous function $n : S \to \mathbb{S}^2$, where $\mathbb{S}^2$ means the unit sphere in $\mathbb{R}^3$.

Definition 6.2.1. Let S be an oriented regular surface in $\mathbb{R}^3$ with an orientation $n : S \to \mathbb{S}^2$. In the classical theory of surfaces, the function n is also called the *Gauss map*.

It is important to remain aware of the distinction between the functions n and $\vec{N}$. Let S be an oriented surface with orientation $n : S \to \mathbb{S}^2$. Suppose that $\vec{X} : U \to \mathbb{R}^3$, where U is an open subset of $\mathbb{R}^2$, parametrizes a neighborhood of S, then the function $\vec{N} : U \to \mathbb{S}^2$ is defined in reference to $\vec{X}$ by Equation (5.9). The functions n and $\vec{N}$ are related by the fact that if $\vec{X}$ is a positively oriented parametrization, then

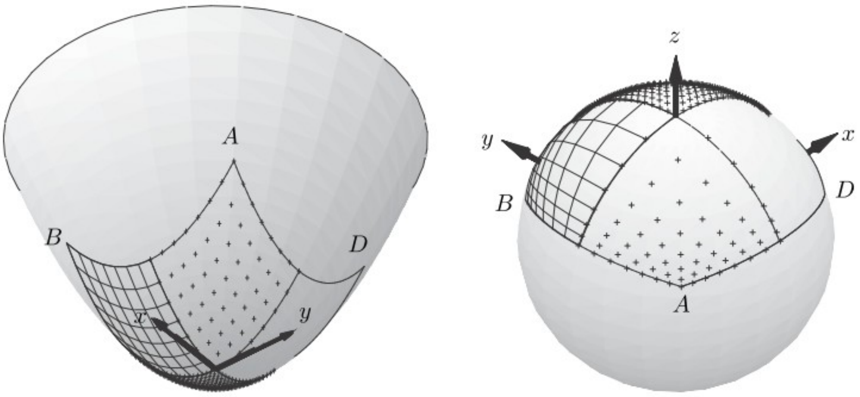
$$\vec{N} = n \circ \vec{X}.$$

Example 6.2.2. Consider as an example a sphere S in $\mathbb{R}^3$ equipped with the orientation n, with the unit vectors normal to S pointing away from the center $\vec{c}$ of the sphere. The sphere can be given as the solution to the equation

$$\|\vec{x} - \vec{c}\|^2 = R^2. \tag{6.10}$$

Recall that $\|\vec{v}\|^2 = \vec{v} \cdot \vec{v}$. If $\vec{x}(t)$ is any curve on the sphere, then by differentiating the relationship in Equation (6.10), one obtains

$$\vec{x}\,'(t) \cdot (\vec{x}(t) - \vec{c}) = 0.$$



(a) Elliptic paraboloid (b) Unit sphere

Figure 6.4. Gauss map on the elliptic paraboloid.

The tangent plane to the sphere S at a point $\vec{p}$ consists of all possible vectors $\vec{x}'(t_0)$, where $\vec{x}(t)$ is a curve on S, with $\vec{x}(t_0) = \vec{p}$. Therefore, at any point $\vec{p}$ on the sphere, there are two options for unit normal vectors:

$$\frac{\vec{p}-\vec{c}}{\|\vec{p}-\vec{c}\|} \qquad \text{or} \qquad -\frac{\vec{p}-\vec{c}}{\|\vec{p}-\vec{c}\|}$$

However, it is the former that provides the outward-pointing orientation n. Thus the Gauss map for the sphere of radius R and center $\vec{c}$ is explicitly

$$n(\vec{p}) = \frac{\vec{p}-\vec{c}}{R}.$$

Furthermore, if S is itself the unit sphere centered at the origin, then the Gauss map is the identity function.

Example 6.2.3. Consider the elliptic paraboloid S defined by the equation $z = x^2 + y^2$. This is an orientable surface, and suppose it is oriented with the unit normal always pointing in a positive z-direction. (Figure 6.4 shows this is possible.) Using the function $F(x, y, z) = z - x^2 - y^2$, the elliptic paraboloid is given by the equation $F(x, y, z) = 0$. By Proposition 5.2.13, for all $(x, y, z) \in S$, the gradient $\vec{\nabla} F(x,y,z)$ is a normal vector, so (since the z-direction is positive) the Gauss map is

$$n(x,y,z) = \frac{(-2x,-2y,1)}{\sqrt{4x^2+4y^2+1}}.$$

Figure 6.4 shows how the Gauss map acts on the patch

$$\{(x,y,z) \in S \mid -1 \leq x \leq 1 \text{ and } -1 \leq y \leq 1\}.$$

It is not hard to show that the image of the Gauss map on the unit sphere is the upper hemisphere. Indeed, using cylindrical coordinates, the Gauss map is

$$n(r,\theta,z) = \frac{(-2r\cos\theta, -2r\sin\theta, 1)}{\sqrt{4r^2+1}}.$$

The function $f(r) = 1/\sqrt{4r^2+1}$ is a decreasing bijection from $[0,+\infty)$ to $(0,1]$. Thus, for any $z_0 \in (0,1]$, there exists a unique $r_0 \in [0,+\infty)$ with $f(r_0) = z_0$. Then, with $\theta \in [0,2\pi]$, the image of $n(r_0,\theta,z_0)$ is a circle on the unit sphere at height z_0. Thus, the image of n is

$$n(S) = \{(x,y,z) \in \mathbb{S}^2 \mid z > 0\}.$$

Example 6.2.4. In contrast to Example 6.2.3, consider the hyperbolic paraboloid given by the parametrization $\vec{X} : \mathbb{R}^2 \to \mathbb{R}^3$, with

$$\vec{X}(u,v) = (u,v,u^2-v^2).$$

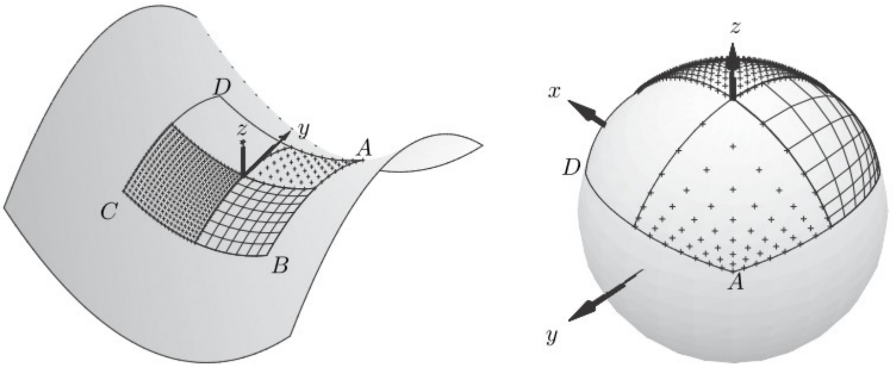
We calculate

$$\vec{X}_u = (1,0,2u) \qquad \text{and} \qquad \vec{X}_v = (0,1,-2v),$$

and thus,

$$\vec{N} = \frac{\vec{X}_u \times \vec{X}_v}{\|\vec{X}_u \times \vec{X}_v\|} = \frac{(-2u,2v,1)}{\sqrt{4u^2+4v^2+1}}.$$

Like Figure 6.4, Figure 6.5 shows the Gauss map for a “square” on the hyperbolic paraboloid. These two examples manifest a central behavior of the Gauss map. On the elliptic paraboloid, the Gauss



(a) Hyperbolic paraboloid (b) Unit sphere

Figure 6.5. Gauss map on the hyperbolic paraboloid.

map preserves the orientation of the square in the sense that if one travels along the boundary in a clockwise sense on the surface, one also travels along the boundary of the image of the square mapped by n in a clockwise sense. On the other hand, with the hyperbolic paraboloid, the Gauss map reverses the orientation of the square.

Proposition 6.2.5. *Let S be a regular surface in $\mathbb{R}^3$, and let $\vec{X} : U \to \mathbb{R}^3$ be a parametrization of a coordinate patch $V = \vec{X}(U)$, where U is an open set in $\mathbb{R}^2$. Define the vector function $\vec{N} : U \to \mathbb{R}^3$ by*

$$\vec{N} = \frac{\vec{X}_u \times \vec{X}_v}{\|\vec{X}_u \times \vec{X}_v\|}.$$

If $\vec{X}$ is of class C^r, then $\vec{N}$ is of class C^{r-1}.

Proof: By Problem 3.1.10, we deduce that if $\vec{F} : U \to \mathbb{R}^3$, $\vec{G} : U \to \mathbb{R}^3$, and $h : U \to \mathbb{R}$ are of class C^1, then the three functions $\vec{F} \cdot \vec{G} : U \to \mathbb{R}$, $\vec{F} \times \vec{G} : U \to \mathbb{R}^3$, and $h\vec{F} : U \to \mathbb{R}^3$ are also of class C^1, and their partial derivatives follow appropriate product rules. By definition,

$$\vec{N} = \frac{\vec{X}_u \times \vec{X}_v}{\sqrt{(\vec{X}_u \times \vec{X}_v) \cdot (\vec{X}_u \times \vec{X}_v)}}.$$

One can see that any partial derivative of any order of $\vec{N}$ will involve the partial derivative of a combination of the above three types of products and the derivative of an expression of the form

$$f(u,v) = \Big((\vec{X}_u \times \vec{X}_v) \cdot (\vec{X}_u \times \vec{X}_v) \Big)^{-k/2},$$

where k is an odd positive integer. Since S is regular, $\|\vec{X}_u \times \vec{X}_v\|$ is never 0, so a particular higher derivative of $\vec{N}$ will exist if that higher derivative exists for $\vec{X}_u$ and for $\vec{X}_v$. The proposition follows. □

One would be correct to think that the different behaviors in Figures 6.4 and 6.5 can be illustrated and quantified by a function between tangent spaces to S and $\mathbb{S}^2$, respectively. This perspective is encapsulated in the notion of the differential of functions between regular surfaces. We develop the more general theory of differentials of functions between manifolds in Chapter 3 of [22]. However, the differential of the Gauss map, though only a particular case of the differentials of functions between surfaces, serves a central role in the rest of this chapter.

Let S be a regular oriented surface with orientation n, and let $\vec{X} : U \to \mathbb{R}^3$ be a regular positively oriented parametrization of a coordinate patch $\vec{X}(U)$ of S. Suppose also that S is of class C^2, which, according to Proposition 6.2.5, implies that $\vec{N}$ is of class C^1. Since $\vec{N} \cdot \vec{N} = 1$ for all $(u,v) \in U$, we have

$$\vec{N} \cdot \vec{N}_u = 0 \qquad \text{and} \qquad \vec{N} \cdot \vec{N}_v = 0 \tag{6.11}$$

for all $(u,v) \in U$. Therefore, both derivatives $\vec{N}_u$ and $\vec{N}_v$ are vector functions such that $\vec{N}_u(q)$ and $\vec{N}_v(q)$ are in T_pS when $\vec{X}(q) = p$.

The vector function $\vec{N} : U \to \mathbb{R}^3$ is itself a parametrized surface, with its image lying in the unit sphere, though not necessarily giving a regular parametrization of $\mathbb{S}^2$. The simple fact in Equation (6.11) indicates that if $\vec{N}$ admits a tangent plane at $q \in U$, then

$$T_pS = T_{\vec{N}(q)}(\mathbb{S}^2) \tag{6.12}$$

as subspaces of $\mathbb{R}^3$. In other words, the sets of vectors $\{\vec{X}_u, \vec{X}_v\}$ and $\{\vec{N}_u, \vec{N}_v\}$ span the same subspace T_pS.

The differential of the Gauss map at a point $p \in S$ is a linear transformation $dn_p : T_pS \to T_{n(p)}(\mathbb{S}^2)$, but by virtue of Equation (6.12), one identifies it as a linear transformation $dn_p : T_pS \to T_pS$. For all $\vec{v} \in T_pS$, one defines $dn_p(\vec{v}) = \vec{w}$ if there exists a curve $\vec{\alpha} : I \to U$ such that

$$\begin{cases} \vec{\alpha}(0) = q, \text{ with } \vec{X}(q) = p, \\ \dfrac{d}{dt}\left(\vec{X} \circ \vec{\alpha}\right)(t)\big|_{t=0} = \vec{v}, \text{ and} \\ \dfrac{d}{dt}\left(\vec{N} \circ \vec{\alpha}\right)(t)\big|_{t=0} = \vec{w}. \end{cases} \tag{6.13}$$

In other words, by writing $\vec{X}(t) = \vec{X} \circ \vec{\alpha}(t)$ and $\vec{N}(t) = \vec{N} \circ \vec{\alpha}(t)$, the differential of the Gauss map satisfies $dn_p(\vec{X}'(0)) = \vec{N}'(0)$.

Using coordinate lines $\vec{X}(t, v_0)$ or $\vec{X}(u_0, t)$ for the curve $\vec{\alpha}(t)$ in the above definition, it is easy to see that

$$\begin{aligned} dn_p(\vec{X}_u) &= \vec{N}_u, \\ dn_p(\vec{X}_v) &= \vec{N}_v. \end{aligned} \tag{6.14}$$

Though the Gauss map $n : S \to \mathbb{S}^2$ is independent of any coordinate systems on S, the differential dn_p requires reference to a regular positively oriented parametrization of a neighborhood of p. However, though different parametrizations of a neighborhood of p induce different coordinate bases on T_pS, the definition in Equation 6.13 remains unchanged and consequently, as a linear transformation of T_pS to itself, is independent of the parametrization.

Problems

6.2.1. Describe the region of the unit sphere covered by the image of the Gauss map for the following surfaces:

(a) The hyperbolic paraboloid given by $z = x^2 - y^2$.
(b) The hyperboloid of one sheet given by $x^2 + y^2 - z^2 = 1$.
(c) The cone with opening angle α given by $z^2 \tan^2 \alpha = x^2 + y^2$.
(d) The right circular cylinder $x^2 + y^2 = R^2$, with R a constant.

6.2.2. What regular surface S has a single point on $\mathbb{S}^2$ as the image of the Gauss map?

6.5 Gaussian and Mean Curvature

We now arrive at two fundamental geometric invariants that encapsulate a considerable amount of useful information about the local shape of a surface. Again, in this section, we must assume that S is a regular surface of class C^2.

Definition 6.5.1. Let κ_1 and κ_2 be the principal curvatures of a regular surface S at a point p. Define

1. the *Gaussian curvature* of S at p as the product $K = \kappa_1 \kappa_2$;
2. the *mean curvature* of S at p as the average $H = \frac{\kappa_1+\kappa_2}{2}$ of the principal curvatures.

By Problem 6.3.6, the matrix for the Gauss map in terms of any particular coordinate system on a neighborhood of p on S is conjugate to the corresponding matrix for a different coordinate system via the change of basis matrix $\left(\frac{\partial x_i}{\partial \bar{x}_j}\right)$. Therefore, since $\det(BAB^{-1}) = \det(A)$ and $\operatorname{Tr}(BAB^{-1}) = \operatorname{Tr}(A)$, which is a standard result in linear algebra, the eigenvalues of the Gauss map, the principal curvatures, the Gaussian curvature, and the mean curvature are invariant under coordinate changes. Furthermore, since $\det(-A) = \det(A)$ when A is a square matrix with an even number of rows, then

$$\begin{aligned} K &= \kappa_1 \kappa_2 = \det(a_i^j) = \det(dn_p), \\ H &= \frac{\kappa_1 + \kappa_2}{2} = -\frac{1}{2}\operatorname{Tr}(a_i^j) = -\frac{1}{2}\operatorname{Tr}(dn_p). \end{aligned}$$

Consequently, as claimed above, the Gaussian curvature and the mean curvature of S at p are geometric invariants. This means that they do not depend on the orientation or position of S in space, and they do not depend on any particular coordinate system on S in a neighborhood of the point p.

In order to calculate the mean curvature $H(u,v)$, one has no choice but to calculate the matrix of the differential of the Gauss map $(a_j^i) = [dn_p]$. However, from a computational perspective, Equation (6.26) leads to a much simpler formula for the Gaussian curvature function $K(u,v)$. Recall that $\det(AB) = \det(A)\det(B)$ for all square matrices of the same size and also that $\det(A^{-1}) = 1/\det(A)$. Then Equation (6.26) implies that

$$K = \frac{\det(L_{ij})}{\det(g_{ij})} = \frac{L_{11}L_{22} - L_{12}^2}{g_{11}g_{22} - g_{12}^2}. \tag{6.37}$$

This equation lends itself readily to calculations since one does not need to fully compute the matrix of the Gauss map, let alone find its eigenvalues. However, we can also obtain an alternate characterization of the Gaussian curvature.

Proposition 6.5.2. *Let S be a regular surface of class C^2, and let V be a neighborhood parametrized by $\vec{X} : U \subset \mathbb{R}^2 \to \mathbb{R}^3$. Define the unit normal vector $\vec{N}$ as*

$$\vec{N} = \frac{\vec{X}_u \times \vec{X}_v}{\|\vec{X}_u \times \vec{X}_v\|}.$$

Then over the domain U, the Gaussian curvature is the unique function $K(u, v)$ satisfying

$$\vec{N}_u \times \vec{N}_v = K(u, v)\vec{X}_u \times \vec{X}_v$$

Proof: From the definition of the (a_j^i) functions in Equation (6.22), we have

$$\vec{N}_u \times \vec{N}_v = (a_1^1\vec{X}_u + a_1^2\vec{X}_v) \times (a_2^1\vec{X}_u + a_2^2\vec{X}_v).$$

It is then easy to see that

$$\vec{N}_u \times \vec{N}_v = \det(a_j^i)\vec{X}_u \times \vec{X}_v.$$

The result follows since $K = \det(a_j^i)$. □

Example 6.5.3 (Spheres). Consider the sphere parametrized by the vector function

$$\vec{X}(u, v) = (R\cos u \sin v, R\sin u \sin v, R\cos v),$$

with $(u, v) \in (0, 2\pi) \times (0, \pi)$. Example 6.1.5 and Example 6.3.3 gave us

$$(g_{ij}) = \begin{pmatrix} R^2\sin^2 v & 0 \\ 0 & R^2 \end{pmatrix} \quad \text{and} \quad (L_{ij}) = \begin{pmatrix} -R\sin^2 v & 0 \\ 0 & -R \end{pmatrix}.$$

Using Equation (6.37), it is then easy to see that the Gaussian curvature function on the sphere is

$$K(u,v)=\frac{R^2\sin^2 v}{R^4\sin^2 v}=\frac{1}{R^2},$$

which is a constant function. (Note that we assumed that $v\neq 0,\ \pi$, which correspond to the north and south poles of the parametrization. However, another parametrization that includes the north and south poles would show that at these points as well we have $K=1/R^2$.)

The matrix of the Gauss map is then

$$[dn_p]=-Lg^{-1}=\begin{pmatrix}-\frac{1}{R} & 0\\ 0 & -\frac{1}{R}\end{pmatrix},$$

from which one immediately deduces that the principal curvatures are $\kappa_1(u,v)=\kappa_2(u,v)=\frac{1}{R}$. This shows that all points on the sphere are umbilical points. In addition, the mean curvature is also a constant function $H(u,v)=\frac{1}{R}$.

Example 6.5.4 (Function Graphs). Consider the graph of a function $f:U\subset\mathbb{R}^2\to\mathbb{R}$. The graph can be parametrized by $\vec{X}:U\to\mathbb{R}^3$, with

$$\vec{X}(u,v)=(u,v,f(u,v)).$$

Problem 6.3.7 asks the reader to calculate the matrix (L_{ij}). It is not hard to show that

$$(g_{ij})=\begin{pmatrix}1+(f_u)^2 & f_uf_v\\ f_vf_u & 1+(f_v)^2\end{pmatrix}\qquad\text{and}\qquad (L_{ij})=\frac{1}{\sqrt{1+f_u^2+f_v^2}}\begin{pmatrix}f_{uu} & f_{uv}\\ f_{vu} & f_{vv}\end{pmatrix},$$

where f_u is the typical shorthand to mean $\frac{\partial f}{\partial u}$. But then $\det(g)=1+f_u^2+f_v^2$, and we find that the Gaussian curvature function on a function graph is

$$K(u,v)=\frac{1}{(1+f_u^2+f_v^2)^2}\begin{vmatrix}f_{uu} & f_{uv}\\ f_{vu} & f_{vv}\end{vmatrix}=\frac{f_{uu}f_{vv}-f_{uv}^2}{(1+f_u^2+f_v^2)^2}.$$

This result allows us to rephrase the second derivative test in the calculus of a function f from $\mathbb{R}^2$ to $\mathbb{R}$ as follows: if f has continuous second partial derivatives and (u_0,v_0) is a critical point (i.e., $f_u(u_0,v_0)=f_v(u_0,v_0)=0$), then

1. (u_0, v_0) is a local maximum if $K(u_0, v_0) > 0$ and $f_{uu}(u_0, v_0) < 0$;
2. (u_0, v_0) is a local minimum if $K(u_0, v_0) > 0$ and $f_{uu}(u_0, v_0) > 0$;
3. (u_0, v_0) is a saddle point if $K(u_0, v_0) < 0$;
4. the test is inconclusive if $K(u_0, v_0) = 0$.

In the language we have introduced in this chapter, local minima and local maxima of the function $z = f(u, v)$ are elliptic points, saddle points are hyperbolic points, and points where the second derivative test is inconclusive are either parabolic or planar points.

Example 6.5.5 (Pseudosphere). A *tractrix* is a curve in the plane with parametric equations

$$\vec{x}(t) = (t - \tanh t, \operatorname{sech} t),$$

and it has the x-axis as an asymptote. The *pseudosphere* is defined as half of the surface of revolution of a tractrix about its asymptote. More precisely, we can parametrize the pseudosphere by

$$\vec{X}(u, v) = (\operatorname{sech} v \cos u, \operatorname{sech} v \sin u, v - \tanh v),$$

with $u \in [0, 2\pi)$ and $v \in [0, \infty)$. (See Figure 6.10 for a picture of the tractrix and the pseudosphere.) We leave it as an exercise for the reader to prove that

$$(g_{ij}) = \begin{pmatrix} \operatorname{sech}^2 v & 0 \\ 0 & \tanh^2 v \end{pmatrix} \quad \text{and} \quad (L_{ij}) = \begin{pmatrix} \operatorname{sech} v \tanh v & 0 \\ 0 & -\operatorname{sech} v \tanh v \end{pmatrix}.$$

We find that the Gaussian curvature for the pseudosphere is $K = -1$, which motivates the name “pseudosphere” since it is analogous to the unit sphere but with a constant Gaussian curvature of -1 instead of 1.

Proposition 6.5.6. *Let S be a regular oriented surface of class C^2 with Gauss map $n : S \to \mathbb{S}^2$, and let p be a point on S. Call $K(p)$ the Gaussian curvature of S at p, and suppose that $K(p) \neq 0$. Let B_ε be the ball of radius ε around p and define $V_\varepsilon = B_\varepsilon \cap S$. Calling $K(p)$ the Gaussian curvature of S at p, we have*

$$|K(p)| = \lim_{\varepsilon \to 0} \frac{\operatorname{Area}(n(V_\varepsilon))}{\operatorname{Area}(V_\varepsilon)}.$$

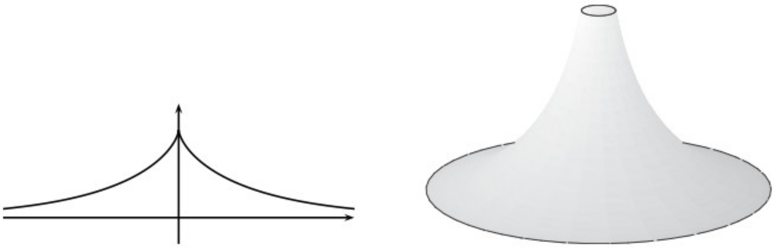


Figure 6.10. Tractrix and pseudosphere.

In other words, the absolute value of the Gaussian curvature at a point p *is the limit around* p *of the ratio of the surface area on* $\mathbb{S}^2$ *mapped under the Gauss map to the corresponding surface area on* S*.*

Proof: Let $\vec{X} : U \to \mathbb{R}^3$ be a regular parametrization of a neighborhood of $p = \vec{X}(u_0, v_0)$, where U is an open subset of $\mathbb{R}^2$. Since $\vec{X}(U)$ is an open set, $V_\varepsilon \subset \vec{X}(U)$ for all ε small enough. Furthermore, since we assumed that $K(p) \neq 0$, by the continuity of the Gaussian curvature function $K : U \to \mathbb{R}$, we deduce that K does not change sign for ε chosen small enough. Therefore, from now on, we assume that K does not change sign.

Define $U_\varepsilon = \vec{X}^{-1}(V_\varepsilon)$, the preimage of the neighborhood V_ε under $\vec{X}$. Since $\vec{X}$ is bijective as a regular parametrization, $\{(u_0, v_0)\}$ is the unique point in all U_ε for all $\varepsilon > 0$. Then by the formula for surface area,

$$\text{Area}(V_\varepsilon) = \iint_{V_\varepsilon} dA = \iint_{U_\varepsilon} \|\vec{X}_u \times \vec{X}_v\| \, du \, dv.$$

Similarly, on the unit sphere,

$$\text{Area}(n(V_\varepsilon)) = \iint_{U_\varepsilon} \|\vec{N}_u \times \vec{N}_v\| \, du \, dv.$$

However, by Proposition 6.5.2, we also have

$$\text{Area}(n(V_\varepsilon)) = \iint_{U_\varepsilon} |K(u, v)| \|\vec{X}_u \times \vec{X}_v\| \, du \, dv.$$

By the Mean Value Theorem for double integrals, for every $\varepsilon > 0$, there exist points $(u_\varepsilon, v_\varepsilon)$ and $(u'_\varepsilon, v'_\varepsilon)$ in the open set U_ε such that

$$\iint_{U_\varepsilon} \|\vec{X}_u \times \vec{X}_v\| \, du \, dv = \|\vec{X}_u(u_\varepsilon, v_\varepsilon) \times \vec{X}_v(u_\varepsilon, v_\varepsilon)\|$$

and

$$\iint_{U_\varepsilon} \|\vec{N}_u \times \vec{N}_v\| \, du \, dv = |K(u'_\varepsilon, v'_\varepsilon)| \, \|\vec{X}_u(u'_\varepsilon, v'_\varepsilon) \times \vec{X}_v(u'_\varepsilon, v'_\varepsilon)\|.$$

Thus, since $\lim_{\varepsilon\to 0}(u_\varepsilon, v_\varepsilon) = \lim_{\varepsilon\to 0}(u'_\varepsilon, v'_\varepsilon) = (u_0, v_0)$, we have

$$\begin{aligned}\lim_{\varepsilon\to 0} \frac{\operatorname{Area}(n(V_\varepsilon))}{\operatorname{Area}(V_\varepsilon)} &= \lim_{\varepsilon\to 0} \frac{|K(u'_\varepsilon, v'_\varepsilon)| \, \|\vec{X}_u(u'_\varepsilon, v'_\varepsilon) \times \vec{X}_v(u'_\varepsilon, v'_\varepsilon)\|}{\|\vec{X}_u(u_\varepsilon, v_\varepsilon) \times \vec{X}_v(u_\varepsilon, v_\varepsilon)\|} \\ &= \frac{|K(u_0, v_0)| \|\vec{X}_u(u_0, v_0) \times \vec{X}_v(u_0, v_0)\|}{\|\vec{X}_u(u_0, v_0) \times \vec{X}_v(u_0, v_0)\|} \\ &= |K(u_0, v_0)| = |K(p)|. \qquad \square\end{aligned}$$

Problems

6.5.1. Calculate the Gaussian curvature of the torus parametrized by

$$\vec{X}(u, v) = ((a + b\cos v)\cos u, (a + b\cos v)\sin u, b\sin v)$$

where $a > b$ are constants and $(u, v) \in (0, 2\pi) \times (0, 2\pi)$.

6.5.2. Consider a regular space curve $\vec{\gamma} : I \to \mathbb{R}^3$ and the tangential surface defined by

$$\vec{X}(t, u) = \vec{\gamma}(t) + u\vec{\gamma}'(t)$$

for $(t, u) \in I \times \mathbb{R}$. Calculate the mean and Gaussian curvature functions.

6.5.3. Let $\vec{\alpha}(t)$ and $\vec{\beta}(t)$ be differentiable vector functions with common domain I. Define the *secant surface* between the two resulting curves by

$$\vec{X}(t, u) = (1 - u)\vec{\alpha}(t) + u\vec{\beta}(t)$$

for $(t, u) \in I \times \mathbb{R}$. Assume that the corresponding surface is regular.

Proof: Recall the formula for surface area introduced in multivariable calculus that gives the surface area of the region R on S as

$$A(R) = \iint\limits_R dA = \iint\limits_Q \|\vec{X}_u \times \vec{X}_v\| \, du \, dv. \tag{6.5}$$

(See [23, Section 7.4] or [28, Section 17.7] for an explanation of Equation (6.5).)

By Problem 3.1.3, for any two vectors $\vec{v}$ and $\vec{w}$ in $\mathbb{R}^3$, the following identity holds:

$$(\vec{v} \times \vec{w}) \cdot (\vec{v} \times \vec{w}) = (\vec{v} \cdot \vec{v})(\vec{w} \cdot \vec{w}) - (\vec{v} \cdot \vec{w})^2.$$

Therefore,

$$\|\vec{X}_u \times \vec{X}_v\|^2 = (\vec{X}_u \cdot \vec{X}_u)(\vec{X}_v \cdot \vec{X}_v) - (\vec{X}_u \cdot \vec{X}_v)^2 = g_{11}g_{22} - g_{12}^2, \tag{6.6}$$

and the proposition follows because $g_{12} = g_{21}$. ☐

Proposition 6.1.7 is interesting in itself as it leads to another property of the first fundamental form. It is obvious from the definition of the first fundamental form that $g_{11}(u,v) \geq 0$ and $g_{22}(u,v) \geq 0$ for all $(u,v) \in U$. However, since $\|\vec{X}_u \times \vec{X}_v\|^2 = \det(g)$ and since $\vec{X}_u \times \vec{X}_v$ is never $\vec{0}$ on a regular surface, we deduce that $\det(g) = g_{11}g_{22} - g_{12} > 0$ for all $(u,v) \in U$. In other words, the matrix of functions g is always a *positive definite* matrix.

Example 6.1.8. Consider the regular surface S parametrized by $\vec{X}(u,v) = (v\cos u, v \sin u, \ln v)$, with $(u,v) \in [0, 2\pi] \times (0, \infty) = U$. (From a practical standpoint, it is not so important that U is not an open subset of $\mathbb{R}^2$, but it should be understood that S requires two coordinate neighborhoods to satisfy the criteria for being a regular surface. See Figure 6.3.) Let $Q = [0, 2\pi] \times [1, 2]$, and let's calculate the area of $R = \vec{X}(Q)$.

It's not hard to show that

$$(g_{ij}) = \begin{pmatrix} v^2 & 0 \\ 0 & 1 + \frac{1}{v^2} \end{pmatrix}.$$

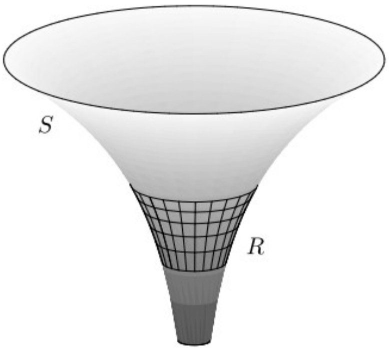

Figure 6.3. Surface area patch for Example 6.1.8.

Then Proposition 6.1.7 gives

$$\begin{aligned} A(R) &= \int_0^{2\pi}\int_1^2 \sqrt{v^2+1}\,dv\,du = 2\pi\Big[\frac{1}{2}v\sqrt{v^2+1}+\frac{1}{2}\sinh^{-1}v\Big]_1^2 \\ &= \pi\left(2\sqrt{5}-\sqrt{2}+\ln\left(\frac{2+\sqrt{5}}{1+\sqrt{2}}\right)\right). \end{aligned}$$

As we have done for many quantities on curves and surfaces, we wish to see how the functions in the first fundamental form change under a coordinate transformation. In order to avoid confusion with various coordinate systems, we introduce some notations that will become more common in future topics. Suppose that an open subset V of a regular surface S can be parametrized by two different sets of coordinates (x_1, x_2) and $(\bar{x}_1, \bar{x}_2)$. If we write $\vec{X}(x_1, x_2)$ and $\vec{Y}(\bar{x}_1, \bar{x}_2)$ for the specific parametrizations, then the function $F = \vec{Y}^{-1} \circ \vec{X}$ is a diffeomorphism between two open subsets of $\mathbb{R}^2$ and

$$(\bar{x}_1, \bar{x}_2) = F(x_1, x_2).$$

For convenience, we will often simply write

$$\begin{cases} \bar{x}_1 = \bar{x}_1(x_1, x_2), \\ \bar{x}_2 = \bar{x}_2(x_1, x_2) \end{cases}$$

to indicate the dependency of one set of variables on the other. Vice versa, we can write

$$(x_1, x_2) = F^{-1}(\bar{x}_1, \bar{x}_2) \quad \text{or simply} \qquad \begin{cases} x_1 = x_1(\bar{x}_1, \bar{x}_2), \\ x_2 = x_2(\bar{x}_1, \bar{x}_2). \end{cases}$$

Now $\vec{Y}(\bar{x}_1, \bar{x}_2) = \vec{X}(x_1(\bar{x}_1, \bar{x}_2), x_2(\bar{x}_1, \bar{x}_2))$ for the respective parametrizations. Let g_{ij} be the coefficient functions in the first fundamental form for S parametrized by x_1, x_2, and let $\bar{g}_{ij}$ be the coefficient functions for S parametrized by $\bar{x}_1, \bar{x}_2$. Then by the chain rule,

$$\bar{g}_{ij} = \vec{Y}_{\bar{x}_i} \cdot \vec{Y}_{\bar{x}_j} = \left(\vec{X}_{x_1} \frac{\partial x_1}{\partial \bar{x}_i} + \vec{X}_{x_2} \frac{\partial x_2}{\partial \bar{x}_i} \right) \cdot \left(\vec{X}_{x_1} \frac{\partial x_1}{\partial \bar{x}_j} + \vec{X}_{x_2} \frac{\partial x_2}{\partial \bar{x}_j} \right).$$

After some reorganization, we find

$$\bar{g}_{ij} = \sum_{k=1}^{2} \sum_{l=1}^{2} \frac{\partial x_k}{\partial \bar{x}_i} \frac{\partial x_l}{\partial \bar{x}_j} g_{kl}. \tag{6.7}$$

This type of transformation of coordinates is our first (nontrivial) encounter with tensors. In modern terminology, the collection of the quantities g_{ij} defined at each point of $p \in S$ is referred to as the components of the *metric tensor* of S. Though the first fundamental form, as a bilinear form on T_pS, is independent of any particular parametrization, the specific functions g_{ij} depend on the parametrization, but one knows that they behave according to Equation (6.7) under coordinate changes. Because the g_{ij} functions satisfy this particular identity, we call the matrix of functions $g = (g_{ij})$ a tensor of type $(0, 2)$. Later on, as further study will lead to more complicated geometric objects, we will develop a comprehensive theory of tensors in differential geometry.

The value of the first fundamental form is that, given the metric tensor, one can use the appropriate formulas for arc length, for angles between curves and for areas of regions without knowing the specific parametrization of the surface. An additional benefit of the first fundamental form and the metric tensor is that one can still use them to study the geometry of surfaces in higher dimensions.

Suppose that S is a regular surface in $\mathbb{R}^n$ and consider a parametrization of a coordinate patch $\vec{X} : U \to \mathbb{R}^n$, where U is an open subset of $\mathbb{R}^2$. Define the functions $g_{ij} = \vec{X}_i \cdot \vec{X}_j$ as before. Then Equations (6.1) and (6.2) still provide the appropriate formulas for arc length and the angle between vectors in T_pS. In addition, Proposition 6.1.7 generalizes to the following.

Proposition 6.1.9. *Let S be a regular surface in $\mathbb{R}^n$, with $n \geq 3$, and let $\vec{X} : U \to \mathbb{R}^n$ be a parametrization of a coordinate patch of S, where U is an open subset of $\mathbb{R}^2$. Let Q be a compact subset of U and call $R = \vec{X}(Q)$ the compact subset of S. The area of R is given by*

$$A(R) = \iint_Q \sqrt{\det(g)}\, du\, dv. \tag{6.8}$$

Proof: The proof of Equation (6.4) relied on the fact that S is a regular surface in $\mathbb{R}^3$ and made reference to the cross product of $\vec{X}_u$ and $\vec{X}_v$, namely, using the formula

$$\iint_Q \|\vec{X}_u \times \vec{X}_v\|\, du\, dv$$

from multivariable calculus. The Riemann sum behind this integral involves approximating the surface area traced out by $\vec{X}$ over $[u_i, u_{i+1}] \times [v_i, v_{i+1}]$ by a parallelogram spanned on two sides by $\vec{X}_u(u^*, v^*)$ and $\vec{X}_v(u^*, v^*)$, where (u^*, v^*) is a selection point in $[u_i, u_{i+1}] \times [v_i, v_{i+1}]$.

In order to find a formula for the surface area of a regular surface in $\mathbb{R}^n$, one cannot refer to any formula using the cross product since the cross product is only defined in $\mathbb{R}^3$. However, the approach used by the Riemann sum is still the right one. Therefore, one must find a convenient formula for the area of the parallelogram spanned by $\vec{X}_u$ and $\vec{X}_v$ in $\mathbb{R}^n$.

Regardless of the dimension of the ambient Euclidean space, we can calculate the area of these parallelograms as $\|\vec{X}_u\|\,\|\vec{X}_v\| \sin\theta$, where θ is the angle between the two vectors. One cannot get $\sin\theta$ directly but one can obtain $\cos\theta$ from $\vec{X}_u \cdot \vec{X}_v = \|\vec{X}_u\|\,\|\vec{X}_v\| \cos\theta$.

Thus,

$$\begin{aligned}
& & (\vec{X}_u \cdot \vec{X}_v)^2 &= (\vec{X}_u \cdot \vec{X}_u)(\vec{X}_v \cdot \vec{X}_v)\cos^2\theta \\
\Longrightarrow & & (\vec{X}_u \cdot \vec{X}_v)^2 &= (\vec{X}_u \cdot \vec{X}_u)(\vec{X}_v \cdot \vec{X}_v)(1-\sin^2\theta) \\
\Longrightarrow & & (\vec{X}_u \cdot \vec{X}_u)(\vec{X}_v \cdot \vec{X}_v) - (\vec{X}_u \cdot \vec{X}_v)^2 &= (\vec{X}_u \cdot \vec{X}_u)(\vec{X}_v \cdot \vec{X}_v)\sin^2\theta \\
\Longleftrightarrow & & \sqrt{(\vec{X}_u \cdot \vec{X}_u)(\vec{X}_v \cdot \vec{X}_v) - (\vec{X}_u \cdot \vec{X}_v)^2} &= \|\vec{X}_u\|\,\|\vec{X}_v\|\sin\theta.
\end{aligned}$$

Thus, at each point $(u,v) \in U$, we have $\sqrt{\det(g)} = \|\vec{X}_u\|\,\|\vec{X}_v\|\sin\theta$. Taking the limit of the Riemann sum as the norm of a mesh that goes to 0 gives Equation (6.8). □

Because of Equation (6.1), a few mathematicians and most physicists use an alternative notation for the metric tensor. These authors describe the metric tensor by saying that the "line element" in a coordinate patch is given by

$$ds^2 = g_{11}(u,v)\,du^2 + 2g_{12}(u,v)\,du\,dv + g_{22}(u,v)\,dv^2. \tag{6.9}$$

This notation has the advantage that one can write it concisely on a single line instead of in matrix format. However, one should not forget that it not only leads to Equation (6.1) for arc length of a curve on a surface but that it also leads to the Equation (6.2) for angles between curves on the surface and the formula in Proposition 6.1.9 that gives the area of regions on the surface.

Problems

6.1.1. Calculate the metric tensor for the following regular surfaces:

- (a) The plane parametrized by $\vec{X}(s,t) = \vec{u} + s\vec{v} + t\vec{w}$ with $(s,t) \in \mathbb{R}^3$.
- (b) The surface with parametrization $\vec{X}(u,v) = (u^2 - v, uv, u)$.
- (c) The helicoid parametrized by $\vec{X}(u,v) = (v\cos u, v\sin u, au)$ for some $a \in \mathbb{R}$.

6.1.2. Calculate the metric tensor for the following families of conic surfaces:

- (a) The ellipsoid $\vec{X}(u,v) = (a\cos u\sin v, b\sin u\sin v, c\cos v)$.
- (b) The elliptic paraboloid $\vec{X}(u,v) = (av\cos u, bv\sin u, v^2)$.

between the horizontal and vertical directions, it increases the purple–green angle and decreases the green–red angle. Thus, not all angles are preserved.

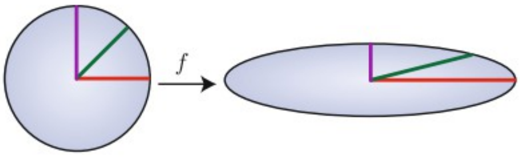

FIGURE 3.30. A linear equiareal map with distortion factor $\lambda = 2$

The above example is very special, because f is linear, but it illustrates the infinitesimal picture for a general equiareal map. That is, if $f : S_1 \to S_2$ is any equiareal map, then for every $p \in S_1$, orthonormal bases of T_pS_1 and $T_{f(p)}S_2$ can be chosen such that the matrix representing the linear transformation $df_p : T_pS_1 \to T_{f(p)}S_2$ has the form $A = \begin{pmatrix} \lambda & 0 \\ 0 & 1/\lambda \end{pmatrix}$ for some $\lambda > 0$ (Exercise 3.88). Thus, an equiareal map avoids distorting infinitesimal area through the balancing act of expanding one direction while compressing the other to compensate. The expansion–contraction factor λ is a function of p.

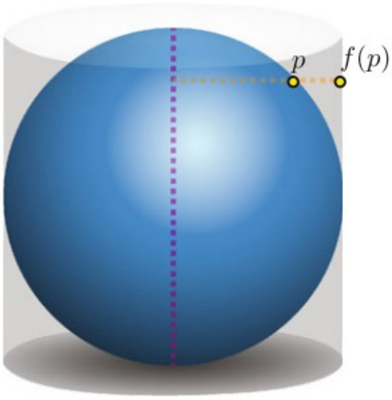
The most famous example of an equiareal map comes from Archimedes. The domain is the sphere with the north and south poles removed: $S^2 - \{(0,0,\pm 1)\}$. The range is the following cylinder:

$$C = \{(x,y,z) \in \mathbb{R}^3 \mid x^2 + y^2 = 1 \text{ and } -1 < z < 1\}.$$

The function $f : S^2 - \{(0,0,\pm 1)\} \to C$ is pictured in Fig. 3.31. It sends each $p \in S^2 - \{(0,0,\pm 1)\}$ to the point $f(p) \in C$ that is nearest to p. This nearest point will have the same z-value as p. If you imagine that the z-axis emits light, and the sphere is made of glass with a speck of paint at p, then $f(p)$ is the speck's shadow on the cylinder. A formula for this shadowing of the sphere onto the cylinder is

$$f(x,y,z) = \left(\frac{x}{\sqrt{x^2+y^2}}, \frac{y}{\sqrt{x^2+y^2}}, z \right). \tag{3.18}$$

THEOREM 3.69 (**Archimedes's Theorem**).
The function f in Eq. 3.18 is equiareal.



Archimedes used this theorem to discover the area of a sphere (it equals the area of the cylinder, which was previously known). According to legend, Archimedes asked that an image of his proof be inscribed on his tombstone. Since he predated the invention of calculus, his proof was much more involved than this one:

FIGURE 3.31. An equiareal map from the sphere to the cylinder

PROOF. The spherical coordinate chart $\sigma : \underbrace{(0, 2\pi) \times (0, \pi)}_{U} \to S^2$ was defined in Example 3.24 (on page 129) as

$$\sigma(\theta, \phi) = (\sin\phi\cos\theta, \sin\phi\sin\theta, \cos\phi).$$

Let $q = (\theta, \phi) \in U$ and let $p = \sigma(q)$. We computed in that example that $|\sigma_\theta \times \sigma_\phi| = \sin\phi$. Since $\{\sigma_\theta, \sigma_\phi\}$ is a basis of T_pS^2, the definition of area distortion gives

$$\|df_p\| = \frac{|df_p(\sigma_\theta) \times df_p(\sigma_\phi)|}{|\sigma_\theta \times \sigma_\phi|} = \frac{|df_p(\sigma_\theta) \times df_p(\sigma_\phi)|}{\sin\phi}.$$

It remains to demonstrate that $|df_p(\sigma_\theta) \times df_p(\sigma_\phi)| = \sin\phi$, so that $\|df_p\| = 1$, as desired.

The composition $\tilde{\sigma} = f \circ \sigma : U \to C$ is a surface patch for C, whose formula simplifies to

$$\tilde{\sigma}(\theta, \phi) = (\cos(\theta), \sin(\theta), \cos\phi).$$

Since $df_p(\sigma_\theta) = \tilde{\sigma}_\theta$ and $df_p(\sigma_\phi) = \tilde{\sigma}_\phi$, we learn that

$$|df_p(\sigma_\theta) \times df_p(\sigma_\phi)| = |\tilde{\sigma}_\theta \times \tilde{\sigma}_\phi| = |(-\sin\theta, \cos\theta, 0) \times (0, 0, -\sin\phi)| = \sin\phi,$$

which completes the proof. □

From the formulas in the previous proof, you can verify what is apparent in Fig. 3.32; namely, $\|df_p\| = 1$, because an expansion of length in the latitudinal (σ_θ) direction is balanced by a contraction of length in the longitudinal (σ_ϕ) direction. In fact, with respect to the orthonormal bases $\left\{\frac{\sigma_\theta}{|\sigma_\theta|}, \frac{\sigma_\phi}{|\sigma_\phi|}\right\}$ and $\left\{\frac{\tilde{\sigma}_\theta}{|\tilde{\sigma}_\theta|}, \frac{\tilde{\sigma}_\phi}{|\tilde{\sigma}_\phi|}\right\}$, the linear transformation df_p is represented by the matrix $\begin{pmatrix} 1/\sin\phi & 0 \\ 0 & \sin\phi \end{pmatrix}$; compare to Example 3.68. The expansion–contraction factor, $\lambda = 1/\sin\phi$, equals 1 along the equator and approaches infinity as p approaches the poles.

Archimedes's theorem can be used to create a flat rectangular map of the spherical Earth with desirable properties. Specifically,the **Lambert projection** is obtained by projecting a globe onto the cylinder (via the function f from Eq. 3.18) and then unwrapping the cylinder into a flat rectangle (via the inverse of the cylinder's surface patch in Example 3.23 on page 128). This process and the resulting map are pictured in Fig. 3.33. The orange ellipses help you visualize the separate vertical and horizontal distortion factors of the projection at several points. Technically, they are the images of equal-sized round circles under the derivative of the projection (from globe to map) at a grid of equally spaced points along the map.

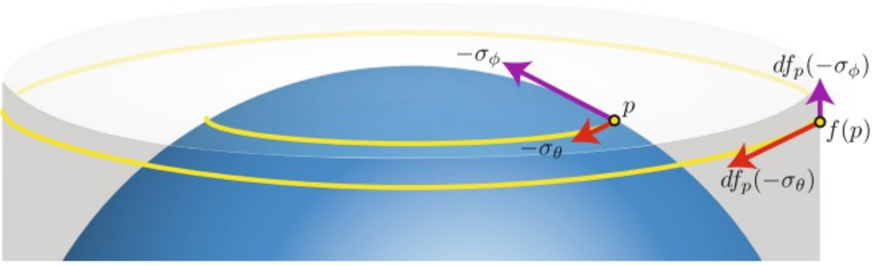


FIGURE 3.32. $\|df_p\| = 1$ because the vectors at p span the same area as the vectors at $f(p)$

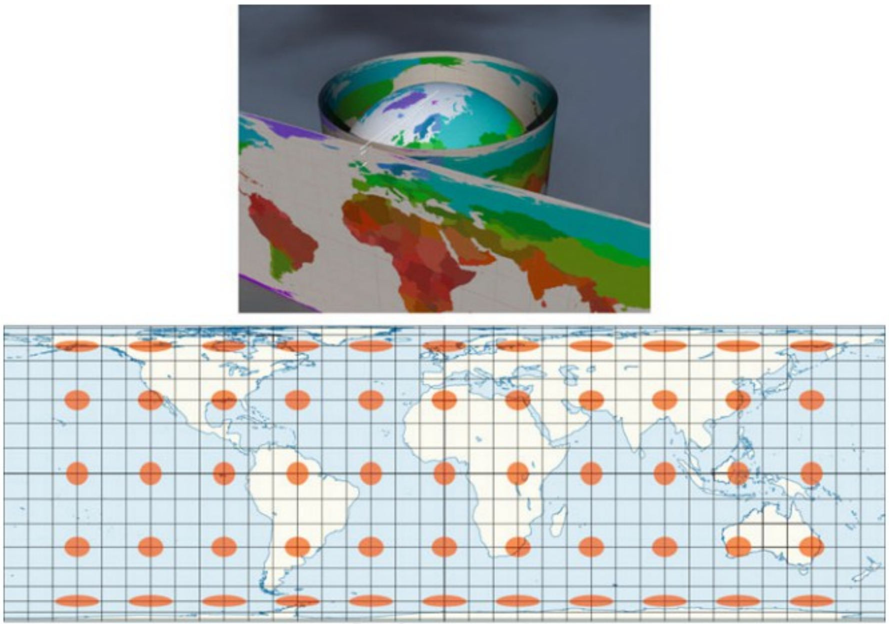
According to Archimedes's theorem, the Lambert projection creates an "equal-area" map. The area of every continent or country on the spherical globe equals the area of its projection onto this rectangular map. The map therefore correctly displays relative areas, such as the fact that Africa is about 3.7 times the size of Australia. A common trivial modification is to compress the Lambert map horizontally. For example, the **Gall–Peters map** is nothing more than the Lambert map horizontally compressed until the expansion–contraction factor equals 1 along the 45° parallels north and south ($\phi = \pi/4$ and $\phi = 3\pi/4$), rather than along the equator. Shapes appear undistorted along these two special parallels, which are shown as thick orange lines in Fig. 3.33.

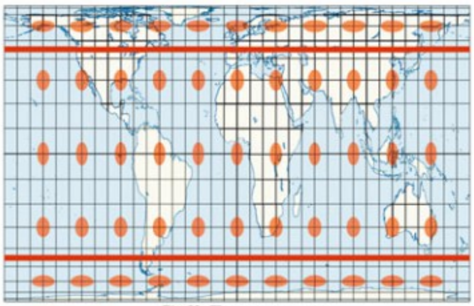
Although these equal-area maps represent area accurately, we saw in Fig. 3.30 that they distort angles and shapes. The distortion is extreme near the poles. Could a map of the Earth preserve angles? This question leads to our second generalization of isometries:

DEFINITION 3.70.
Let S_1, S_2 be a pair of regular surfaces. A diffeomorphism $f : S_1 \to S_2$ is called ***conformal*** *if df preserves angles, that is, if*

$$\angle(x, y) = \angle(df_p(x), df_p(y)) \text{ for all } p \in S_1 \text{ and all } x, y \in T_pS_1.$$



Lambert projection



Gall-Peters map

FIGURE 3.33. Equal-area maps of the Earth

EXAMPLE 3.71. *Let* $\lambda > 0$. *Let* $f = L_A : \mathbb{R}^2 \to \mathbb{R}^2$ *denote the linear transformation represented by the matrix* $A = \left(\begin{smallmatrix} \lambda & 0 \\ 0 & \lambda \end{smallmatrix}\right)$, *that is,* $f(p) = \lambda p$. *Let* $p \in \mathbb{R}^2$ *and* $x, y \in T_p\mathbb{R}^2 = \mathbb{R}^2$. *Notice that* $df_p(x) = f(x) = \lambda x$. *Thus*

$$\begin{aligned} \angle(df_p(x), df_p(y)) = \cos^{-1}\left(\frac{\langle df_p(x), df_p(y)\rangle}{|df_p(x)||df_p(y)|}\right) &= \cos^{-1}\left(\frac{\langle \lambda x, \lambda y\rangle}{|\lambda x||\lambda y|}\right) \\ &= \cos^{-1}\left(\frac{\langle x, y\rangle}{|x||y|}\right) = \angle(x, y), \end{aligned}$$

so f *is conformal. Figure 3.34 shows the effect of* f *(with* $\lambda = 2$*) on a circle and some angles.*

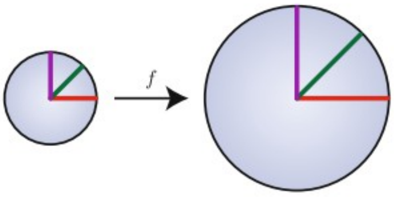


FIGURE 3.34. A linear conformal map with distortion factor $\lambda = 2$

The above example is very special, because f is linear, but it illustrates the infinitesimal picture for a general conformal map. That is, if $f : S_1 \to S_2$ is any conformal map, then for every $p \in S_1$, there exist orthonormal bases of T_pS_1 and $T_{f(p)}S_2$ with respect to which the linear transformation df_p is represented by a matrix of the form $A = \left(\begin{smallmatrix} \lambda & 0 \\ 0 & \lambda \end{smallmatrix}\right)$. The distortion factor λ typically depends on p, and is the factor by which df_p uniformly scales the norms of all vectors. In summary:

PROPOSITION 3.72.
A diffeomorphism $f : S_1 \to S_2$ is conformal if and only if there exists a smooth positive-valued function $\lambda : S_1 \to \mathbb{R}$ such that
$\langle df_p(x), df_p(y)\rangle_{f(p)} = \lambda(p)^2 \cdot \langle x, y\rangle_p$ *for all $p \in S_1$ and all $x, y \in T_pS_1$.*

PROOF. Follows from Exercise 3.89. ☐

The best-known example of a conformal map is the **stereographic projection** function $f : S^2 - \{(0, 0, 1)\} \to \mathbb{R}^2$. By definition, $f(p)$ gives the xy-coordinates of the intersection of the plane $z = -1$ with the line containing $(0, 0, 1)$ and p; see Fig. 3.35 (some authors instead project onto the plane $z = 0$; see Exercise 3.93).

PROPOSITION 3.73.
The stereographic projection function f is conformal.

PROOF. We first must describe a formula for f. An arbitrary point $p \in S^2$ can be expressed as $p = (\underbrace{r\cos\theta}_{x}, \underbrace{r\sin\theta}_{y}, \underbrace{\pm\sqrt{1-r^2}}_{z})$ for some angle θ and some $r > 0$. Its image $f(p)$ will have the form $(R\cos\theta, R\sin\theta)$ for some $R > 0$. To complete our description of f (and to understand f^{-1}), we must relate R and r. By similar triangles,

$$R = \frac{2r}{1-z} = \frac{2r}{1 \pm \sqrt{1-r^2}} \overset{\text{solve for } r}{\Longrightarrow} r = \frac{4R}{R^2+4}. \tag{3.19}$$

In summary, a formula for f^{-1} is

$$f^{-1}(R\cos\theta, R\sin\theta) = \left(r\cos\theta, r\sin\theta, \pm\sqrt{1-r^2}\right), \quad \text{where} \quad r = \frac{4R}{R^2+4}.$$

The symbol "±" equals 1 if $R > 2$ and equals -1 if $R < 2$.

$f(p)$
$\frac{\partial}{\partial R}$
$-\frac{\partial}{\partial \theta}$

FIGURE 3.35. Stereographic projection is conformal because its derivative scales the green and red vectors by the same factor

Now we prove that f is conformal. It is equivalent to prove that its inverse $f^{-1} : \mathbb{R}^2 \to S^2 - \{(0,0,1)\}$ is conformal. Let $q = (R\cos\theta, R\sin\theta) \in \mathbb{R}^2$. A basis for $T_q\mathbb{R}^2 = \mathbb{R}^2$ is

$$\frac{\partial}{\partial\theta} = (-R\sin\theta, R\cos\theta), \quad \frac{\partial}{\partial R} = \frac{q}{|q|} = (\cos\theta, \sin\theta).$$

These two vectors are orthogonal. Their images under $d(f^{-1})_q$ are also orthogonal:

$$d(f^{-1})_q\left(\frac{\partial}{\partial\theta}\right) = (-r\sin\theta, r\cos\theta, 0), \quad d(f^{-1})_q\left(\frac{\partial}{\partial R}\right) = \frac{dr}{dR}\left(\cos\theta, \sin\theta, \frac{\pm r}{\sqrt{1-r^2}}\right).$$

We have identified a pair of orthogonal vectors sent by $d(f^{-1})_q$ to a pair of orthogonal vectors, so it will suffice to verify that these vectors are scaled by the same amount; think about why this will suffice, or see Exercise 3.89 for more details. For this, it is straightforward to compute

$$\lambda = \frac{|d(f^{-1})_q\left(\frac{\partial}{\partial\theta}\right)|}{|\frac{\partial}{\partial\theta}|} = \frac{|d(f^{-1})_q\left(\frac{\partial}{\partial R}\right)|}{|\frac{\partial}{\partial R}|} = \frac{4}{4+R^2}. \tag{3.20}$$

□

Figure 3.36 shows a map made from a stereographic projection of the globe (turned upside down in order to depict the northern hemisphere). This map even includes part of the southern hemisphere (overlaid white), although an unbounded map would be required to include all of the southern hemisphere. This figure also depicts an artistic representation of stereographic projection as the shadowing from a light source positioned at the pole. In addition to these still images, we recommend the YouTube video *Stereographic projection of the Riemann sphere* for visualizing the conformal property of stereographic projection.

Stereographic projection is important within mathematics, but not within map-making. Cartographers care much more about a different conformal map—the **Mercator projection**, illustrated in Fig. 3.37. This well-recognized projection has greatly influenced our collective mental image of the Earth.

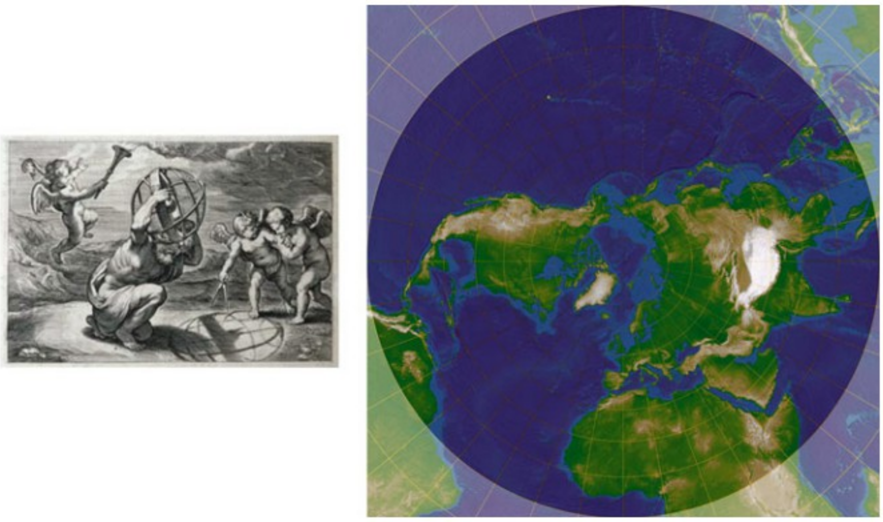

FIGURE 3.36. Stereographic projection map of northern hemisphere

EXAMPLE 3.74 (The Mercator Projection). *The idea is to modify the spherical coordinate chart so it becomes conformal. Recall from Example 3.24 on page 129 the spherical coordinate chart* $\sigma : \underbrace{(0,2\pi)\times(0,\pi)}_{U} \to S^2$ *defined as*

$$\sigma(\theta,\phi) = (\sin\phi\cos\theta, \sin\phi\sin\theta, \cos\phi).$$

We computed in that example that

$$\sigma_\theta = (-\sin\phi\sin\theta, \sin\phi\cos\theta, 0), \qquad \sigma_\phi = (\cos\phi\cos\theta, \cos\phi\sin\theta, -\sin\phi).$$

The vectors σ_θ *and* σ_ϕ *are orthogonal, but* σ *is not conformal, because*

$$\sin\phi = |\sigma_\theta| \neq |\sigma_\phi| = 1.$$

We can fix this problem by precomposing σ *with a function that appropriately warps the vertical axis of the domain. That is, we define the function*

$$\Psi : \underbrace{(0,2\pi)\times(a,b)}_{\tilde{U}} \to \underbrace{(0,2\pi)\times(0,\pi)}_{U}$$

***18.** Let $\lambda_1, \dots, \lambda_m$ be the normal curvatures at $p \in S$ along directions making angles $0, 2\pi/m, \dots, (m-1)2\pi/m$ with a principal direction, $m > 2$. Prove that

$$\lambda_1 + \cdots + \lambda_m = mH,$$

where H is the mean curvature at p.

***19.** Let $C \subset S$ be a regular curve in S. Let $p \in C$ and $\alpha(s)$ be a parametrization of C in p by arc length so that $\alpha(0) = p$. Choose in $T_p(S)$ an orthonormal positive basis $\{t, h\}$, where $t = \alpha'(0)$. The *geodesic torsion* τ_g of $C \subset S$ at p is defined by

$$\tau_g = \left\langle \frac{dN}{ds}(0), h \right\rangle.$$

Prove that

a. $\tau_g = (k_1 - k_2)\cos\varphi \sin\varphi$, where φ is the angle from e_1 to t and t is the unit tangent vector corresponding to the principal curvature k_1.

b. If τ is the torsion of C, n is the (principal) normal vector of C and $\cos\theta = \langle N, n \rangle$, then

$$\frac{d\theta}{ds} = \tau - \tau_g.$$

c. The lines of curvature of S are characterized by having geodesic torsion identically zero.

***20.** (*Dupin's Theorem.*) Three families of surfaces are said to form a *triply orthogonal system* in an open set $U \subset R^3$ if a unique surface of each family passes through each point $p \in U$ and if the three surfaces that pass through p are pairwise orthogonal. Use part c of Exercise 19 to prove Dupin's theorem: *The surfaces of a triply orthogonal system intersect each other in lines of curvature.*

3-3. The Gauss Map in Local Coordinates

In the preceding section, we introduced some concepts related to the local behavior of the Gauss map. To emphasize the geometry of the situation, the definitions were given without the use of a coordinate system. Some simple examples were then computed directly from the definitions; this procedure, however, is inefficient in handling general situations. In this section, we shall obtain the expressions of the second fundamental form and of the differential of the Gauss map in a coordinate system. This will give us a systematic method for computing specific examples. Moreover, the general expressions thus obtained are essential for a more detailed investigation of the concepts introduced above.

All parametrizations $\mathbf{x}\colon U \subset R^2 \to S$ considered in this section are assumed to be compatible with the orientation N of S; that is, in $\mathbf{x}(U)$,

$$N = \frac{\mathbf{x}_u \wedge \mathbf{x}_v}{|\mathbf{x}_u \wedge \mathbf{x}_v|}.$$

Let $\mathbf{x}(u, v)$ be a parametrization at a point $p \in S$ of a surface S, and let $\alpha(t) = \mathbf{x}(u(t), v(t))$ be a parametrized curve on S, with $\alpha(0) = p$. To simplify the notation, we shall make the convention that all functions to appear below denote their values at the point p.

The tangent vector to $\alpha(t)$ at p is $\alpha' = \mathbf{x}_u u' + \mathbf{x}_v v'$ and

$$dN(\alpha') = N'(u(t), v(t)) = N_u u' + N_v v'.$$

Since N_u and N_v belong to $T_p(S)$, we may write

$$\begin{aligned} N_u &= a_{11}\mathbf{x}_u + a_{21}\mathbf{x}_v, \\ N_v &= a_{12}\mathbf{x}_u + a_{22}\mathbf{x}_v, \end{aligned} \tag{1}$$

and therefore,

$$dN(\alpha') = (a_{11}u' + a_{12}v')\mathbf{x}_u + (a_{21}u' + a_{22}v')\mathbf{x}_v;$$

hence,

$$dN\begin{pmatrix} u' \\ v' \end{pmatrix} = \begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix}\begin{pmatrix} u' \\ v' \end{pmatrix}.$$

This shows that in the basis $\{\mathbf{x}_u, \mathbf{x}_v\}$, dN is given by the matrix (a_{ij}), $i, j = 1, 2$. Notice that this matrix is not necessarily symmetric, unless $\{\mathbf{x}_u, \mathbf{x}_v\}$ is an orthonormal basis.

On the other hand, the expression of the second fundamental form in the basis $\{\mathbf{x}_u, \mathbf{x}_v\}$ is given by

$$\begin{aligned} II_p(\alpha') &= -\langle dN(\alpha'), \alpha'\rangle = -\langle N_u u' + N_v v', \mathbf{x}_u u' + \mathbf{x}_v v'\rangle \\ &= e(u')^2 + 2fu'v' + g(v')^2, \end{aligned}$$

where, since $\langle N, \mathbf{x}_u\rangle = \langle N, \mathbf{x}_v\rangle = 0$,

$$\begin{aligned} e &= -\langle N_u, \mathbf{x}_u\rangle = \langle N, \mathbf{x}_{uu}\rangle, \\ f &= -\langle N_v, \mathbf{x}_u\rangle = \langle N, \mathbf{x}_{uv}\rangle = \langle N, \mathbf{x}_{vu}\rangle = -\langle N_u, \mathbf{x}_v\rangle, \\ g &= -\langle N_v, \mathbf{x}_v\rangle = \langle N, \mathbf{x}_{vv}\rangle. \end{aligned}$$

We shall now obtain the values of a_{ij} in terms of the coefficients e, f, g. From Eq. (1), we have

$$\begin{aligned} -f &= \langle N_u, \mathbf{x}_v \rangle = a_{11}F + a_{21}G, \\ -f &= \langle N_v, \mathbf{x}_u \rangle = a_{12}E + a_{22}F, \\ -e &= \langle N_u, \mathbf{x}_u \rangle = a_{11}E + a_{21}F, \\ -g &= \langle N_v, \mathbf{x}_v \rangle = a_{12}F + a_{22}G, \end{aligned} \tag{2}$$

where E, F, and G are the coefficients of the first fundamental form in the basis $\{\mathbf{x}_u, \mathbf{x}_v\}$ (cf. Sec. 2-5). Relations (2) may be expressed in matrix form by

$$-\begin{pmatrix} e & f \\ f & g \end{pmatrix} = \begin{pmatrix} a_{11} & a_{21} \\ a_{12} & a_{22} \end{pmatrix} \begin{pmatrix} E & F \\ F & G \end{pmatrix}; \tag{3}$$

hence,

$$\begin{pmatrix} a_{11} & a_{21} \\ a_{12} & a_{22} \end{pmatrix} = -\begin{pmatrix} e & f \\ f & g \end{pmatrix} \begin{pmatrix} E & F \\ F & G \end{pmatrix}^{-1},$$

where $(\ )^{-1}$ means the inverse matrix of $(\ )$. It is easily checked that

$$\begin{pmatrix} E & F \\ F & G \end{pmatrix}^{-1} = \frac{1}{EG - F^2} \begin{pmatrix} G & -F \\ -F & E \end{pmatrix},$$

whence the following expressions for the coefficients (a_{ij}) of the matrix of dN in the basis $\{\mathbf{x}_u, \mathbf{x}_v\}$:

$$\begin{aligned} a_{11} &= \frac{fF - eG}{EG - F^2}, \\ a_{12} &= \frac{gF - fG}{EG - F^2}, \\ a_{21} &= \frac{eF - fE}{EG - F^2}, \\ a_{22} &= \frac{fF - gE}{EG - F^2}. \end{aligned}$$

For completeness, it should be mentioned that relations (1), with the above values, are known as the *equations of Weingarten*.

From Eq. (3) we immediately obtain

$$K = \det(a_{ij}) = \frac{eg - f^2}{EG - F^2}. \tag{4}$$

To compute the mean curvature, we recall that $-k_1$, $-k_2$ are the eigenvalues of dN. Therefore, k_1 and k_2 satisfy the equation

$$dN(v) = -kv = -kIv \quad \text{for some } v \in T_p(S),\, v \neq 0,$$

where I is the identity map. It follows that the linear map $dN + kI$ is not invertible; hence, it has zero determinant. Thus,

$$\det\begin{pmatrix} a_{11}+k & a_{12} \\ a_{21} & a_{22}+k \end{pmatrix} = 0$$

or

$$k^2 + k(a_{11} + a_{22}) + a_{11}a_{22} - a_{21}a_{12} = 0.$$

Since k_1 and k_2 are the roots of the above quadratic equation, we conclude that

$$H = \frac{1}{2}(k_1 + k_2) = -\frac{1}{2}(a_{11} + a_{22}) = \frac{1}{2}\frac{eG - 2fF + gE}{EG - F^2}; \tag{5}$$

hence,

$$k^2 - 2Hk + K = 0,$$

and therefore,

$$k = H \pm \sqrt{H^2 - K}. \tag{6}$$

From this relation, it follows that if we choose $k_1(q) \geq k_2(q)$, $q \in S$, then the functions k_1 and k_2 are continuous in S. Moreover, k_1 and k_2 are differentiable in S, except perhaps at the umbilical points ($H^2 = K$) of S.

In the computations of this chapter, it will be convenient to write for short

$$\langle u \wedge v, w\rangle = (u, v, w) \quad \text{for any } u, v, w \in R^3.$$

We recall that this is merely the determinant of the 3×3 matrix whose columns (or lines) are the components of the vectors u, v, w in the canonical basis of R^3.

Example 1. We shall compute the Gaussian curvature of the points of the torus covered by the parametrization (cf. Example 6 of Sec. 2-2)

$$\mathbf{x}(u, v) = ((a + r\cos u)\cos v, (a + r\cos u)\sin v, r\sin u),$$
$$0 < u < 2\pi, \quad 0 < v < 2\pi.$$

For the computation of the coefficients e, f, g, we need to know N (and thus $\mathbf{x}_u$ and $\mathbf{x}_v$), $\mathbf{x}_{uu}$, $\mathbf{x}_{uv}$, and $\mathbf{x}_{vv}$:

$$\begin{aligned}
\mathbf{x}_u &= (-r\sin u\cos v, -r\sin u\sin v, r\cos u),\\
\mathbf{x}_v &= (-(a + r\cos u)\sin v, (a + r\cos u)\cos v, 0),\\
\mathbf{x}_{uu} &= (-r\cos u\cos v, -r\cos u\sin v, -r\sin u),\\
\mathbf{x}_{uv} &= (r\sin u\sin v, -r\sin u\cos v, 0),\\
\mathbf{x}_{vv} &= (-(a + r\cos u)\cos v, -(a + r\cos u)\sin v, 0).
\end{aligned}$$

From these, we obtain

$$\begin{aligned}
E &= \langle \mathbf{x}_u, \mathbf{x}_u\rangle = r^2, \quad F = \langle \mathbf{x}_u, \mathbf{x}_v\rangle = 0,\\
G &= \langle \mathbf{x}_v, \mathbf{x}_v\rangle = (a + r\cos u)^2.
\end{aligned}$$

Introducing the values just obtained in $e = \langle N, \mathbf{x}_{uu}\rangle$, we have, since $|\mathbf{x}_u \wedge \mathbf{x}_v| = \sqrt{EG - F^2}$,

$$e = \left\langle \frac{\mathbf{x}_u \wedge \mathbf{x}_v}{|\mathbf{x}_u \wedge \mathbf{x}_v|}, \mathbf{x}_{uu} \right\rangle = \frac{(\mathbf{x}_u, \mathbf{x}_v, \mathbf{x}_{uu})}{\sqrt{EG - F^2}} = \frac{r^2(a + r\cos u)}{r(a + r\cos u)} = r.$$

Similarly, we obtain

$$\begin{aligned}
f &= \frac{(\mathbf{x}_u, \mathbf{x}_v, \mathbf{x}_{uv})}{r(a + r\cos u)} = 0,\\
g &= \frac{(\mathbf{x}_u, \mathbf{x}_v, \mathbf{x}_{vv})}{r(a + r\cos u)} = \cos u(a + r\cos u).
\end{aligned}$$

Finally, since $K = (eg - f^2)/(EG - F^2)$, we have that

$$K = \frac{\cos u}{r(a + r\cos u)}.$$

From this expression, it follows that $K = 0$ along the parallels $u = \pi/2$ and $u = 3\pi/2$; the points of such parallels are therefore parabolic points. In the region of the torus given by $\pi/2 < u < 3\pi/2$, K is negative (notice that $r > 0$ and $a > r$); the points in this region are therefore hyperbolic points. In the region given by $0 < u < \pi/2$ or $3\pi/2 < u < 2\pi$, the curvature is positive and the points are elliptic points (Fig. 3-15).

As an application of the expression for the second fundamental form in coordinates, we shall prove a proposition which gives information about the

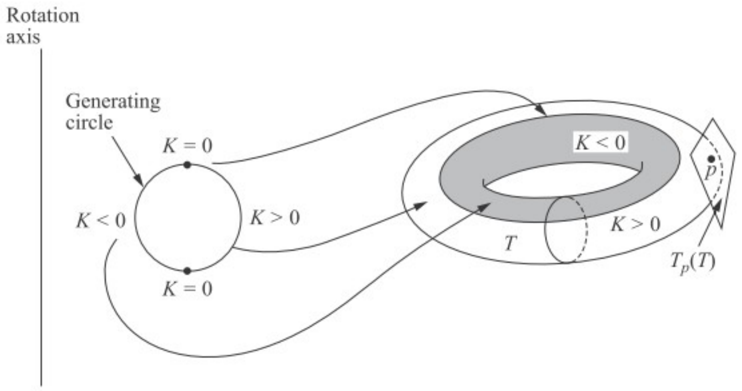

Figure 3-15

position of a surface in the neighborhood of an elliptic or a hyperbolic point, relative to the tangent plane at this point. For instance, if we look at an elliptic point of the torus of Example 1, we find that the surface lies on one side of the tangent plane at such a point (see Fig. 3-15). On the other hand, if p is a hyperbolic point of the torus T and $V \subset T$ is any neighborhood of p, we can find points of V on both sides of $T_p(S)$, however small V may be. This example reflects a general local fact that is described in the following proposition.

PROPOSITION 1. *Let* $\mathrm{p} \in \mathrm{S}$ *be an elliptic point of a surface* S. *Then there exists a neighborhood* V *of* p *in* S *such that all points in* V *belong to the same side of the tangent plane* $\mathrm{T_p(S)}$. *Let* $\mathrm{p} \in \mathrm{S}$ *be a hyperbolic point. Then in each neighborhood of* p *there exist points of* S *in both sides of* $\mathrm{T_p(S)}$.

Proof. Let $\mathbf{x}(u, v)$ be a parametrization in p, with $\mathbf{x}(0, 0) = p$. The distance d from a point $q = \mathbf{x}(u, v)$ to the tangent plane $T_p(S)$ is given by (Fig. 3-16)

$$d = \langle \mathbf{x}(u, v) - \mathbf{x}(0, 0), N(p) \rangle.$$

Since $\mathbf{x}(u, v)$ is differentiable, we have Taylor's formula:

$$\mathbf{x}(u, v) = \mathbf{x}(0, 0) + \mathbf{x}_u u + \mathbf{x}_v v + \tfrac{1}{2}(\mathbf{x}_{uu} u^2 + 2\mathbf{x}_{uv} uv + \mathbf{x}_{vv} v^2) + \bar{R},$$

where the derivatives are taken at $(0, 0)$ and the remainder $\bar{R}$ satisfies the condition

$$\lim_{(u,v)\to(0,0)} \frac{\bar{R}}{u^2 + v^2} = 0.$$

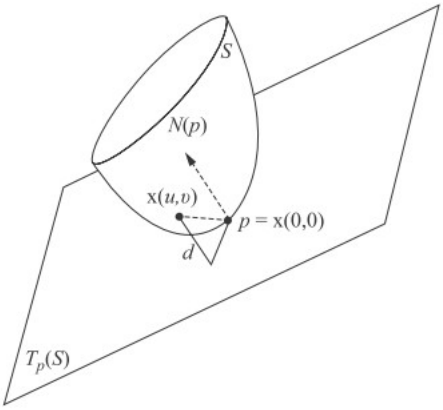

Figure 3-16

It follows that

$$\begin{aligned} d &= \langle \mathbf{x}(u, v) - \mathbf{x}(0, 0), N(p)\rangle \\ &= \tfrac{1}{2}\{\mathbf{x}_{uu}, N(p)\rangle u^2 + 2\langle \mathbf{x}_{uv}, N(p)\rangle uv + \langle \mathbf{x}_{vv}, N(p)\rangle v^2\} + R \\ &= \tfrac{1}{2}(eu^2 + 2fuv + gv^2) + R = \tfrac{1}{2}II_p(w) + R, \end{aligned}$$

where $w = \mathbf{x}_u u + \mathbf{x}_v v$, $R = \langle \bar{R}, N(p)\rangle$, and $\lim_{w\to 0}(R/|w|^2) = 0$.

For an elliptic point p, $II_p(w)$ has a fixed sign. Therefore, for all (u, v) sufficiently near p, d has the same sign as $II_p(w)$; that is, all such (u, v) belong to the same side of $T_p(S)$.

For a hyperbolic point p, in each neighborhood of p there exist points (u, v) and $(\bar{u}, \bar{v})$ such that $II_p(w/|w|)$ and $II_p(\bar{w}/|\bar{w}|)$ have opposite signs (here $\bar{w} = \mathbf{x}_u\bar{u} + \mathbf{x}_v\bar{v}$); such points belong therefore to distinct sides of $T_p(S)$.

Q.E.D.

No such statement as Prop. 1 can be made in a neighborhood of a parabolic or a planar point. In the above examples of parabolic and planar points (cf. Examples 3 and 6 of Sec. 3-2) the surface lies on one side of the tangent plane and may have a line in common with this plane. In the following examples we shall show that an entirely different situation may occur.

Example 2. The "monkey saddle" (see Fig. 3-17) is given by

$$x = u, \quad y = v, \quad z = u^3 - 3v^2u.$$

A direct computation shows that at (0, 0) the coefficients of the second fundamental form are $e = f = g = 0$; the point (0, 0) is therefore a planar point. In any neighborhood of this point, however, there are points in both sides of its tangent plane.

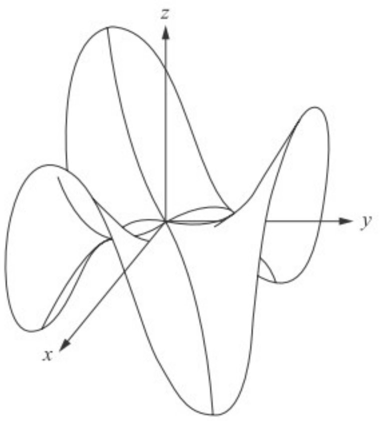

Figure 3-17

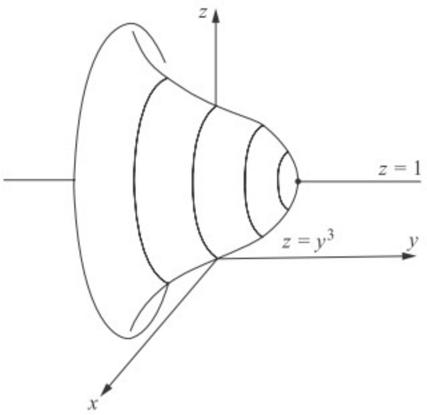

Figure 3-18

Example 3. Consider the surface obtained by rotating the curve $z = y^3$, $-1 < z < 1$, about the line $z = 1$ (see Fig. 3-18). A simple computation shows that the points generated by the rotation of the origin O are parabolic points. We shall omit this computation, because we shall prove shortly (Example 4) that the parallels and the meridians of a surface of revolution are lines of curvature; this, together with the fact that, for the points in question, the meridians (curves of the form $y = x^3$) have zero curvature and the parallel is a normal section, will imply the above statement.

Notice that in any neighborhood of such a parabolic point there exist points in both sides of the tangent plane.

The expression of the second fundamental form in local coordinates is particularly useful for the study of the asymptotic and principal directions. We first look at the asymptotic directions.

Let $\mathbf{x}(u, v)$ be a parametrization at $p \in S$, with $\mathbf{x}(0, 0) = p$, and let $e(u, v) = e$, $f(u, v) = f$, and $g(u, v) = g$ be the coefficients of the second fundamental form in this parametrization.

We recall that (see Def. 9 of Sec. 3-2) a connected regular curve C in the coordinate neighborhood of $\mathbf{x}$ is an asymptotic curve if and only if for any parametrization $\alpha(t) = \mathbf{x}(u(t), v(t))$, $t \in I$, of C we have $II(\alpha'(t)) = 0$, for all $t \in I$, that is, if and only if

$$e(u')^2 + 2fu'v' + g(v')^2 = 0, \quad t \in I. \tag{7}$$

Because of that, Eq. (7) is called the *differential equation of the asymptotic curves.* In the next section we shall give a more precise meaning to this expression. For the time being, we want to draw from Eq. (7) only the following useful conclusion: *A necessary and sufficient condition for a parametrization in a neighborhood of a hyperbolic point* ($\mathrm{eg} - \mathrm{f}^2 < 0$) *to be such that* *the coordinate curves of the parametrization are asymptotic curves is that* $\mathrm{e} = \mathrm{g} = 0$.

In fact, if both curves $u = \text{const.}$, $v = v(t)$ and $u = u(t)$, $v = \text{const.}$ satisfy Eq. (7), we obtain $e = g = 0$. Conversely, if this last condition holds and $f \neq 0$, Eq. (7) becomes $fu'v' = 0$, which is clearly satisfied by the coordinate lines.

We shall now consider the principal directions, maintaining the notations already established.

A connected regular curve C in the coordinate neighborhood of $\mathbf{x}$ is a line of curvature if and only if for any parametrization $\alpha(t) = \mathbf{x}(u(t), v(t))$ of C, $t \in I$, we have (cf. Prop. 3 of Sec. 3-2)

$$dN(\alpha'(t)) = \lambda(t)\alpha'(t).$$

It follows that the functions $u'(t)$, $v'(t)$ satisfy the system of equations

$$\begin{aligned} \frac{fF - eG}{EG - F^2}u' + \frac{gF - fG}{EG - F^2}v' &= \lambda u', \\ \frac{eF - fE}{EG - F^2}u' + \frac{fF - gE}{EG - F^2}v' &= \lambda v'. \end{aligned}$$

By eliminating λ in the above system, we obtain the *differential equation of the lines of curvature*,

$$(fE - eF)(u')^2 + (gE - eG)u'v' + (gF - fG)(v')^2 = 0,$$

which may be written, in a more symmetric way, as

$$\begin{vmatrix} (v')^2 & -u'v' & (u')^2 \\ E & F & G \\ e & f & g \end{vmatrix} = 0. \tag{8}$$

Using the fact that the principal directions are orthogonal to each other, it follows easily from Eq. (8) that *a necessary and sufficient condition for the coordinate curves of a parametrization to be lines of curvature in a neighborhood of a nonumbilical point is that* $F = f = 0$.

Example 4 (*Surfaces of Revolution*)**.** Consider a surface of revolution parametrized by (cf. Example 4 of Sec. 2-3; we have replaced f and g by φ and ψ, respectively)

$$\begin{aligned} \mathbf{x}(u, v) = (\varphi(v)\cos u, \varphi(v)\sin u, \psi(v)), \\ 0 < u < 2\pi, \quad a < v < b, \quad \varphi(v) \neq 0. \end{aligned}$$

The coefficients of the first fundamental form are given by

$$E = \varphi^2, \quad F = 0, \quad G = (\varphi')^2 + (\psi')^2.$$

It is convenient to assume that the rotating curve is parametrized by arc length, that is, that

$$(\varphi')^2 + (\psi')^2 = G = 1.$$

The computation of the coefficients of the second fundamental form is straightforward and yields

$$\begin{aligned} e &= \frac{(\mathbf{x}_u, \mathbf{x}_v, \mathbf{x}_{uu})}{\sqrt{EG - F^2}} = \frac{1}{\sqrt{EG - F^2}} \begin{vmatrix} -\varphi \sin u & \varphi' \cos u & -\varphi \cos u \\ \varphi \cos u & \varphi' \sin u & -\varphi \sin u \\ 0 & \psi' & 0 \end{vmatrix} \\ &= -\varphi\psi' \\ f &= 0, \\ g &= \psi'\varphi'' - \psi''\varphi'. \end{aligned}$$

Since $F = f = 0$, we conclude that the parallels ($v =$ const.) and the meridians ($u =$ const.) of a surface of revolution are lines of curvature of such a surface (this fact was used in Example 3).

Because

$$K = \frac{eg - f^2}{EG - F^2} = -\frac{\psi'(\psi'\varphi'' - \psi''\varphi')}{\varphi}$$

and φ is always positive, it follows that the parabolic points are given by either $\psi' = 0$ (the tangent line to the generator curve is perpendicular to the axis of rotation) or $\varphi'\psi'' - \psi'\varphi'' = 0$ (the curvature of the generator curve is zero). A point which satisfies both conditions is a planar point, since these conditions imply that $e = f = g = 0$.

It is convenient to put the Gaussian curvature in still another form. By differentiating $(\varphi')^2 + (\psi')^2 = 1$ we obtain $\varphi'\varphi'' = -\psi'\psi''$. Thus,

$$K = -\frac{\psi'(\psi'\varphi'' - \psi''\varphi')}{\varphi} = -\frac{(\psi')^2\varphi'' + (\varphi')^2\varphi''}{\varphi} = -\frac{\varphi''}{\varphi}. \qquad \textbf{(9)}$$

Equation (9) is a convenient expression for the Gaussian curvature of a surface of revolution. It can be used, for instance, to determine the surfaces of revolution of constant Gaussian curvature (cf. Exercise 7).

To compute the principal curvatures, we first make the following general observation: *If a parametrization of a regular surface is such that* $F = f = 0$, *then the principal curvatures are given by* e/E and g/G. In fact, in this case, the Gaussian and the mean curvatures are given by (cf. Eqs. (4) and (5))

$$K = \frac{eg}{EG}, \quad H = \frac{1}{2}\frac{eG + gE}{EG}.$$

Since K is the product and $2H$ is the sum of the principal curvatures, our assertion follows at once.

Thus, the principal curvatures of a surface of revolution are given by

$$\frac{e}{E} = -\frac{\psi'\varphi}{\varphi^2} = -\frac{\psi'}{\varphi}, \quad \frac{g}{G} = \psi'\varphi'' - \psi''\varphi'; \tag{10}$$

hence, the mean curvature of such a surface is

$$H = \frac{1}{2}\frac{-\psi' + \varphi(\psi'\varphi'' - \psi''\varphi')}{\varphi}. \tag{11}$$

Example 5. Very often a surface is given as the graph of a differentiable function (cf. Prop. 1, Sec. 2-2) $z = h(x, y)$, where (x, y) belong to an open set $U \subset R^2$. It is, therefore, convenient to have at hand formulas for the relevant concepts in this case. To obtain such formulas let us parametrize the surface by

$$\mathbf{x}(u, v) = (u, v, h(u, v)), \quad (u, v) \in U,$$

where $u = x$, $v = y$. A simple computation shows that

$$\mathbf{x}_u = (1, 0, h_u), \quad \mathbf{x}_v = (0, 1, h_v), \quad \mathbf{x}_{uu} = (0, 0, h_{uu}),$$
$$\mathbf{x}_{uv} = (0, 0, h_{uu}), \quad \mathbf{x}_{vv} = (0, 0, h_{vv}).$$

Thus

$$N(x, y) = \frac{(-h_x, -h_y, 1)}{(1 + h_x^2 + h_y^2)^{1/2}}$$

is a unit normal field on the surface, and the coefficients of the second fundamental form in this orientation are given by

$$e = \frac{h_{xx}}{(1 + h_x^2 + h_y^2)^{1/2}},$$
$$f = \frac{h_{xy}}{(1 + h_x^2 + h_y^2)^{1/2}},$$
$$g = \frac{h_{yy}}{(1 + h_x^2 + h_y^2)^{1/2}}.$$

From the above expressions, any needed formula can be easily computed. For instance, from Eqs. (4) and (5) we obtain the Gaussian and mean curvatures:

$$K = \frac{h_{xx}h_{yy} - h_{xy}^2}{(1 + h_x^2 + h_y^2)^2},$$

$$2H = \frac{(1 + h_x^2)h_{yy} - 2h_x h_y h_{xy} + (1 + h_y^2)h_{xx}}{(1 + h_x^2 + h_y^2)^{3/2}}.$$

There is still another, perhaps more important, reason to study surfaces given by $z = h(x, y)$. It comes from the fact that locally any surface is the graph of a differentiable function (cf. Prop. 3, Sec. 2-2). Given a point p of a surface S, we can choose the coordinate axis of R^3 so that the origin O of the coordinates is at p and the z axis is directed along the positive normal of S at p (thus, the xy plane agrees with $T_p(S)$). It follows that a neighborhood of p in S can be represented in the form $z = h(x, y)$, $(x, y) \in U \subset R^2$, where U is an open set and h is a differentiable function (cf. Prop. 3, Sec. 2-2), with $h(0, 0) = 0$, $h_x(0, 0) = 0$, $h_y(0, 0) = 0$ (Fig. 3-19).

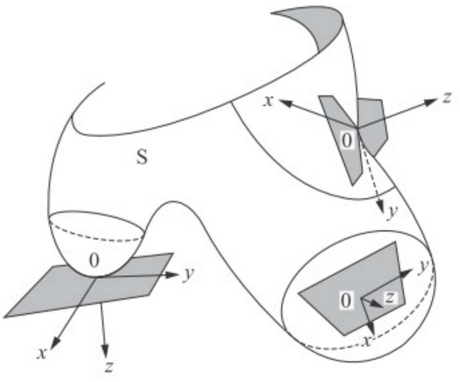

Figure 3-19. Each point of S has a neighborhood that can be written as $z = h(x, y)$.

The second fundamental form of S at p applied to the vector $(x, y) \in R^2$ becomes, in this case,

$$h_{xx}(0, 0)x^2 + 2h_{xy}(0, 0)xy + h_{yy}(0, 0)y^2.$$

In elementary calculus of two variables, the above quadratic form is known as the *Hessian* of h at $(0, 0)$. Thus, the Hessian of h at $(0, 0)$ is the second fundamental form of S at p.

Let us apply the above considerations to give a geometric interpretation of the Dupin indicatrix. With the notation as above, let $\epsilon > 0$ be a small number such that

$$C = \{(x, y) \in T_p(S);\, h(x, y) = \epsilon\}$$

is a regular curve (we may have to change the orientation of the surface to achieve $\epsilon > 0$). We want to show that if p is not a planar point, the curve C is "approximately" similar to the Dupin indicatrix of S at p (Fig. 3-20).

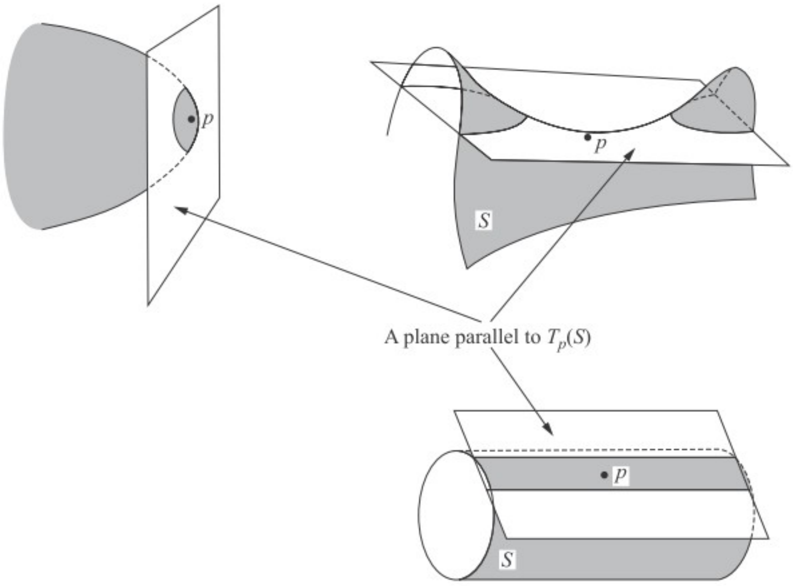

Figure 3-20

To see this, let us assume further that the x and y axes are directed along the principal directions, with the x axis along the direction of maximum principal curvature. Thus, $f = h_{xy}(0, 0) = 0$ and

$$k_1(p) = \frac{e}{E} = h_{xx}(0, 0), \quad k_2(p) = \frac{g}{G} = h_{yy}(0, 0).$$

By developing $h(x, y)$ into a Taylor's expansion about $(0, 0)$, and taking into account that $h_x(0, 0) = 0 = h_y(0, 0)$, we obtain

$$\begin{aligned} h(x, y) &= \tfrac{1}{2}(h_{xx}(0, 0)x^2 + 2h_{xy}(0, 0)xy + h_{yy}(0, 0)y^2) + R \\ &= \tfrac{1}{2}(k_1x^2 + k_2y^2) + R, \end{aligned}$$

where

$$\lim_{(x,y)\to(0,0)} \frac{R}{x^2 + y^2} = 0.$$

Thus, the curve C is given by

$$k_1x^2 + k_2y^2 + 2R = 2\epsilon.$$

Now, if p is not a planar point, we can consider $k_1x^2 + k_2y^2 = 2\epsilon$ as a first-order approximation of C in a neighborhood of p. By using the similarity transformation,

$$x = \bar{x}\sqrt{2\epsilon}, \quad y = \bar{y}\sqrt{2\epsilon},$$

we have that $k_1x^2 + k_2y^2 = 2\epsilon$ is transformed into the curve

$$k_1\bar{x}^2 + k_2\bar{y}^2 = 1,$$

which is the Dupin indicatrix at p. This means that *if* p *is a nonplanar point, the intersection with* S *of a plane parallel to* $\mathrm{T_p(S)}$ *and close to* p *is, in a first-order approximation, a curve similar to the Dupin indicatrix at* p.

If p is a planar point, this interpretation is no longer valid (cf. Exercise 11).

To conclude this section we shall give a geometrical interpretation of the Gaussian curvature in terms of the Gauss map $N: S \to S^2$. Actually, this was how Gauss himself introduced this curvature.

To do this, we first need a definition.

Let S and $\bar{S}$ be two oriented regular surfaces. Let $\varphi: S \to \bar{S}$ be a differentiable map and assume that for some $p \in S$, $d\varphi_p$ is nonsingular. We say that φ is *orientation-preserving* at p if given a positive basis $\{w_1, w_2\}$ in $T_p(S)$, then $\{d\varphi_p(w_1), d\varphi_p(w_2)\}$ is a positive basis in $T_{\varphi(p)}(\bar{S})$. If $\{d\varphi_p(w_1), d\varphi_p(w_2)\}$ is not a positive basis, we say that φ is *orientation-reversing* at p.

We now observe that both S and the unit sphere S^2 are embedded in R^3. Thus, an orientation N on S induces an orientation N in S^2. Let $p \in S$ be such that dN_p is nonsingular. Since for a basis $\{w_1, w_2\}$ in $T_p(S)$

$$dN_p(w_1) \wedge dN_p(w_2) = \det(dN_p)(w_1 \wedge w_2) = K\, w_1 \wedge w_2,$$

the Gauss map N will be orientation-preserving at $p \in S$ if $K(p) > 0$ and orientation-reversing at $p \in S$ if $K(p) < 0$. Intuitively, this means the following (Fig. 3-21): An orientation of $T_p(S)$ induces an orientation of small closed curves in S around p; the image by N of these curves will have the same or the opposite orientation to the initial one, depending on whether p is an elliptic or hyperbolic point, respectively.

To take this fact into account we shall make the convention that the area of the image by N of a region contained in a connected neighborhood $V \subset S$ where $K \neq 0$ is positive if $K > 0$ and negative if $K < 0$ (since V is connected, K does not change sign in V).

Now we can state the promised geometric interpretation of the Gaussian curvature K, for $K \neq 0$.

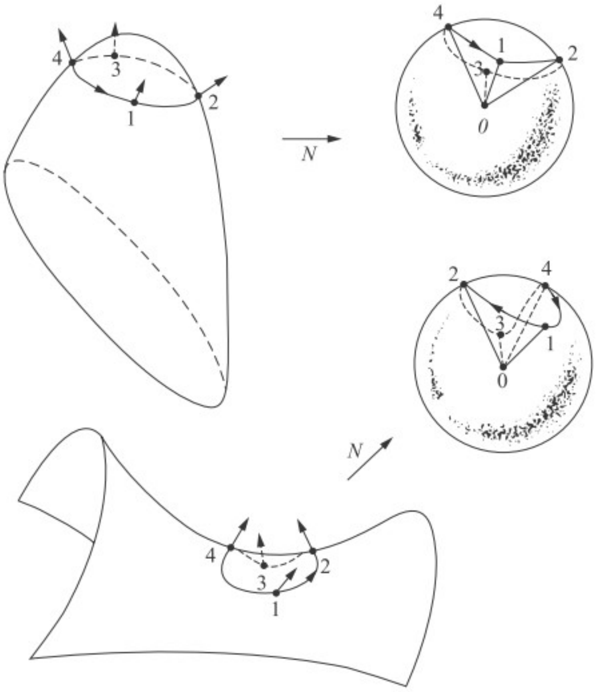

Figure 3-21. The Gauss map preserves orientation at an elliptic point and reverses it at a hyperbolic point.

PROPOSITION 2. *Let* p *be a point of a surface* S *such that the Gaussian curvature* $\mathrm{K(p)} \neq 0$, *and let* V *be a connected neighborhood of* p *where* K *does not change sign. Then*

$$\mathrm{K(p)} = \lim_{\mathrm{A}\to 0} \frac{\mathrm{A}'}{\mathrm{A}},$$

where A *is the area of a region* $\mathrm{B} \subset \mathrm{V}$ *containing* p*,* A′ *is the area of the image of* B *by the Gauss map* $\mathrm{N}\colon \mathrm{S} \to \mathrm{S}^2$*, and the limit is taken through a sequence of regions* $\mathrm{B_n}$ *that converges to* p*, in the sense that any sphere around* p *contains all* $\mathrm{B_n}$*, for* n *sufficiently large.*

Proof. The area A of B is given by (cf. Sec. 2-5)

$$A = \iint_R |\mathbf{x}_u \wedge \mathbf{x}_v|\, du\, dv,$$

where $\mathbf{x}(u, v)$ is a parametrization in p, whose coordinate neighborhood contains V (V can be assumed to be sufficiently small) and R is the region in the uv plane corresponding to B. The area A' of $N(B)$ is

$$A' = \iint_R |N_u \wedge N_v|\, du\, dv.$$

Using Eq. (1), the definition of K, and the above convention, we can write

$$A' = \iint_R K|\mathbf{x}_u \wedge \mathbf{x}_v|\, du\, dv. \qquad \textbf{(12)}$$

Going to the limit and denoting also by R the area of the region R, we obtain

$$\lim_{A\to 0} \frac{A'}{A} = \lim_{R\to 0} \frac{A'/R}{A/R} = \frac{\lim\limits_{R\to 0}(1/R) \iint_R K|\mathbf{x}_u \wedge \mathbf{x}_v|\, du\, dv}{\lim\limits_{R\to 0}(1/R) \iint_R |\mathbf{x}_u \wedge \mathbf{x}_v|\, du\, dv}$$
$$= \frac{K|\mathbf{x}_u \wedge \mathbf{x}_v|}{|\mathbf{x}_u \wedge \mathbf{x}_v|} = K$$

(notice that we have used the mean value theorem for double integrals), and this proves the proposition. **Q.E.D.**

Remark. Comparing the proposition with the expression of the curvature

$$k = \lim_{s\to 0} \frac{\sigma}{s}$$

of a plane curve C at p (here s is the arc length of a small segment of C containing p, and σ is the arc length of its image in the indicatrix of tangents; cf. Exercise 3 of Sec. 1-5), we see that the Gaussian curvature K is the analogue, for surfaces, of the curvature k of plane curves.

EXERCISES

1. Show that at the origin $(0, 0, 0)$ of the hyperboloid $z = axy$ we have $K = -a^2$ and $H = 0$.

***2.** Determine the asymptotic curves and the lines of curvature of the helicoid $x = v\cos u$, $y = v\sin u$, $z = cu$, and show that its mean curvature is zero.

***3.** Determine the asymptotic curves of the catenoid

$$\mathbf{x}(u, v) = (\cosh v \cos u, \cosh v \sin u, v).$$

4. Determine the asymptotic curves and the lines of curvature of $z = xy$.

5. Consider the parametrized surface (Enneper's surface)

$$\mathbf{x}(u, v) = \left(u - \frac{u^3}{3} + uv^2,\ v - \frac{v^3}{3} + vu^2,\ u^2 - v^2\right)$$

The lemma follows by using two adapted gradient fields to compute the relative characteristics.

Note that $\chi(D^n) = 1$: use a Morse function on $(D^n, \emptyset, S^{n-1})$ with just one minimum.

If X is boundaryless and Y is with boundary, then the very same argument used when Y is boundaryless allows us to extend the multiplicative property.

Lemma 14.8.

$$\chi(X \times Y) = \chi(X)\chi(Y) \ .$$

In particular,

$$\chi(X \times D^n) = \chi(X) \ .$$

14.6.1. Additive property of χ. If (W, V_0, V_1), (W', V_0', V_1') are triads and $\phi : V_1 \to V_0'$ is a diffeomorphism, we get a new composite triad (W'', V_0, V_1'), where $W'' = W \amalg_\phi W'$. Any couple of relative fields v and v' with isolated zeros on the given two triads, respectively, can be glued together to produce a relative field v'' having as zeros the union of the zeros of v and v', each one keeping its index. Then we have

$$\chi(W'', V_0, V_1') = \chi(W, V_0, V_1) + \chi(W', V_0', V_1') \ .$$

This additive property of χ has remarkable consequences.

14.6.2. A baby TQFT. In Section 10.8, we have roughly outlined the axioms of a so-called TQFT and posed the question about the existence of any "nontrivial" one. We use χ to provide a first nontrivial example. Consider $\mathbf{CAT}_\eta(n+1)$. Associate to every object M the vector space $Z(M) = \mathbb{C}$. To every arrow f, carried by a triad (W, M_0, M_1), associate the unitary $\mathbb{C}$-linear map

$$Z(f) : Z(M_0) \to Z(M_1), \ \ z \to e^{i\chi(W, M_0)} z \ .$$

By the additive property of χ, it is easy to check that all axioms are satisfied. This shows, at least, that there are not logical contradictions within the given pattern of axioms.

14.7. E-P characteristic of tubular neighbourhoods and the Gauss map

The identity $\chi(X \times D^n) = \chi(X)$ is a special case of the following.

Proposition 14.9. *Let $p : U \to X$ be a closed tubular neighbourhood of a submanifold X of some Y. Then $\chi(U) = \chi(X)$.*

Proof. It is enough to show the equality for an ϵ-neighbourhood $N_\epsilon(X)$ of the zero section X of a vector bundle $\pi : E \to X$ endowed with a field of positive definite scalar products on every fibre. Let v be a tangent field on X with nondegenerate zeros. Define the field on $N_\epsilon(X)$,

$$w(z) = (z - p(z)) + v(p(z)) \ .$$

We check that w is a field on the triad $(N_\epsilon(X), \emptyset, \partial N_\epsilon(X))$ and that the zeros of w coincide with the zeros of v, are nondegenerate, and keep the sign. The proposition follows. ■

In the special case $X \subset \mathbb{R}^k$, assume that U has been constructed using the standard metric on $\mathbb{R}^k$. By removing from the interior of U a system of pairwise disjoint small open disks $\mathcal{D}_p$ around each zero of w, we get a manifold W with boundary $(\amalg_p S^{k-1}_p) \amalg \partial U$ on which the normalized field $\mathfrak{w} := w/||w||$ is well-defined, as well as the map $\mathfrak{w} : W \to S^{k-1}$. The restriction of $\mathfrak{w}$ to ∂U is a field of unitary vectors pointing out from U (in fact normal to the boundary). This restriction, say $g_{\partial U}$, is called the *Gauss map of the hypersurface* ∂U.

Corollary 14.10. *Let $p : U \to X$ be a tubular neighbourhood of X in $\mathbb{R}^k$. Then*

$$\chi(X) = \deg(g_{\partial U})$$

where $g_{\partial U}$ is the Gauss map of the hypersurface ∂U.

The corollary follows by computing the characteristic as the sum of zero indices and using the bordism invariance of the degree.

If X itself is an oriented hypersurface in $\mathbb{R}^k$, $k \geq 2$, we can define its Gauss map $g_X : X \to S^{k-1}$, where this field of oriented unitary normal vectors along X is determined by the fact that, for every $x \in X$, $g_X(x) \oplus T_xX = T_x\mathbb{R}^k$ as oriented vector spaces, where $\mathbb{R}^k$ is endowed with the standard orientation. In this case, ∂U consists of two parallel copies of X with opposite orientations. The last corollary specializes to the following:

Corollary 14.11. *Let X be an oriented hypersurface of $\mathbb{R}^k$.*

(1) *If k is even, then $\chi(X) = 0$.*

(2) *If k is odd, then*

$$\chi(X) = 2\deg(g_X)$$

where g_X is the Gauss map of X.

The corollary follows by using that the degree of the antipodal map $a_{k-1} : S^{k-1} \to S^{k-1}$ is equal to $(-1)^k$.

Remark 14.12. We can compute inductively the characteristic of real and complex projective spaces by decomposing $\mathbf{P}^n(K)$ as the union of a tubular neighbourhood of $\mathbf{P}^{n-1}(K) \subset \mathbf{P}^n(K)$ and its complement and applying Proposition 14.9 together with the additivity of χ.

14.8. Nontriviality of $\eta_\bullet$ and $\Omega_\bullet$

The integer E-P characteristic is *not* invariant up to bordism. For example, $[S^2] = [S^1 \times S^1] = 0 \in \eta_2$, but $\chi(S^2) = 2 \neq 0 = \chi(S^1 \times S^1)$. On the other hand, the E-P characteristic mod(2) is bordism invariant.

Proposition 14.13. *Let* $[X] = 0 \in \eta_n$. *Then* $\chi_{(2)}(X) = 0 \in \mathbb{Z}/2\mathbb{Z}$.

Proof. If n is odd, we know in general that $\chi(X) = 0$. Assume that n is even. Let $X = \partial W$, W being a compact manifold with boundary. Take the double $D(W)$. The double $D(W)$ can be presented as the composition of the triad

$$(X \times D^1, \emptyset, (X \times \{-1\} \amalg (X \times \{1\})))$$

followed by two copies of the triad

$$(W, X, \emptyset)$$

glued to $X \times D^1$ along $X \times \{\pm 1\}$, respectively. By the additive property

$$\chi(D(W)) = \chi(X \times D^1) + 2\chi(W, X, \emptyset) \ .$$

By Lemmas 14.8 and 14.7 and the fact that $n + 1$ is odd and the double is boundaryless, we have

$$\chi(X) = \chi(D(W)) - 2\chi(W, X, \emptyset) = 2\chi(W) \in \mathbb{Z}$$

so that

$$\chi_{(2)}(X) = 0 \in \mathbb{Z}/2\mathbb{Z} \ . \qquad \blacksquare$$

As an immediate corollary, we have the *nontriviality of* η_{2n} *and* Ω_{4n}.

Corollary 14.14. *For every* $n \geq 1$, $\eta_{2n} \neq 0$ *and* $\Omega_{4n} \neq 0$.

Proof. We know that $\chi(\mathbf{P}^{2n}(\mathbb{R})) = 1$; hence $[\mathbf{P}^{2n}(\mathbb{R})] \neq 0 \in \eta_{2n}$. Similarly $\chi_{(2)}(\mathbf{P}^{2n}(\mathbb{C})) = 1$; hence $[\mathbf{P}^{2n}(\mathbb{C})] \neq 0 \in \Omega_{4n}$. ■

By using the multiplicative property of χ and the obvious fact that it is additive under disjoint union, we also have the following.

Gauss map of the hypersurface $\mathcal{V}$.

von Bedeutung sind, findet man im Band 4 *Bezugssysteme* der *Grundlagen der Physikalischen und Mathematischen Geodäsie.*

Die Koordinaten der Beobachtungsstation $\mathbf{R}_S$ beziehen sich auf ein erdfestes Bezugssystem und die des topozentrischen Ortsvektors $\mathbf{R}$ entweder auf ein raumfestes oder ein erdfestes Bezugssystem. Zur Modellbildung muss deshalb ein einheitlicher Bezugsrahmen vereinbart werden, auf den sich die Koordinaten der Vektoren der geometrischen Grundgleichung beziehen. Im Prinzip kann auch ein beliebig bewegtes Bezugssystem gewählt werden, also beispielsweise auch das erdfeste Bezugssystem. In diesem Fall muss die Bewegungsgleichung (7.2) um die entsprechenden Trägheitskräfte erweitert werden.

Im Folgenden wird der Fall angenommen, dass die in einem erdfesten Bezugsrahmen gewonnenen Beobachtungen des topozentrischen Ortsvektors $\mathbf{R}(t)$ wie auch die geozentrischen Ortsvektoren der Beobachtungsstationen $\mathbf{R}_S(t)$ in das Newton-System transformiert werden, in dem die Bewegungsgleichung für die geozentrische Satellitenposition $\mathbf{r}(t)$ gilt. Häufig wird als Bezugssystem, in dem die Beobachtungsgleichungen formuliert werden, das wahre raumfeste Äquatorsystem zum momentanen Zeitpunkt t (CRFt, auch mit $\tilde{\mathcal{A}}(t)$ bezeichnet) gewählt. Man beachte, dass es sich dabei ebenfalls um ein bewegtes Bezugssystem handelt, das sich bzgl. eines raumfesten Bezugssystems um die Effekte der Nutation und Präzession bewegt. Deshalb sind in der Bewegungsgleichung entsprechende Trägheitskräfte zu berücksichtigen. Im Prinzip sind aber auch andere Festlegungen möglich (siehe auch Schneider 1990, 1988, 1999; Newcomb 1892, 1960).

7.1.1 Transformation der Ortsvektoren der Beobachtungsstationen

Als „erdraumbezogenes Bezugssystem“, in dem beispielsweise die Koordinaten der Beobachtungsstationen definiert sind, wird ein vereinbarter erdfester Bezugsrahmen einer bestimmten Epoche t_S gewählt. Verwendet man die Bezugsrahmen des IERS (International Earth Rotation and Reference System Service – McCarthy, Petit (Hrsg.), 2004; IERS Conventions, 2010), so handelt es sich hierbei um den ITRF t_S (ITRF International conventional Terrestrial Reference Frame zur Epoche t_S), auch mit $\mathcal{G}(t_S)$ bezeichnet. Als Bezugssystem, in dem die Beobachtungsgleichungen formuliert werden, wird das wahre raumfeste Äquatorsystem zum momentanen Zeitpunkt t (CRFt, auch mit $\tilde{\mathcal{A}}(t)$ bezeichnet) gewählt.

Die Transformation der Stationskoordinaten $\mathbf{R}_S$, definiert im vereinbarten erdfesten Bezugsrahmen der Epoche t_s, $\mathcal{G}(t_S)$, in den wahren raumfesten Bezugsrahmen (true Celestial Reference Frame CRFt), entspricht dem wahren raumfesten Äquatorsystem $\tilde{\mathcal{A}}(t)$) zum Zeitpunkt t, beinhaltet die Drehungen zufolge der Polbewegung und die tägliche Rotation der Erde, bestehend aus der:

- Transformation vom vereinbarten erdfesten Bezugsrahmen der Epoche t_s (ITRF t_s auch mit $\mathcal{G}(\boldsymbol{t_s})$ bezeichnet) in den wahren erdfesten Bezugsrahmen derselben Epoche t_s (Terrestrial Reference Frame TRF t_s, auch mit $\tilde{\mathcal{G}}(\boldsymbol{t_s})$ bezeichnet): Polbewegung sowie der

- Transformation vom wahren erdfesten Bezugsrahmen t_{s} (true Terrestrial Reference Frame – TRF t_{s}) in den wahren raumfesten Bezugsrahmen der Epoche t (true celestial reference frame – CRFt, auch mit $\tilde{\mathcal{A}}(t)$ bezeichnet): tägliche Drehung.

Die Transformation der rechtwinklig-kartesischen Koordinaten des vereinbarten erdfesten Bezugsrahmens der Epoche t_{S} (ITRFt_{S}) in Koordinaten des wahren raumfesten Bezugsrahmens der Epoche t (CRFt) gelingt durch die Folge von drei Drehungen

$$\begin{pmatrix} \mathbf{e}_1 \\ \mathbf{e}_2 \\ \mathbf{e}_3 \end{pmatrix}_{\mathrm{CRF}t} = \mathbf{S}(x_P, y_P, -\,\mathrm{GAST}) \begin{pmatrix} \mathbf{e}_1 \\ \mathbf{e}_2 \\ \mathbf{e}_3 \end{pmatrix}_{\mathrm{ITRF}t_S} \tag{7.3}$$

mit der Drehmatrix $\mathbf{S}$, die zwei Drehungen zufolge der Polbewegung, ausgedrückt durch die Polkoordinaten (x_P, y_P), und die tägliche Drehung, ausgedrückt durch die scheinbare Sternzeit des Meridians von Greenwich, beschreibt

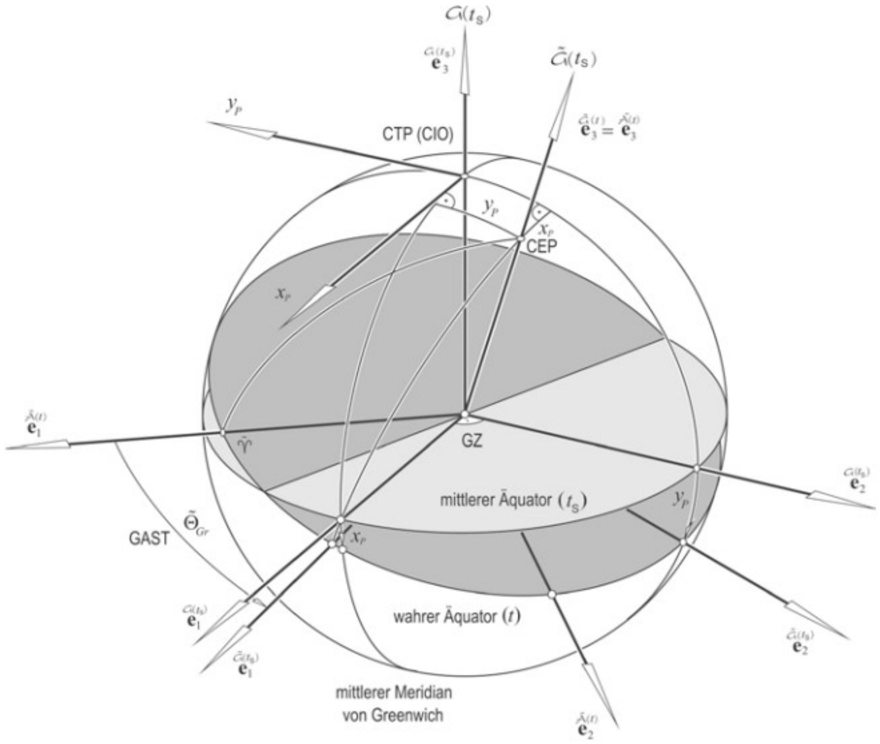
$$\mathbf{S}(x_P, y_P, -\mathrm{GAST}) := \mathbf{D}_3(-\mathrm{GAST})\ \mathbf{D}_1(y_P)\ \mathbf{D}_2(x_P) \tag{7.4}$$

Die beteiligten Koordinatensysteme sind in der Abb. 7.1 dargestellt. Das wahre raumfeste Äquatorsystem $\tilde{\mathcal{A}}(t)$ ist durch den wahren raumfesten Äquator (true celestial equator) und durch den wahren raumfesten Ephemeridenpol (true Celestial Ephemeris Pole – CEP) in Richtung $(\mathbf{e}_3)_{\tilde{\mathcal{C}}(t_{\mathsf{S}})} \equiv (\mathbf{e}_3)_{\tilde{\mathcal{A}}(t)}$ definiert. Das mittlere (vereinbarte) globale geozentrische Bezugssystem $\mathcal{C}(t_{\mathsf{S}})$ ist durch den vereinbarten mittleren erdfesten Äquator (conventional mean terrestrial equator) und den vereinbarten erdfesten Pol (Conventional Terrestrial Pole – CTP) in Richtung $(\mathbf{e}_3)_{\mathcal{C}(t_{\mathsf{S}})}$ zur Epoche t_{S} definiert. Die Lage des CEP bzgl. dem CTP ist durch die Parameter der Polbewegung (Polkoordinaten (x_P, y_P)) beschrieben.

Der Winkel zwischen der x-Achse $(\mathbf{e}_1)_{\tilde{\mathcal{A}}(t)}$ des wahren raumfesten Äquatorsystems $\tilde{\mathcal{A}}(t)$ (Richtung des wahren Frühlingspunktes zur Epoche t) und der x-Achse $(\mathbf{e}_1)_{\tilde{\mathcal{C}}(t_{\mathsf{S}})}$ des wahren globalen geozentrischen Koordinatensystems $\tilde{\mathcal{C}}(t_{\mathsf{S}})$ (die in der mittleren astronomischen Meridianebene von Greenwich liegt) ist durch den Stundenwinkel $t_{\tilde{\mathcal{C}}(t_{\mathsf{S}})}$ des wahren Frühlingspunktes von Greenwich, der scheinbaren Sternzeit des Meridians von Greenwich (GAST), definiert. Die scheinbare Sternzeit Greenwich GAST unterliegt einer ständigen i. Allg. ungleichförmigen Veränderung wegen der Rotation der Erde. Sie kann aus der mittleren Sternzeit Greenwich (Greenwich Mean Siderial Time – GMST) berechnet werden. Die mittlere Sternzeit Greenwich GMST selbst erhält man aus einem zeitlichen Polynomansatz, der aus der Differenz der aus Beobachtungen erhaltenen Weltzeit UT1 (Universal Time 1 – UT1) und der Atomzeit UTC (Universal Time Coordinated – UTC) abgeleitet wird:

$$\Delta t = UTC - UT1. \tag{7.5}$$

Die Integration von Δt über einen Tag ergibt die Veränderungen der Tageslänge (Length Of the Day – LOD). Die Zeitdifferenz Δt kann nicht in Form



$\mathcal{G}(t_{\mathrm{S}})$
$\mathbf{e}_3^{\mathcal{G}(t_{\mathrm{S}})}$
$\tilde{\mathcal{G}}(t_{\mathrm{S}})$
y_P
CTP (CIO)

Abb. 7.1 Transformation vom vereinbarten erdfesten Bezugsrahmen der Epoche t_{S} (ITRF t_{S}, auch mit $\mathcal{G}(t_{\mathrm{S}})$ bezeichnet) in den wahren raumfesten Bezugsrahmen der Epoche t (CRFt, auch mit $\tilde{\mathcal{A}}(t)$ bezeichnet)

einer analytischen Funktion angegeben werden. Sie muss zusammen mit den Polkoordinaten (x_P, y_P) durch Beobachtung erfasst werden und kann erst im Nachhinein bekannt gegeben werden.

7.1.2 Transformation der topozentrischen Ortsvektoren zum Satelliten

Für die Transformation des topozentrischen Satellitenortes $\mathbf{R}(t)$ in das wahre raumfeste Äquatorsystem zum momentanen Zeitpunkt t, $\tilde{\mathcal{A}}(t)$, ist entscheidend, in welchem System die topozentrischen Richtungen (Rektaszensionen und Deklinationen) zum Satelliten erhalten worden waren. I. Allg. wird es sich um einen mittleren raumfesten Bezugsrahmen zur Epoche $t_0 = \mathrm{J}2000{,}0$ (ICRFt_0) handeln. Die Transformation der rechtwinklig-kartesischen Koordinaten bzgl. des mittleren raumfesten Bezugsrahmens der Epoche $t_0 = \mathrm{J}2000{,}0$ (ICRFt_0, auch mit $\mathcal{A}(t_0)$ bezeichnet) in Koordinaten des wahren raumfesten Äquatorsystems zum momentanen Zeitpunkt t (CRFt, auch mit $\tilde{\mathcal{A}}(t)$ bezeichnet) gelingt durch die Folge von sechs Drehungen $\mathbf{D}$, die in zwei Drehmatrizen, die Präzession $\mathbf{P}$ und die Nutation $\mathbf{N}$ zusammengefasst sind (Mathews et al. 2002):

- Transformation vom mittleren raumfesten Bezugsrahmen der Epoche $t_0 = \text{J2000,0}$ ($\mathcal{A}(t_0)$), in den mittleren raumfesten Bezugsrahmen t ($\mathcal{A}(t)$): ***Präzession,***
- Transformation vom mittleren raumfesten Bezugsrahmen der Epoche t (ICRFt) in den wahren raumfesten Bezugsrahmen zur selben Epoche t ($\tilde{\mathcal{A}}(t)$): ***Nutation.***

Die gesamte Transformation lautet:

$$\begin{pmatrix} \mathbf{e}_1 \\ \mathbf{e}_2 \\ \mathbf{e}_3 \end{pmatrix}_{\text{CRF}t} = \mathbf{D}(-\zeta, \vartheta, -z, \varepsilon_s, -\Delta\psi, -\varepsilon_s - \Delta\varepsilon) \begin{pmatrix} \mathbf{e}_1 \\ \mathbf{e}_2 \\ \mathbf{e}_3 \end{pmatrix}_{\text{ICRF}t_0} \tag{7.6}$$

mit der Drehmatrix

$$\mathbf{D}(-\zeta, \vartheta, -z, \varepsilon_s, -\Delta\psi, -\varepsilon_s - \Delta\varepsilon) = \mathbf{N}(\varepsilon_s, -\Delta\psi, -\varepsilon_s - \Delta\varepsilon)\ \mathbf{P}(-\zeta, \vartheta, -z). \tag{7.7}$$

Die ersten drei hintereinandergeschalteten Drehungen beschreiben nach Newcomb die allgemeine (lunisolare und planetare) Präzession $\mathbf{P}$ für den Zeitraum zwischen den Epochen $t_0 = \text{J2000,0}$ und t, (Abb. 7.2)

$$\mathbf{P}(-\zeta, \vartheta, -z) := \mathbf{D}_3(-z)\ \mathbf{D}_2(\vartheta)\ \mathbf{D}_3(-\zeta) \tag{7.8}$$

mit den äquatorialen Präzessionsparametern

$$\begin{aligned} \zeta &= 2306{,}''2181\,T + 0{,}''30188\,T^2 + 0{,}''017998\,T^3, \\ \vartheta &= 2004{,}''3109\,T - 0{,}''42665\,T^2 - 0{,}''041833\,T^3, \\ z &= 2306{,}''2181\,T + 1{,}''09468\,T^2 + 0{,}''018203\,T^3, \end{aligned} \tag{7.9}$$

wobei die Zeitdifferenz T in Julianischen Jahrhunderten der baryzentrischen dynamischen Zeit TDB ***(Barycentric Dynamical Time – TDB)*** einzusetzen ist

$$T = (t - J2000{,}0)\big/36525{,}0. \tag{7.10}$$

Die Größe t ist das Julianische Datum der Berechnungsepoche. Diese Parameter entstammen einem numerischen Modell, das von der IAU im Jahre 1976 verbindlich angenommen worden ist. Obwohl in der Zwischenzeit genauere Werte bekannt sind, werden diese vereinbarten Parameter noch beibehalten, um die Gültigkeit und Konsistenz der Systeme über einen angemessenen Zeitraum zu gewährleisten.

Die Transformation vom mittleren raumfesten Äquatorsystem $\mathcal{A}(t)$ ins wahre raumfeste Äquatorsystem $\tilde{\mathcal{A}}(t)$ wird durch die astronomische Nutation $\mathbf{N}$ zur Epoche t beschrieben:

$$\begin{pmatrix} \mathbf{e}_1 \\ \mathbf{e}_2 \\ \mathbf{e}_3 \end{pmatrix}_{\tilde{\mathcal{A}}(t)} = \mathbf{N}(\varepsilon_s, -\Delta\psi, -\varepsilon_s - \Delta\varepsilon) \begin{pmatrix} \mathbf{e}_1 \\ \mathbf{e}_2 \\ \mathbf{e}_3 \end{pmatrix}_{\mathcal{A}(t)}. \tag{7.11}$$

7.2 Bewegungsgleichung des Satelliten im wahren Äquatorsystem

Für die Formulierung der Bewegungsgleichung des Satelliten $\mathbf{r}(t)$ im wahren raumfesten Äquatorsystem $\widetilde{\mathcal{A}}(t)$ müssen die Trägheitskräfte berücksichtigt werden. Der geozentrische Ortsvektor $\mathbf{r}(t)$ hängt über die Bewegungsgleichung

$$\ddot{\mathbf{r}}(t) = \frac{d^2\mathbf{r}}{dt^2} = \mathbf{a}(t;\ \boldsymbol{\alpha}, \mathbf{x}_\mathrm{I},\ \mathbf{x}_\mathrm{R}) \tag{7.16}$$

bezogen auf ein im Geozentrum definiertes Newton-System (im vorliegenden Fall das mittlere raumfeste Äquatorsystem) $\mathcal{N} \equiv \mathcal{A}(t)$, von den auf den Satelliten wirkenden Feldstärken des Gravitationsfeldes und der Störbeschleunigungen ab

$$\mathbf{a}(t_k;\ \mathbf{x}_i,\ \mathbf{x}_\mathrm{R}) = \mathbf{a}_\mathrm{K}(t_k) + \mathbf{a}_\mathrm{R}(t_k) + \mathbf{a}_\mathrm{St}(t_k) \tag{7.17}$$

Die Zeitableitung der Bahnfunktion, $\ddot{\mathbf{r}}(t) = d^2\mathbf{r}/dt^2$, bezieht sich dabei auf das Newton-System $\mathcal{A}(t)$. Die Drehmatrix

$$\mathbf{D}(-\zeta, \vartheta, -z, \varepsilon_s, -\Delta\psi, -\varepsilon_s - \Delta\varepsilon) = \mathbf{N}(\varepsilon_s, -\Delta\psi, -\varepsilon_s - \Delta\varepsilon)\ \mathbf{P}(-\zeta, \vartheta, -z) \tag{7.18}$$

general relativistic effects) and will not be expounded here. We are primarily concerned with gravitation on and external to the solid and liquid Earth since this is the domain of most applications. The internal field can also be modeled for specialized purposes (such as submarine navigation), but internal geophysical modeling, for example, is done usually in terms of the sources (mass density distribution), rather than the resulting field.

3.02.1.2 Coordinate Systems

Modeling the Earth's gravitational field depends on the choice of coordinate system. Customarily, owing to the Earth's general shape, a spherical polar coordinate system serves for most applications, and virtually all global models use these coordinates. However, the Earth is slightly flattened at the poles, and an ellipsoidal coordinate system has also been advocated for some near-Earth applications. We note that the geodetic coordinates associated with a geodetic datum (based on an ellipsoid) are never used in a foundational sense to model the field since they do not admit to a separation-of-variables solution of Laplace' differential equation (Section 3.02.4.1).

Spherical polar coordinates, described with the aid of **Figure 1**, comprise the spherical colatitude, θ, the longitude, λ, and the radial distance, r. Their relation to Cartesian coordinates is

$$\begin{aligned} x &= r\sin\theta\cos\lambda \\ y &= r\sin\theta\sin\lambda \\ z &= r\cos\theta \end{aligned} \qquad [1]$$

Considering Earth's polar flattening, a better approximation, than a sphere, of its (ocean) surface is an ellipsoid of revolution. Such a surface is generated by rotating an ellipse about its minor axis (polar axis). The two focal points of the best-fitting, Earth-centered ellipsoid (ellipse) are located in the equator about $E = 522$ km from the center of the Earth. A given ellipsoid, with specified semiminor axis, b, and linear eccentricity, E, defines the set of ellipsoidal coordinates, as described in **Figure 2**. The longitude is the same as in the spherical case. The colatitude, δ, is the complement of the so-called reduced latitude; and the distance coordinate, u, is the semiminor axis of the confocal ellipsoid through the point in question. We call (δ, λ, u) ellipsoidal coordinates; they are also known as spheroidal coordinates, or Jacobi ellipsoidal coordinates. Their relation to Cartesian coordinates is given by

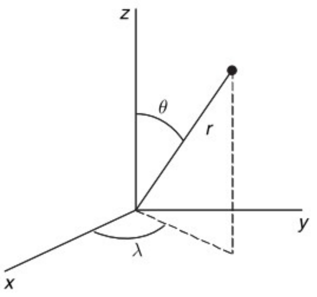

Figure 1 Spherical polar coordinates.

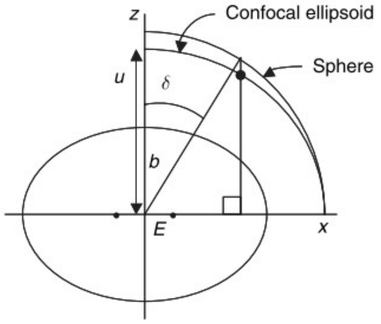

Figure 2 Ellipsoidal coordinates.

$$\begin{aligned} x &= \sqrt{u^2+E^2}\sin\delta\cos\lambda \\ y &= \sqrt{u^2+E^2}\sin\delta\sin\lambda \\ z &= u\cos\delta \end{aligned} \qquad [2]$$

Points on the given ellipsoid all have $u = b$; and, all surfaces, $u =$ constant, are confocal ellipsoids (the analogy to the spherical case, when $E = 0$, should be evident).

3.02.1.3 Preliminary Definitions and Concepts

The gravitational potential, V, of the Earth is generated by its total mass density distribution. For applications on the Earth's surface it is useful to include the potential, ϕ, associated with the centrifugal acceleration due to Earth's rotation. The sum, $W = V + \phi$, is then known, in geodetic terminology, as the gravity potential, distinct from gravitational potential. It is further advantageous to define a relatively simple reference potential, or normal potential, that accounts for the bulk of the gravity potential

(Section 3.02.5.2). The normal gravity potential, U, is defined as a gravity potential associated with a best-fitting ellipsoid, the normal ellipsoid, which rotates with the Earth and is also a surface of constant potential in this field. The difference between the actual and the normal gravity potentials is known as the disturbing potential: $T = W - U$; it thus excludes the centrifugal potential. The normal gravity potential accounts for approximately 99.999 5% of the total potential.

The gradient of the potential is an acceleration, gravity or gravitational acceleration, depending on whether or not it includes the centrifugal acceleration. Normal gravity, γ, comprises 99.995% of the total gravity, g, although the difference in magnitudes, the gravity disturbance, δg, can be as large as several parts in 10^4. A special kind of difference, called the gravity anomaly, Δg, is defined as the difference between gravity at a point, P, and normal gravity at a corresponding point, Q, where $W_P = U_Q$, and P and Q are on the same perpendicular to the normal ellipsoid.

The surface of constant gravity potential, W_0, that closely approximates mean sea level is known as the geoid. If the constant normal gravity potential, U_0, on the normal ellipsoid is equal to the constant gravity potential of the geoid, then the gravity anomaly on the geoid is the difference between gravity on the geoid and normal gravity on the ellipsoid at respective points, P_0, Q_0, sharing the same perpendicular to the ellipsoid. The separation between the geoid and the ellipsoid is known as the geoid undulation, N, or also the geoid height (**Figure 3**). A simple Taylor expansion of the normal gravity potential along the ellipsoid perpendicular yields the following important formula:

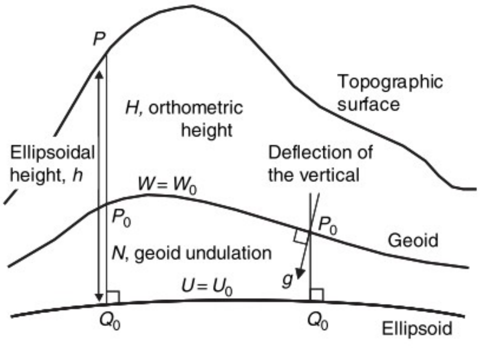

Figure 3 Relative geometry of geoid and ellipsoid.

$$N = \frac{T}{\gamma} \qquad [3]$$

This is Bruns' equation, which is accurate to a few millimeters in N, and which can be extended to $N = T/\gamma - (W_0 - U_0)/\gamma$ for the general case, $W_0 \neq U_0$. The gravity anomaly (on the geoid) is the gravity disturbance corrected for the evaluation of normal gravity on the ellipsoid instead of the geoid. This correction is $N\,\partial\gamma/\partial h = (\partial\gamma/\partial h)(T/\gamma)$, where h is height along the ellipsoid perpendicular. We have $\delta g = -\partial T/\partial h$, and hence

$$\Delta g = -\frac{\partial T}{\partial h} + \frac{1}{\gamma}\frac{\partial \gamma}{\partial h} T \qquad [4]$$

The slope of the geoid with respect to the ellipsoid is also the angle between the corresponding perpendiculars to these surfaces. This angle is known as the deflection of the vertical, that is, the deflection of the plumb line (perpendicular to the geoid) relative to the perpendicular to the normal ellipsoid. The deflection angle has components, ξ, η, respectively, in the north and east directions. The spherical approximations to the gravity disturbance, anomaly, and deflection of the vertical are given by

$$\begin{aligned} \delta g &= -\frac{\partial T}{\partial r}, & \Delta g &= -\frac{\partial T}{\partial r} - \frac{2}{r} T \\ \xi &= \frac{1}{\gamma}\frac{\partial T}{r \partial \theta}, & \eta &= -\frac{1}{\gamma}\frac{\partial T}{r \sin\theta\, \partial \lambda} \end{aligned} \qquad [5]$$

where the signs on the derivatives are a matter of convention.

3.02.2 Newton's Law of Gravitation

In its original form, Newton's law of gravitation applies only to idealized point masses. It describes the force of attraction, **F**, experienced by two such solitary masses as being proportional to the product of the masses, m_1 and m_2; inversely proportional to the distance, ℓ, between them; and directed along the line joining them:

$$\mathbf{F} = G\frac{m_1 m_2}{\ell^2}\mathbf{n} \qquad [6]$$

G is a constant, known as Newton's gravitational constant, that takes care of the units between the left- and right-hand sides of the equation; it can be

(Section 3.02.5.2). The normal gravity potential, U, is defined as a gravity potential associated with a best-fitting ellipsoid, the normal ellipsoid, which rotates with the Earth and is also a surface of constant potential in this field. The difference between the actual and the normal gravity potentials is known as the disturbing potential: $T = W - U$; it thus excludes the centrifugal potential. The normal gravity potential accounts for approximately 99.999 5% of the total potential.

The gradient of the potential is an acceleration, gravity or gravitational acceleration, depending on whether or not it includes the centrifugal acceleration. Normal gravity, γ, comprises 99.995% of the total gravity, g, although the difference in magnitudes, the gravity disturbance, δg, can be as large as several parts in 10^4. A special kind of difference, called the gravity anomaly, Δg, is defined as the difference between gravity at a point, P, and normal gravity at a corresponding point, Q, where $W_P = U_Q$, and P and Q are on the same perpendicular to the normal ellipsoid.

The surface of constant gravity potential, W_0, that closely approximates mean sea level is known as the geoid. If the constant normal gravity potential, U_0, on the normal ellipsoid is equal to the constant gravity potential of the geoid, then the gravity anomaly on the geoid is the difference between gravity on the geoid and normal gravity on the ellipsoid at respective points, P_0, Q_0, sharing the same perpendicular to the ellipsoid. The separation between the geoid and the ellipsoid is known as the geoid undulation, N, or also the geoid height (**Figure 3**). A simple Taylor expansion of the normal gravity potential along the ellipsoid perpendicular yields the following important formula:

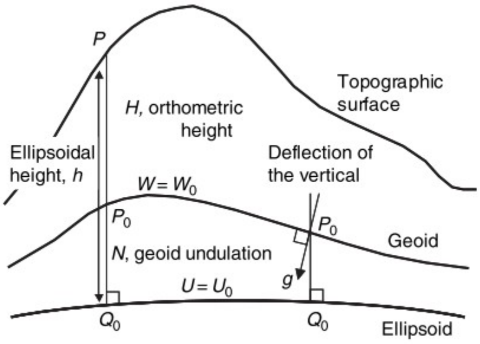

Figure 3 Relative geometry of geoid and ellipsoid.

$$N = \frac{T}{\gamma} \qquad [3]$$

This is Bruns' equation, which is accurate to a few millimeters in N, and which can be extended to $N = T/\gamma - (W_0 - U_0)/\gamma$ for the general case, $W_0 \neq U_0$. The gravity anomaly (on the geoid) is the gravity disturbance corrected for the evaluation of normal gravity on the ellipsoid instead of the geoid. This correction is $N\,\partial\gamma/\partial h = (\partial\gamma/\partial h)(T/\gamma)$, where h is height along the ellipsoid perpendicular. We have $\delta g = -\partial T/\partial h$, and hence

$$\Delta g = -\frac{\partial T}{\partial h} + \frac{1}{\gamma}\frac{\partial \gamma}{\partial h} T \qquad [4]$$

The slope of the geoid with respect to the ellipsoid is also the angle between the corresponding perpendiculars to these surfaces. This angle is known as the deflection of the vertical, that is, the deflection of the plumb line (perpendicular to the geoid) relative to the perpendicular to the normal ellipsoid. The deflection angle has components, ξ, η, respectively, in the north and east directions. The spherical approximations to the gravity disturbance, anomaly, and deflection of the vertical are given by

$$\begin{aligned} \delta g &= -\frac{\partial T}{\partial r}, \qquad & \Delta g &= -\frac{\partial T}{\partial r} - \frac{2}{r} T \\ \xi &= \frac{1}{\gamma}\frac{\partial T}{r \partial \theta}, \qquad & \eta &= -\frac{1}{\gamma}\frac{\partial T}{r \sin\theta\, \partial \lambda} \end{aligned} \qquad [5]$$

where the signs on the derivatives are a matter of convention.

3.02.2 Newton's Law of Gravitation

In its original form, Newton's law of gravitation applies only to idealized point masses. It describes the force of attraction, $\mathbf{F}$, experienced by two such solitary masses as being proportional to the product of the masses, m_1 and m_2; inversely proportional to the distance, ℓ, between them; and directed along the line joining them:

$$\mathbf{F} = G\frac{m_1 m_2}{\ell^2}\mathbf{n} \qquad [6]$$

G is a constant, known as Newton's gravitational constant, that takes care of the units between the left- and right-hand sides of the equation; it can be determined by experiment and the current best value is (Groten, 2004):

$$G = (6.67259 \pm 0.00030) \times 10^{-11}\ \mathrm{m}^3\,\mathrm{kg}^{-1}\,\mathrm{s}^{-2} \quad [7]$$

The unit vector $\mathbf{n}$ in eqn [6] is directed from either point mass to the other, and thus the gravitational force is attractive and applies equally to one mass as the other. Newton's law of gravitation is universal as far as we know, requiring reformulation only in Einstein's more comprehensive theory of general relativity which describes gravitation as a characteristic curvature of the space–time continuum (Newton's formulation assumes instantaneous action and differs significantly from the general relativistic concept only when very large velocities or masses are involved).

We can ascribe a gravitational acceleration to the gravitational force, which represents the acceleration that one mass undergoes due to the gravitational attraction of the other. Specifically, from the law of gravitation, we have (for point masses) the gravitational acceleration of m_1 due to the gravitational attraction of m_2:

$$\mathbf{g} = G\frac{m_2}{\ell^2}\mathbf{n} \quad [8]$$

The vector $\mathbf{g}$ is independent of the mass, m_1, of the body being accelerated (which Galileo found by experiment).

By the law of superposition, the gravitational force, or the gravitational acceleration, due to many point masses is the vector sum of the forces or accelerations generated by the individual point masses. Manipulating vectors in this way is certainly feasible, but fortunately a more appropriate concept of gravitation as a scalar field simplifies the treatment of arbitrary mass distributions.

This more modern view of gravitation (already adopted by Gauss (1777–1855) and Green (1793–1841)) holds that it is a field having a gravitational potential. Lagrange (1736–1813) fully developed the concept of a field, and the potential, V, of the gravitational field is defined in terms of the gravitational acceleration, $\mathbf{g}$, that a test particle would undergo in the field according to the equation

$$\nabla V = \mathbf{g} \quad [9]$$

where ∇ is the gradient operator (a vector). Further elucidation of gravitation as a field grew from Einstein's attempt to incorporate gravitation into his special theory of relativity where no reference frame has special significance above all others. It was necessary to consider that gravitational force is not a real force (i.e., it is not an applied force, like friction or propulsion) – rather, it is known as a kinematic force, that is, one whose action is proportional to the mass on which it acts (like the centrifugal force; see Martin, 1988). Under this precept, the geometry of space is defined intrinsically by the gravitational fields contained therein.

We continue with the classical Newtonian potential, but interpret gravitation as an acceleration different from the acceleration induced by real, applied forces. This becomes especially important when considering the measurement of gravitation (Section 3.02.6.1). The gravitational potential, V, is a 'scalar' function, and, as defined here, V is derived directly on the basis of Newton's law of gravitation. To make it completely consistent with this law and thus declare it a Newtonian potential, we must impose the following conditions:

$$\lim_{\ell\to\infty} \ell V = Gm \quad \text{and} \quad \lim_{\ell\to\infty} V = 0 \quad [10]$$

Here, m is the attracting mass, and we say that the potential is regular at infinity. It is easy to show that the gravitational potential at any point in space due to a point mass, in order to satisfy eqns [8]–[10], must be

$$V = \frac{Gm}{\ell} \quad [11]$$

where, again, ℓ is the distance between the mass and the point at which the potential is expressed. Note that V for $\ell = 0$ does not exist in this case; that is, the field of a point mass has a singularity. We use here the convention that the potential is always positive (in contrast to physics, where it is usually defined to be negative, conceptually closer to potential energy).

Applying the law of superposition, the gravitational potential of many point masses is the sum of the potentials of the individual points (see **Figure 4**):

$$V_P = G\sum_j \frac{m_j}{\ell_j} \quad [12]$$

And, for infinitely many points in a closed, bounded region with infinitesimally small masses, $\mathrm{d}m$, the summation in eqn [12] changes to an integration,

$$V_P = G\int_{\text{mass}} \frac{\mathrm{d}m}{\ell} \quad [13]$$

or, changing variables (i.e., units), $\mathrm{d}m = \rho\,\mathrm{d}v$, where ρ represents density (mass per volume) and $\mathrm{d}v$ is a volume element, we have (**Figure 5**)

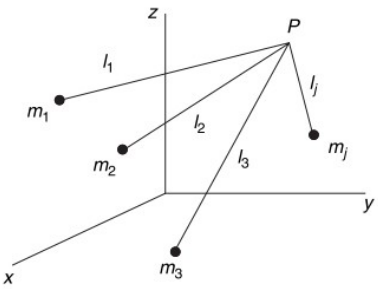

Figure 4 Discrete set of mass points (superposition principle).

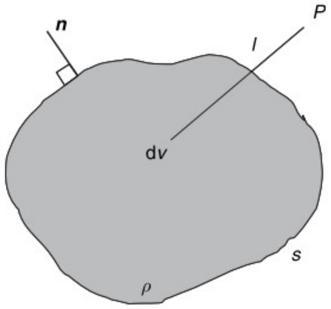

Figure 5 Continuous density distribution.

$$V_P = G\iiint_{\text{volume}} \frac{\rho}{\ell}\,\mathrm{d}v \qquad [14]$$

In eqn [14], ℓ is the distance between the evaluation point, P, and the point of integration. In spherical polar coordinates (Section 3.02.1.2), these points are (θ, λ, r) and (θ', λ', r'), respectively. The volume element in this case is given by $\mathrm{d}v = r'^2 \sin\theta'\,\mathrm{d}\lambda'\,\mathrm{d}\theta'\,\mathrm{d}r'$. V and its first derivatives are continuous everywhere – even in the case that P is on the bounding surface or inside the mass distribution, where there is the apparent singularity at $\ell = 0$. In this case, by changing to a coordinate system whose origin is at P, the volume element becomes $\mathrm{d}v = \ell^2 \sin\psi\,\mathrm{d}\alpha\,\mathrm{d}\psi\,\mathrm{d}\ell$ (for some different colatitude and longitude ψ and α); and, clearly, the singularity disappears – the integral is said to be weakly singular.

Suppose the density distribution over the volume depends only on radial distance (from the center of mass): $\rho = \rho(r')$, and that P is an exterior evaluation point. The surface bounding the masses necessarily is a sphere (say, of radius, R) and because of the spherically symmetric density we may choose the integration coordinate system so that the polar axis passes through P. Then

$$\ell = \sqrt{r'^2 + r^2 - 2r'r\cos\theta'}, \qquad \mathrm{d}\ell = \frac{1}{\ell} r' r \sin\theta'\,\mathrm{d}\theta' \qquad [15]$$

It is easy to show that with this change of variables (from θ to ℓ) the integral [14] becomes simply

$$V(\theta, \lambda, r) = \frac{GM}{r}, \qquad r \geq R \qquad [16]$$

where M is the total mass bounded by the sphere. This shows that to a very good approximation the external gravitational potential of a planet such as the Earth (with concentrically layered density) is the same as that of a point mass.

Besides volumetric mass (density) distributions, it is of interest to consider surface distributions. Imagine an infinitesimally thin layer of mass on a surface, s, where the units of density in this case are those of mass per area. Then, analogous to eqn [14], the potential is

$$V_P = G\iint_s \frac{\rho}{\ell}\,\mathrm{d}s \qquad [17]$$

In this case, V is a continuous function everywhere, but its first derivatives are discontinuous at the surface. Or, one can imagine two infinitesimally close density layers (double layer, or layer of mass dipoles), where the units of density are now those of mass per area times length. It turns out that the potential in this case is given by (see Heiskanen and Moritz, 1967, p. 8)

$$V_P = G\iint_s \rho \frac{\partial}{\partial n}\left(\frac{1}{\ell}\right)\mathrm{d}s \qquad [18]$$

where $\partial/\partial n$ is the directional derivative along the perpendicular to the surface (**Figure 5**). Now, V itself is discontinuous at the surface, as are all its derivatives. In all cases, V is a Newtonian potential, being derived from the basic formula [11] for a point mass that follows from Newton's law of gravitation (eqn [6]).

The following properties of the gravitational potential are useful for subsequent expositions. First, consider Stokes's theorem, for a vector function, **f**, defined on a surface, **s**:

$$\iint_s (\nabla \times \mathbf{f}) \cdot \mathbf{n}\ \mathrm{d}s = \oint_p \mathbf{f} \cdot \mathrm{d}\mathbf{r} \qquad [19]$$

where p is any closed path in the surface, $\mathbf{n}$ is the unit vector perpendicular to the surface, and $\mathrm{d}\mathbf{r}$ is a differential displacement along the path. From eqn [9], we find

$$\nabla \times \mathbf{g} = \mathbf{0} \quad [20]$$

since $\nabla \times \nabla = 0$; hence, applying Stokes's theorem, we find with $F = mg$ that

$$w = \oint \mathbf{F} \cdot \mathbf{ds} = 0 \quad [21]$$

That is, the gravitational field is conservative: the work, w, expended in moving a mass around a closed path in this field vanishes. In contrast, dissipating forces (real forces!), like friction, expend work or energy, which shows again the special nature of the gravitational force.

It can be shown (Kellogg, 1953, p. 156) that the second partial derivatives of a Newtonian potential, V, satisfy the following differential equation, known as Poisson's equation:

$$\nabla^2 V = -4\pi G\rho \quad [22]$$

where $\nabla^2 = \boldsymbol{\nabla} \cdot \boldsymbol{\nabla}$ formally is the scalar product of two gradient operators and is called the Laplacian operator. In Cartesian coordinates, it is given by

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \quad [23]$$

Note that the Laplacian is a scalar operator. Eqn [22] is a local characterization of the potential field, as opposed to the global characterization given by eqn [14]. Poisson's equation holds wherever the mass density, ρ, satisfies certain conditions similar to continuity (Hölder conditions; see Kellogg, 1953, pp. 152–153). A special case of eqn [22] applies for those points where the density vanishes (i.e., in free space); then Poisson's equation turns into Laplace' equation,

$$\nabla^2 V = 0 \quad [24]$$

It is easily verified that the point mass potential satisfies eqn [24], that is,

$$\nabla^2 \left(\frac{1}{\ell}\right) = 0 \quad [25]$$

where $\ell = \sqrt{(x-x')^2+(y-y')^2+(z-z')^2}$ and the mass point is at (x', y', z').

The solutions to Laplace' equation [24] (that is, functions that satisfy Laplace' equations) are known as harmonic functions (here, we also impose the conditions [10] on the solution, if it is a Newtonian potential and if the mass-free region includes infinity). Hence, every Newtonian potential is a harmonic function in free space. The converse is also true: every harmonic function can be represented as a Newtonian potential of a mass distribution (Section 3.02.3.1).

Whether as a volume or a layer density distribution, the corresponding potential is the sum or integral of the source value multiplied by the inverse distance function (or its normal derivative for the dipole layer). This function depends on both the source points and the computation point and is known as a Green's function. It is also known as the 'kernel' function of the integral representation of the potential. Functions of this type also play a dominant role in representing the potential as solutions to boundary-value problems (BVPs), as shown in subsequent sections.

3.02.3 Boundary-Value Problems

If the density distribution of the Earth's interior and the boundary of the volume were known, then the problem of determining the Earth's gravitational potential field is solved by the volume integral of eqn [14]. In reality, of course, we do not have access to this information, at least not the density, with sufficient detail. (The Preliminary Reference Earth Model (PREM), of Dziewonsky and Anderson (1981), still in use today by geophysicists, represents a good profile of Earth's radial density, but does not attempt to model in detail the lateral density heterogeneities.) In this section, we see how the problem of determining the exterior gravitational potential can be solved in terms of surface integrals, thus making exclusive use of accessible measurements on the surface.

3.02.3.1 Green's Identities

Formally, eqn [24] represents a partial differential equation for V. Solving this equation is the essence of the determination of the Earth's external gravitational potential through potential theory. Like any differential equation, a complete solution is obtained only with the application of boundary conditions, that is, imposing values on the solution that it must assume at a boundary of the region in which it is valid. In our case, the boundary is the Earth's surface and the exterior space is where eqn [24] holds (the atmosphere and other celestial bodies are neglected for the moment). In order to study the solutions to these BVPs (to show that solutions exist and are unique), we take advantage of some very important theorems and identities. It is noted that only a rather elementary introduction to BVPs is offered here with no attempt to address the much larger field of solutions to partial differential equations.

The first, seminal result is Gauss' divergence theorem (analogous to Stokes' theorem, eqn [19]),

$$\iiint_v \nabla\cdot\mathbf{f}\ \mathrm{d}v = \iint_s f_n\,\mathrm{d}s \qquad [26]$$

where **f** is an arbitrary (differentiable) vector function and $f_n = \mathbf{n}\cdot\mathbf{f}$ is the component of **f** along the outward unit normal vector, **n** (see **Figure 5**). The surface, s, encloses the volume, v. Equation [26] says that the sum of how much **f** changes throughout the volume, that is, the net effect, ultimately, is equivalent to the sum of its values projected orthogonally with respect to the surface. Conceptually, a volume integral thus can be replaced by a surface integral, which is important since the gravitational potential is due to a volume density distribution that we do not know, but we do have access to gravitational quantities on a surface by way of measurements.

Equation [26] applies to general vector functions that have continuous first derivatives. In particular, let U and V be two scalar functions having continuous second derivatives, and consider the vector function $\mathbf{f} = U\nabla V$. Then, since $\mathrm{n}\cdot\nabla = \partial/\partial n$, and

$$\nabla\cdot(U\nabla V) = \nabla U\cdot\nabla V + U\nabla^2 V \qquad [27]$$

we can apply Gauss' divergence theorem to get Green's first identity,

$$\iiint_v \left(\nabla U\cdot\nabla V + U\nabla^2 V\right)\mathrm{d}v = \iint_s U\frac{\partial V}{\partial n}\,\mathrm{d}s \qquad [28]$$

Interchanging the roles of U and V in eqn [28], one obtains a similar formula, which, when subtracted from eqn [28], yields Green's second identity,

$$\iiint_v \left(U\nabla^2 V - V\nabla^2 U\right)\mathrm{d}v = \iint_s \left(U\frac{\partial V}{\partial n} - V\frac{\partial U}{\partial n}\right)\mathrm{d}s \qquad [29]$$

This is valid for any U and V with continuous derivatives up to second order.

Now let $U = 1/\ell$, where ℓ is the usual distance between an integration point and an evaluation point. And, suppose that the volume, v, is the space exterior to the Earth (i.e., Gauss' divergence theorem applies to any volume, not just volumes containing a mass distribution). With reference to **Figure 6**, consider the evaluation point, P, to be inside the volume (free space) that is bounded by the surface, s; P is thus outside the Earth's surface. Let V be a solution to eqn [24], that is, it is the gravitational potential of the Earth. From the volume, v, exclude the volume bounded by a small sphere, σ, centered at P. This sphere becomes part of the surface that bounds the volume, v. Then, since U, by our definition, is a point mass potential, $\nabla^2 U = 0$ everywhere in v (which excludes the interior of the small sphere around P); and, the second identity [29] gives

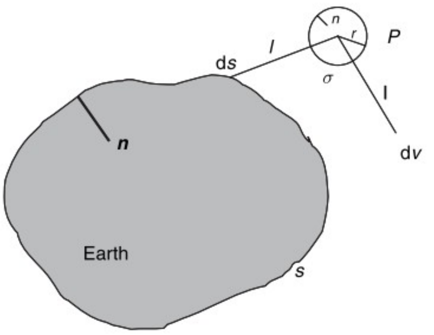

Figure 6 Geometry for special case of Green's third identity.

$$\iint_s \left(\frac{1}{\ell}\frac{\partial V}{\partial n} - V\frac{\partial}{\partial n}\left(\frac{1}{\ell}\right)\right)\mathrm{d}s + \iint_\sigma \left(\frac{1}{\ell}\frac{\partial V}{\partial n} - V\frac{\partial}{\partial n}\left(\frac{1}{\ell}\right)\right)\mathrm{d}\sigma = 0 \qquad [30]$$

The unit vector, **n**, represents the perpendicular pointing away from v. On the small sphere, **n** is opposite in direction to $\ell = r$, and the second integral becomes

$$\begin{aligned}\iint_\sigma \left(-\frac{1}{r}\frac{\partial V}{\partial r} + V\frac{\partial}{\partial r}\left(\frac{1}{r}\right)\right)\mathrm{d}\sigma &= -\iint_\Omega \frac{1}{r}\frac{\partial V}{\partial r}r^2\,\mathrm{d}\Omega \\ &\quad -\iint_\Omega V\,\mathrm{d}\Omega \\ &= -\iint_\Omega \frac{\partial V}{\partial r}r\,\mathrm{d}\Omega - 4\pi\bar{V}\end{aligned} \qquad [31]$$

where $\mathrm{d}\sigma = r^2\mathrm{d}\Omega$, Ω is the solid angle, 4π, and $\bar{V}$ is an average value of V on σ. Now, in the limit as the radius of the small sphere shrinks to zero, the right-hand side of eqn [31] approaches $0 - 4\pi V_P$. Hence, eqn [30] becomes (Kellogg, 1953, p. 219)

$$V_P = \frac{1}{4\pi}\iint_s \left(\frac{1}{\ell}\frac{\partial V}{\partial n} - V\frac{\partial}{\partial n}\left(\frac{1}{\ell}\right)\right)\mathrm{d}s \qquad [32]$$

with **n** pointing down (away from the space outside the Earth). This is a special case of Green's third identity. A change in sign of the right-hand side transforms **n** to a normal unit vector pointing into v, away from the masses, which conforms more to an Earth-centered coordinate system.

The right-hand side of eqn [32] is the sum of single- and double-layer potentials and thus shows that every harmonic function (i.e., a function that satisfies Laplace' equation) can be written as a Newtonian potential. Equation [32] is also a solution to a BVP; in this case, the boundary values are independent values of V and of its normal derivative, both on s (Cauchy problem). Below and in Section 3.02.4.1, we encounter another BVP in which the potential and its normal derivative are given in a specified linear combination on s. Using a similar procedure and with some extra care, it can be shown (see also Courant and Hilbert, 1962, vol. II, p. 256 (footnote)) that if P is on the surface, then

$$V_P = \frac{1}{2\pi}\iint_s \left(\frac{1}{\ell}\frac{\partial V}{\partial n} - V\frac{\partial}{\partial n}\left(\frac{1}{\ell}\right)\right) \mathrm{d}s \qquad [33]$$

where n points into the masses. Comparing this to eqn [32], we see that V is discontinuous as one approaches the surface; this is due to the double-layer part (see eqn [18]).

Equation [32] demonstrates that a solution to a particular BVP exists. Specifically, we are able to measure the potential (up to a constant) and its derivatives (the gravitational acceleration) on the surface and thus have a formula to compute the potential anywhere in exterior space, provided we also know the surface, s. Other BVPs also have solutions under appropriate conditions; a discussion of existence theorems is beyond the present scope and may be found in (Kellogg, 1953). Equation [33] has deep geodetic significance. One objective of geodesy is to determine the shape of the Earth's surface. If we have measurements of gravitational quantities on the Earth's surface, then conceptually we are able to determine its shape from eqn [33], where it would be the only unknown quantity. This is the basis behind the work of Molodensky *et al.* (1962), to which we return briefly at the end of this section.

3.02.3.2 Uniqueness Theorems

Often the existence of a solution is proved simply by finding one (as illustrated above). Whether such as solution is the only one depends on a corresponding uniqueness theorem. That is, we wish to know if a certain set of boundary values will yield just one potential in space. Before considering such theorems, we classify the BVPs that are typically encountered when determining the exterior potential from measurements on a boundary. In all cases, it is an exterior BVP; that is, the gravitational potential, V, is harmonic ($\nabla^2 V = 0$) in the space exterior to a closed surface that contains all the masses. The exterior space thus contains infinity. Interior BVPs can be constructed, as well, but are not applicable to our objectives.

- *Dirichlet problem* (*or, BVP of the first kind*). Solve for V in the exterior space, given its values everywhere on the boundary.
- *Neumann problem* (*or, BVP of the second kind*). Solve for V in the exterior space, given values of its normal derivative everywhere on the boundary.
- *Robin problem* (*mixed BVP, or BVP of the third kind*). Solve for V in the exterior space, given a linear combination of it and its normal derivative on the boundary.

Using Green's identities, we prove the following theorems for these exterior problems; similar results hold for the interior problems.

Theorem 1. If V is harmonic (hence continuously differentiable) in a closed region, v, and if V vanishes everywhere on the boundary, s, then V also vanishes everywhere in the region, v.

Proof. Since $V = 0$ on s, Green's first identity (eqn [28]) with $U = V$ gives

$$\iiint_v (\nabla V)^2 \,\mathrm{d}v = \iint_s V\frac{\partial V}{\partial n}\,\mathrm{d}s = 0 \qquad [34]$$

The integral on the left side is therefore always zero, and the integrand is always non-negative. Hence, $\boldsymbol{\nabla} V = \mathbf{0}$ everywhere in v, which implies that $V = \text{constant}$ in v. Since V is continuous in v and $V = 0$ on s, that constant must be zero; and so $V = 0$ in v.

This theorem solves the Dirichlet problem for the trivial case of zero boundary values and it enables the following uniqueness theorem for the general Dirichlet problem.

Theorem 2 (*Stokes' theorem*). If V is harmonic (hence continuously differentiable) in a closed region, v, then V is uniquely determined in v by its values on the boundary, s.

Proof. Suppose the determination is not unique: that is, suppose there are V_1 and V_2, both harmonic

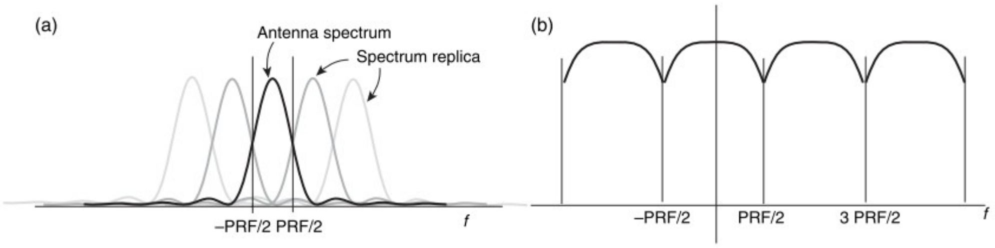

Figure 38 The azimuth signal is sampled at the PRF. The resulting discrete time signal in azimuth has a circular spectrum with all energy at frequency higher than the PRF aliased into the circular bandwidth of the PRF. (a) Illustrates the replicas of the continuous spectrum that are aliased, and (b) the resulting circular spectrum.

azimuth signals are inherently derived from pulses acquired along track, the azimuth signal is a discrete time signal sampled at the PRF. The actual discrete time spectrum is then a circular spectrum, with all energy at frequencies higher than the PRF aliased into the range of one PRF (**Figure 38**).

Thus without knowledge of the geometry of the spacecraft and the observation, it is often difficult to know the actual Doppler centroid, since one usually estimates it from the spectrum only in the range of the PRF. One can process the data with an incorrect Doppler centroid, off by some number of PRFs (also called 'ambiguities') for instance, and the imagery will look almost correct. Since the signal is sampled, the matched filter spectrum for the actual centroid will be the same as for the incorrect centroid as long as the centroid is wrong by an integer number of ambiguities. However, the range migration correction is in terms of absolute Doppler, so if the wrong ambiguity is used, the images will be poorly focused in range (because energy is spread in range for each scatterer) and in azimuth (because the compression uses incomplete information for each scatterer).

If the attitude of the platform is known, then the Doppler can be computed from

$$f_{\mathrm{D}} = -\frac{2\vec{v}\cdot\hat{l}}{\lambda} = -\frac{2v}{\lambda}\sin\theta\sin\phi_{\mathrm{sq}} \qquad [116]$$

where $\vec{v}$ is the velocity vector, $\hat{l}$ is the look vector from antenna to target, θ is the look angle, and ϕ_{sq} is the squint angle. If the attitude parameters are not known, then one has to estimate the ambiguity. This can be done by trial and error – examine the focus for a variety of integer ambiguity choices – or by one of several automated techniques. A popular method of ambiguity estimation is to split the azimuth spectrum into two pieces and process each with a particular Doppler ambiguity assumption. If the correction is the right one, both side bands will be adjusted to the correct range and the two images produced will be properly registered in range. If the correction is not right, there will be a residual shift between the two images in range. From the magnitude of this shift it is often possible to estimate the correct ambiguity. Unfortunately the imagery are lower resolution in azimuth and defocused in range, so estimating the shift is sometimes difficult.

Speckle

Radar images are naturally noisy because of the coherent interaction of the electro-magnetic wave with scatterers within a resolution cell, known as speckle. Speckle is an important part of the radar literature, as it is an important limitation of the imagery that many people have worked hard to minimize. It is also an important concept for interferometry, which exploits the spatially fixed properties of speckle to extract phase differences between images. The normalized backscatter cross-section σ_0 is an average quantity for a naturally varying random surface. For homogenous surfaces made up of a continuum of scatterers, the backscatter cross-section is a measure of the roughness of the surface and its natural reflectivity, as shown in a previous section. Viewing the SAR imaging process as a lens (**Figure 39**), after imaging, the random (complex) surface reflectivity is convolved with the sinc-function impulse response of the imaging system, accounting for the random differential path length introduced by surface roughness.

In a given resolution element, we consider the sum of the collection of small independent scatterers, where each scatterer has its own amplitude and phase

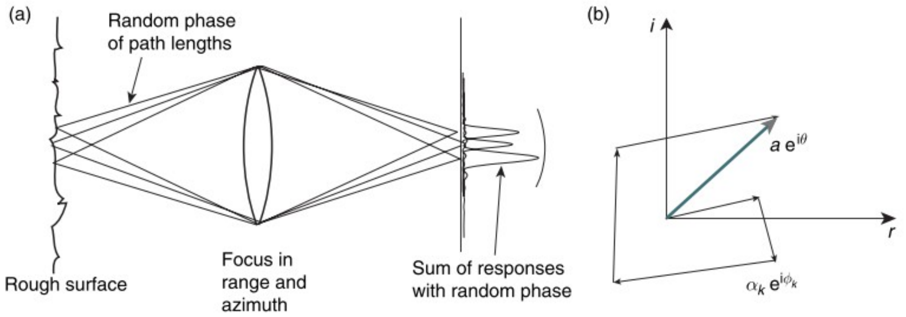

Figure 39 Illustration of the concept of radar imaging of a random surface (a) and the coherent sum of independent scatterers as a phasor (b).

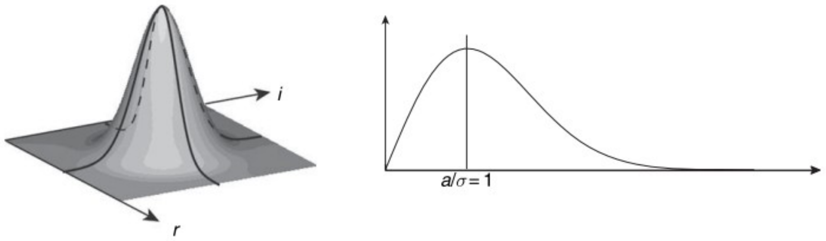

Figure 40 The real and imaginary parts of a SAR image are circularly Gaussian (*left*). The amplitude of the SAR pixel is Rayleigh distributed, with peak at a = σ.

$$a e^{j\theta} = \sum_{k=1}^{N} \alpha_k e^{j\phi_k} \qquad [117]$$

If α_k and ϕ_k are statistically independent of each other and α_k are identically distributed with mean $\bar{\alpha}$ and second moment $\overline{\alpha^2}$, and ϕ_k are uniformly distributed in the interval $[-\pi, \pi]$, then one can show that for large N

$$r = a\cos\theta \qquad [118]$$

$$i = a\sin\theta \qquad [119]$$

are Gaussian-distributed zero-mean random variables with joint probability density function

$$p_{\mathrm{RI}}(r, i) = \frac{1}{2\pi\sigma^2} e^{-(r^2+i^2)/2\sigma^2} \qquad [120]$$

where $\sigma^2 = \overline{\alpha^2}/2$ (**Figure 40**). The variance of the real and imaginary parts of the SAR image are related to the mean power of the intrinsic scatterers but are zero mean random variables themselves. As such for homogeneous areas, averaging many complex pixels together in a region will eventually reduce the signal to zero on average and not improve the quality of the image. This is a common mistake among beginners. It is the amplitude of the image, a, or its intensity (power), $I = a^2$, that interests us.

For the amplitude $a = \sqrt{r^2 + i^2}$, we can use the rules of transformation of random variables (multiply the distribution by the Jacobian of the transformation and substitute in the new variables) to get the distribution

$$p_A(a) = \frac{a}{\sigma^2} e^{-a^2/2\sigma^2}, \quad a \geq 0 \qquad [121]$$

which is known as the Rayleigh distribution (**Figure 40**). The phase is uniformly distributed over the interval $(-\pi, \pi)$

$$p_\Theta(\theta) = \frac{1}{2\pi}, \quad -\pi < \theta < \pi \qquad [122]$$

The mean and variance of the amplitude are

$$\bar{a} = \sqrt{\frac{\pi}{2}}\sigma \qquad [123]$$

$$\sigma_a^2 = \left(2 - \frac{\pi}{2}\right)\sigma^2 \qquad [124]$$

Clearly the mean amplitude of the image scales with the variability in the image, which is related to the mean backscattered power $\overline{\alpha^2}$ of the scatterers comprising the resolution element. The brighter the image, the noisier the image, and vice-versa. Thus, at some signal level such that the signal level returned is sufficiently larger than the thermal noise in an image, having a more powerful radar does not necessarily improve image quality.

The intensity, or power, of the image $I = a^2$ has an exponential distribution

$$p_I(I) = \frac{1}{\bar{I}} e^{-I/\bar{I}}, \quad I \geq 0 \qquad [125]$$

with mean and variance

$$\bar{I} = 2\sigma^2, \quad \sigma_I^2 = 4\sigma^4 \qquad [126]$$

The mean power is equal to its standard deviation, as expected from the mean amplitude scaling with σ. In the display and analysis of an image with only 'one look,' meaning processed at full resolution using the full synthetic aperture, the SNR of the intensity image is just I since $\bar{I}^2/\sigma_j^2 = 1_j$ the brighter the image, the noisier. In the design of a radar system, one must have sufficient power to receive a return from the surface above the thermal noise (satisfying the radar equation, where $\overline{\alpha^2}$ is related to the backscattering cross-section), but not so high that we are wasting power. For interferometry, we will soon see however that more power in general is better!

The radiometric resolution is defined as the ability to discriminate surfaces of different brightnesses. It has been defined to be

$$Q = 10 \log\left(\frac{\bar{I} + \sigma_I}{\bar{I} - \sigma_I}\right) \qquad [127]$$

which is something like the distance apart in amplitude of discriminable amplitudes. For a single-look image, that distance is infinite. In order to improve this situation, it is often necessary to average many pixels together. The act of averaging N independent (Gaussian, but also approximately true for non-Gaussian) random variables with identical distributions reduces the variance by a factor of N. Thus for

$$I' = \frac{1}{N} \sum_{k=1}^{N} I_k \qquad [128]$$

we have $\bar{I}' = \bar{I}$, $\sigma_{I'}^2 = \sigma_I^2/N$, and the radiometric resolution becomes

$$Q = 10 \log\left(\frac{\bar{I}' + \sigma_{I'}}{\bar{I}' - \sigma_{I'}}\right) = 10 \log\left(\frac{\sqrt{N} + 1}{\sqrt{N} - 1}\right) \qquad [129]$$

The resolution distance approaches 0 for arbitrarily large N. This averaging technique is often called 'taking looks' because it can be shown to be equivalent to segmenting the azimuth spectrum into separate frequency bands, forming a power image from each band, then stacking the images in an average. Since azimuth band corresponds to a particular look direction relative to a target on the ground, this technique is called taking looks.

Of course averaging together a large number of pixels will lower the intrinsic resolution of the image, so designing the system to have a larger bandwidth is desirable if radiometric resolution is important. Note also that there is a limit to how far one can go to improve the statistics. The improvement above assumes that all the pixels come from the same distribution. If the scene is variable in intrinsic brightness, not all the benefits will be realized.

If there is a bright target within a resolution cell, then there is a mean value associated with the Gaussian random variables (**Figure 41**). This complex random variable has a Rician distribution given by

$$p_A(a) = \frac{a}{\sigma^2} e^{-(a^2+s^2)/2\sigma^2} I_0\left(\frac{as}{\sigma^2}\right), \quad a \geq 0 \qquad [130]$$

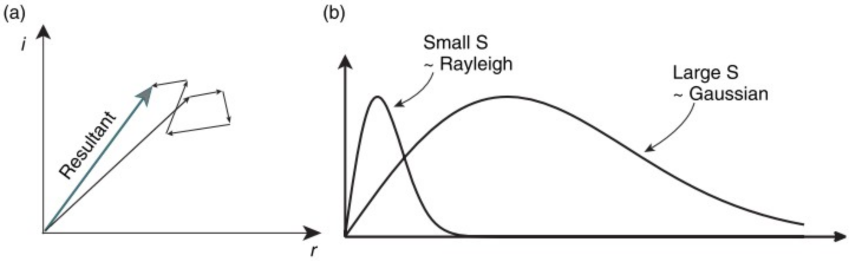

Figure 41 (a) A phasor diagram with a bright specular target (within a scattering cell. (b) The Rician distribution of the amplitude.

where I_0 is the modified Bessel function of the first kind and s is the specular target strength. This distribution approaches a Gaussian distribution for large s relative to σ. The distribution of the phase, which is uniform for $s=0$, becomes more peaked as s grows, eventually approximating a Gaussian also:

$$p_{\Theta}(\theta) \rightarrow \frac{s/\sigma}{\sqrt{2\pi}} \mathrm{e}^{-s^2\theta^2/2\sigma^2} \qquad [131]$$

Often specular targets are used for calibration of the radar. If the specular target is not sufficiently bright, then the amplitude and phase will be corrupted by the background random scatterers.

Another way to model the surface is in terms of a general reflectivity function that is statistical in nature. Since

$$\Gamma_{\mathrm{zcc}}(x', r') = \iint \mathrm{d}r\, \mathrm{d}x \Gamma(x, r) \times \operatorname{sinc}\Big(\frac{\pi}{\Delta X}(x'-x)\Big) \operatorname{sinc}\Big(\frac{\pi}{\Delta R}(r'-r)\Big) \qquad [132]$$

if Γ is a statistical function, the power that is meaningful is the expected power scattered back from the resolution cell, which is related by scale factors and geometric normalizations to $E\{\Gamma\Gamma^*\}$. Writing this out explicitly, we have

$$E\{\Gamma_{\mathrm{zcc}}\Gamma^*_{\mathrm{zcc}}\}(x', r') = \int \mathrm{d}x_1 \int \mathrm{d}x_2 \int \mathrm{d}r_1 \int \mathrm{d}r_2 \times E\{\Gamma(x_1, r_1)\Gamma^*(x_2, r_2)\} \qquad [133]$$

$$= \operatorname{sinc}\Big(\frac{\pi}{\Delta X}(x'-x_1)\Big) \operatorname{sinc}\Big(\frac{\pi}{\Delta X}(x'-x_2)\Big) \qquad [134]$$

$$= \operatorname{sinc}\Big(\frac{\pi}{\Delta R}(r'-r_1)\Big) \operatorname{sinc}\Big(\frac{\pi}{\Delta R}(r'-r_2)\Big) \qquad [135]$$

If the scatterers that comprise the reflectivity are uncorrelated, then the expected value of the product of the surface with itself when not coaligned would be zero:

$$E\{\Gamma(x_1, r_1)\Gamma^*(x_2, r_2)\} = E\{\Gamma(x_1, r_1)\}E\{\Gamma^*(x_2, r_2)\} = 0 \qquad [136]$$

However, when the surface is self-aligned

$$E\{\Gamma(x_1, r_1)\Gamma^*(x_2, r_2)\} = |\Gamma(x_1, r_1)|^2 \qquad [137]$$

More succinctly,

$$E\{\Gamma(x_1, r_1)\Gamma^*(x_2, r_2)\} = E\{|\Gamma(x_1, r_1)|^2\} \times \delta(x_1-x_2)\delta(r_1-r_2) \qquad [138]$$

Using this expression in eqn [135] simplifies the integrals

$$E\{\Gamma_{\mathrm{zcc}}\Gamma^*_{\mathrm{zcc}}\}(x', r') = \int \mathrm{d}x \int \mathrm{d}r\, E\{|\Gamma(x, r)|^2\} \qquad [139]$$

$$\operatorname{sinc}^2\Big(\frac{\pi}{\Delta X}(x'-x)\Big) \operatorname{sinc}^2\Big(\frac{\pi}{\Delta R}(r'-r)\Big) \qquad [140]$$

$$= E\{|\Gamma|^2\}\Delta X \Delta R \qquad [141]$$

For homogeneous surfaces, we can expect the mean power to be essentially constant over the resolution cell, so we can take the expectation outside the integration. Also the variables x' and r' can profitably be set to zero since there is no dependence on space. Then the integration over the sinc functions produces a constant, which is proportional to the area under them. This turns out to be ΔX and ΔR. So we see that $E\{\Gamma_{\mathrm{zcc}}\Gamma^*_{\mathrm{zcc}}\}$ is related to the normalized backscattering cross-section σ_0 through the function Γ.

Doppler and the Interferometric Baseline

The precise definition of interferometric baseline and phase, and consequently the topographic mapping process, depends on how the SAR data comprising the interferometer are processed. Consequently, a brief overview of the salient aspects of SAR processing is in order.

Processed data from SAR systems are sampled images. Each sample, or pixel, represents some aspect of the physical process of radar backscatter. A resolution element of the imagery is defined by the spectral content of the SAR system. Fine resolution in the range direction is achieved typically by transmitting pulses of either short time duration with high peak power, or of a longer time duration with a wide, coded signal bandwidth at lower peak transmit power. Resolution in range is inversely proportional to this bandwidth. In both cases, the received echo for each pulse is sampled at the required radar signal bandwidth.

For ultra-narrow pulsing schemes, the pulse width is chosen at the desired range resolution, and no further data manipulation is required. For coded pulses, the received echoes are typically processed with a matched filter technique to achieve the desired range resolution. Most spaceborne platforms use chirp-encoding to attain the desired bandwidth and consequent range resolution, where the frequency is linearly changed across the pulse.

$$2\theta_{\mathrm{b.s.}} = X_{\mathrm{ill}}/R = \lambda R/(LR) = \lambda/L \qquad [77]$$

as expected. Thus, the Doppler bandwidth is $f_{\mathrm{D,ill}}$ and by this derivation is also $2v(2\sin\theta_{\mathrm{b.s.}})/\lambda = 2v/L$.

At any given instant, the received signal is composed of the full complement of Doppler frequencies because targets are distributed throughout the beam, each with their own Doppler frequency. In forming the synthetic aperture at some reference time, we are rearranging each of the targets in the range-Doppler image to lie at the Doppler frequency appropriate to that geometry at that reference time. This is not immediately obvious from the signal-theoretical approach to azimuth filtering that was just derived. To be more explicit, we pick a collection of pulses that will be used to form our synthetic aperture, noting that this establishes a position in space at a time instant as a reference for defining Doppler frequencies. We can also model the ground as a collection of point targets arranged in azimuth, such that

$$r_{\mathrm{zc\delta,tot}} = \sum_{k=1}^{N} A_k \mathrm{e}^{-\mathrm{j}\pi(x-x_k)^2/F^2} \operatorname{sinc}\frac{\pi}{\Delta R}\left(R - R_0 - (x-x_k)^2/2R_0\right) \qquad [78]$$

For the sake of this discussion, we allow the sinc function to become a delta function in range and ignore its variability with x, which is small and correctable. Thus,

$$r_{\mathrm{zc\delta}} = \sum_{k=1}^{N} A_k \mathrm{e}^{-\mathrm{j}\pi(x-x_k)^2/F^2} \qquad [79]$$

The azimuth compression process can be written then as

$$\begin{aligned} r_{\mathrm{zcc\delta}}(x) &= \int_{x-X_{\mathrm{ill}}/2}^{x+X_{\mathrm{ill}}/2} r_{\mathrm{zc\delta}}(x')\mathrm{e}^{\mathrm{j}\pi(x'-x)^2/F^2}\,\mathrm{d}x' \\ &= \int_{x-X_{\mathrm{ill}}/2}^{x+X_{\mathrm{ill}}/2} \sum_{k=1}^{N} A_k \mathrm{e}^{-\mathrm{j}\pi(x'-x_k)^2/F^2} \mathrm{e}^{\mathrm{j}\pi(x'-x)^2/F^2}\,\mathrm{d}x' \\ &= \mathrm{e}^{\mathrm{j}\pi x^2/F^2} \int_{x-X_{\mathrm{ill}}/2}^{x+X_{\mathrm{ill}}/2} \sum_{k=1}^{N} A_k \mathrm{e}^{-\mathrm{j}\pi x_k^2/F^2} \mathrm{e}^{\mathrm{j}2\pi x' x_k/F^2} \mathrm{e}^{-\mathrm{j}2\pi x' x/F^2}\,\mathrm{d}x' \\ &= \sum_{k=1}^{N} \mathrm{e}^{\mathrm{j}\pi x^2/F^2} \int_{x-X_{\mathrm{ill}}/2}^{x+X_{\mathrm{ill}}/2} A'_k \mathrm{e}^{-\mathrm{j}2\pi x'(f_{\mathrm{Dx}} - f_{k,\mathrm{Dx}})}\,\mathrm{d}x' \end{aligned} \qquad [80]$$

where $f_{\mathrm{Dx}}(x) = x/F^2$ is the Doppler spatial frequency. From this arrangement of terms, we can recognize that the compressed azimuth signal is just the sum of Fourier transforms of the individual complex exponentials of complex amplitude A'_k. Because the argument of the exponential is the Doppler frequency, we see the transform domain is the Doppler domain, and each exponential (being representative of a scatterer at a particular azimuth location x_k relative to the reference location) transforms to an individual Doppler frequency $f_{k,\mathrm{Dx}}$. Thus, for a general continuous surface, the summation becomes an integration, and we see the compression process consists of focusing the array by applying a quadratic phase correction, followed by a transform that sorts the scatterers into correct Doppler bins for that time reference.

The reason we represent (and in fact execute) the imaging as a convolution in spatial variables is because the processed data the sample spacing independent of range on input and output, which is often desirable. In the focusing Fourier transform approach, the Doppler sample spacing is controlled by the implementation of Fourier transform, which is usually accomplished by fast Fourier transform (FFT). In this case, if the input data are sampled at a spacing $L/2$, the Doppler spacing will be $2/L/N$, where N is the number of points in the FFT.

A.1.5 Other Doppler considerations

If the antenna pattern was isotropic and we have a continuous time system, the phase and Doppler of a single point target would as depicted in Figure 35. Imposing an antenna pattern where the antenna pattern is pointing 'broadside,' that is, orthogonal to the velocity vector, the phase and Doppler history would be truncated according to the extent of the beam (see same figure). It is most commonly the case that the finite extent beam is 'squinted' forward or back with respect to the velocity vector of the sensor. In an aircraft, this is most commonly due to cross winds causing the fuselage to crab. In spacecraft, there is a natural latitude dependent angular offset between the velocity vector of the inertial orbit and the rotating Earth below causing a natural squint (Figure 36). The effect of this squint on the phase and Doppler history of a target is shown in Figure 37. Note the shape of the phase or Doppler does not change, just the range of phases or frequencies considered. Thus, there is a unique relationship between the pointing and the location of the scatterers. In processing data, the extent of the antenna beam (Doppler bandwidth) and the *centroid* of the Doppler, or the degree of squint as represented by the center of the Doppler bandwidth, are specified in one way or another. Figure 38 shows that the spectra are shifted to be centered on the Doppler spread associated with a particular

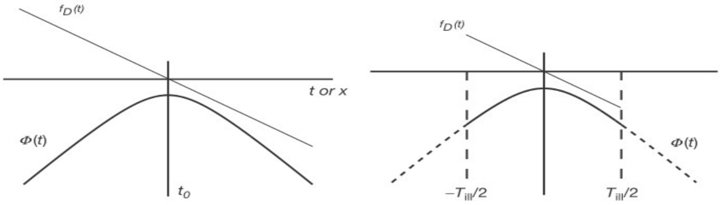

Figure 35 Phase and Doppler history over time for a point target. At left, the trace for a system with an isotropic antenna: the trace keeps going. At right, the finite illumination time of a finite dimension antenna truncates the phase and Doppler history.

squint. It is important to know the squint to ensure that the processing is centered on the proper part of the azimuth spectrum. The centroid specified in processing defines direction from which the ground is imaged after processing.

The squint can be derived from information provided by the spacecraft and radar manufacturer. Often, spacecrafts have sensitive position and attitude sensors that record the information needed to calculate the direction of the antenna boresight. When this information is not available, the Doppler centroid itself can be estimated from the data. This estimated centroid can be used directly in the processing. The centroid generally varies across range, so often the centroid is specified as a function of range.

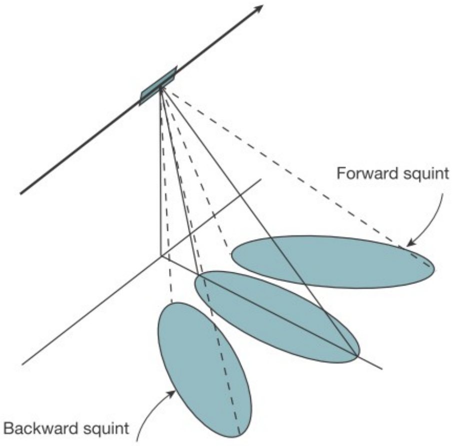

Figure 36 Illustration of forward and backward squint.

To understand the arrangement of spectral energy for a collection of scatterers, consider a collection of point target scatterers all at the same range, but at different azimuths:

$$\begin{aligned} r_{\mathrm{zc\delta,tot}} = {} & A_0 \mathrm{e}^{-\mathrm{j}\pi(x-x_0)^2/F^2} \operatorname{sinc}\frac{\pi}{\Delta R}\left(R-R_0-(x-x_0)^2/2R_0\right) \\ & + A_1 \mathrm{e}^{-\mathrm{j}\pi(x-x_1)^2/F^2} \operatorname{sinc}\frac{\pi}{\Delta R}\left(R-R_0-(x-x_1)^2/2R_0\right) \\ & + \cdots \\ & + A_n \mathrm{e}^{-\mathrm{j}\pi(x-x_n)^2/F^2} \operatorname{sinc}\frac{\pi}{\Delta R}\left(R-R_0-(x-x_n)^2/2R_0\right) \end{aligned} \quad [81]$$

If we ignore the antenna pattern modulation of target energy and denote the azimuth spectrum of an individual scatter response as

$$F(\omega) = \mathrm{F.T.}\left\{\mathrm{e}^{-\mathrm{j}\pi x^2/F^2} \operatorname{sinc}\frac{\pi}{\Delta R}\left(R-R_0-x^2/2R_0\right)\right\} \quad [82]$$

where F.T. denotes the Fourier transform, the spectrum of $r_{\mathrm{zc\delta,tot}}$ would be

$$R_{\mathrm{zc\delta,tot}}(\omega) = F(\omega)\left(A_0\mathrm{e}^{-\mathrm{j}\omega x_0} + A_1\mathrm{e}^{-\mathrm{j}\omega x_1} + \cdots + A_n\mathrm{e}^{-\mathrm{j}\omega x_n}\right) \quad [83]$$

Thus, except for a phase ramp in azimuth frequency space, all scatterers have the same spectrum. Clearly, the process of applying the matched filter neutralizes this common component, and the linear phase terms in frequency distinguish the

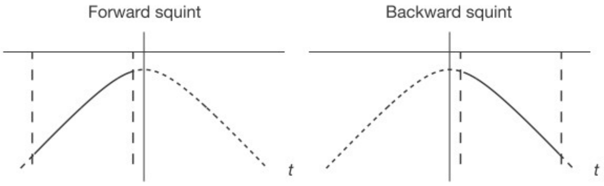

Figure 37 Phase history over time for a point target. At left, the trace for a forward squinted system. At right, the trace for a backward squinted system. Only phase is shown, but with reference to the previous figures, the Doppler history is similarly constrained. Forward (backward) squinted systems see more positive (negative) Doppler frequencies.

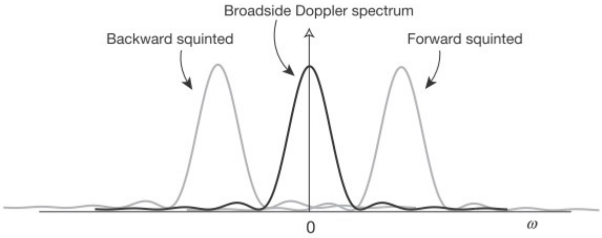

Figure 38 Hypothetical Doppler spectra of broadside, forward and backward squinted signals. For a collection of scatterers over the beam pointed with a particular squint, all scatterers experience the same Doppler frequency spread, so the spectra would be as shown, controlled in extent and magnitude by the antenna pattern in azimuth.

targets in position upon inverse transformation. This again shows the spatial-Doppler duality. The x dependence of the energy's localization in range $x^2/2R_0$ is called the range migration and is seen to be part of the function $F(\omega)$ in the frequency domain. Hence, any effects this may introduce in can be dealt with for all targets simultaneously by manipulating the spectrum.

We ignored the *range migration* term $(x-x_0)2/2R_0$ in the argument to the sinc function in range, but frequently this is not advisable. The processing of data on an orthogonal grid is enforced by the need for high-speed computations, and the most efficient processing methods are those that are separable in range and azimuth and for which FFT-based convolutions can be performed. For broadside imaging, the term can be ignored when $X_{\text{ill}}^2/2R_0$ is a fraction of the range resolution ΔR. In words, when the migration over the full extent of the azimuth matched filter (equivalent to the beam extent on the ground) is smaller than a range resolution element, the azimuth matched filter will catch all the energy for a given scatterer in a single range bin.

A.1.6 The sampled azimuth spectrum and range migration

Since the range migration correction terms depend on the Doppler frequency, one must know the correct Doppler to properly compress the imagery. This is also true for computing the correct azimuth matched filter; however, the sampled nature of the azimuth signal adds an interesting wrinkle to the processing that is often confusing. Since the azimuth signals in inherently derived from pulses acquired along-track, the azimuth signal is a discrete time signal sampled at the PRF. The actual discrete time spectrum is then a circular spectrum, with all energy at frequencies higher than the PRF aliased into the range of one PRF (Figure 39). Thus, without knowledge of the geometry of the spacecraft and the observation, it is often difficult to know the actual Doppler centroid, since one usually estimates it from the spectrum only in the range of the PRF. One can process the data with an incorrect Doppler centroid, off by some number of PRFs (also called *ambiguities*), for instance, and the imagery will look almost correct. Since the signal is sampled, the matched-filter spectrum for the actual centroid will be the same as for the incorrect centroid as long as the centroid is wrong by an integer number of ambiguities. However, the range migration correction is in terms of absolute Doppler, so if the wrong ambiguity is used, the images will be poorly focused in range (because energy is spread in range still for each scattered) and in azimuth (because the compression uses incomplete information for each scatterer).

If the attitude of the platform is known, then the Doppler can be computed from

$$f_{\text{D}}=-\frac{2\,\vec{v}\cdot\hat{l}}{\lambda}=-\frac{2v}{\lambda}\sin\theta\sin\phi_{\text{sq}} \qquad [84]$$

where $\vec{v}$ is the velocity vector, $\hat{l}$ is the look vector from antenna to target, θ is the look angle, and ϕ_{sq} is the squint angle. If the attitude parameters are not known, then one has to estimate the ambiguity. This can be done by trial and error – examine the focus for a variety of integer ambiguity choices – or by one of several automated techniques. A popular method of ambiguity estimation is to split the azimuth spectrum into two pieces and process each with a particular Doppler ambiguity assumption. If the correction is the right one, both side bands will be adjusted to the correct range and the two images produced will be properly registered in range. If the correction is not right, then there will be a residual shift between the two images in range. From the magnitude of this shift, it is often possible to estimate the correct ambiguity. Unfortunately, the imagery is lower resolution in azimuth and defocused in range, so estimating the shift is sometimes difficult.

A.2 The Derivation of the Interferogram from Two Images

As shown leading up to eqn [72], for a general complex scene $\Gamma(x, r)$, the SAR image after compression is given by convolution of r with the point target response

$$\Gamma_{\text{zcc}}(x', r') = \iint \Gamma(x, r)\, r_{\text{zcc}\delta}(x', r'; x, r)\,\mathrm{d}x\,\mathrm{d}r$$
$$= \int \mathrm{d}x \int \mathrm{d}r\,\Gamma(x, r)\mathrm{e}^{-\mathrm{j}4\pi r/\lambda}\cdot\operatorname{sinc}\left(\frac{\pi}{\Delta R}(r'-r)\right)\operatorname{sinc}\left(\frac{\pi}{\Delta X}(x'-x)\right) \qquad [85]$$

which can be verified by substituting $\Gamma(x, r)=\delta(x-x_0, r-R_0)$ to recover the impulse response $r_{\text{zcc}\delta}$.

The SAR image Γ_{zcc} is the convolution of the actual reflectivity with a two-dimensional function similar to a delta function but with finite width (the sinc function). This convolution smears out the intrinsic reflectivity as a point spread function in optics. If the system bandwidths were to become infinite, the sinc functions would become delta functions

$$\operatorname{sinc}\left(\frac{\pi}{\Delta R}(r'-r)\right) \rightarrow \delta(r'-r) \quad \text{as } \Delta R \rightarrow 0 \qquad [86]$$

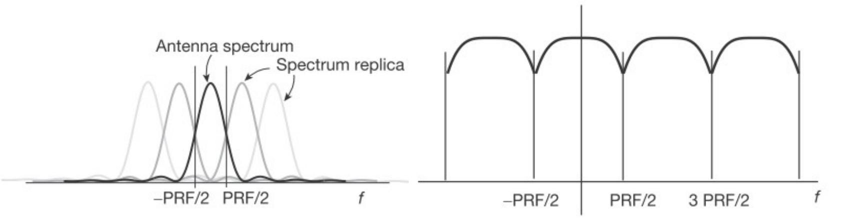

Figure 39 The azimuth signal is sampled at the PRF. The resulting discrete time signal in azimuth has a circular spectrum with all energy at frequency higher than the PRF aliased into the circular bandwidth of the PRF. Left illustrates the replicas of the continuous spectrum that are aliased, right the resulting circular spectrum.

Corollary 14.11

Let X be an oriented hypersurface of $\mathbb{R}^K$.

(1) If K is even, then $\chi(X) = 0$.

(2) If K is odd, then

$\chi(X) = 2\deg(g_X)$ where

g_X is the Gauss map of X.

/B
! -256- - -* ! - /B ? 4 ! 9 1 3 1"
('/ ! 3 '

The lemma follows by using two adapted gradient fields to compute the relative characteristics.

Note that $\chi(D^n) = 1$: use a Morse function on $(D^n, \emptyset, S^{n-1})$ with just one minimum.

If X is boundaryless and Y is with boundary, then the very same argument used when Y is boundaryless allows us to extend the multiplicative property.

Lemma 14.8.

$$\chi(X \times Y) = \chi(X)\chi(Y)\ .$$

In particular,

$$\chi(X \times D^n) = \chi(X)\ .$$

14.6.1. Additive property of χ. If (W, V_0, V_1), (W', V_0', V_1') are triads and $\phi : V_1 \to V_0'$ is a diffeomorphism, we get a new composite triad (W'', V_0, V_1'), where $W'' = W \amalg_\phi W'$. Any couple of relative fields v and v' with isolated zeros on the given two triads, respectively, can be glued together to produce a relative field v'' having as zeros the union of the zeros of v and v', each one keeping its index. Then we have

$$\chi(W'', V_0, V_1') = \chi(W, V_0, V_1) + \chi(W', V_0', V_1')\ .$$

This additive property of χ has remarkable consequences.

14.6.2. A baby TQFT. In Section 10.8, we have roughly outlined the axioms of a so-called TQFT and posed the question about the existence of any "nontrivial" one. We use χ to provide a first nontrivial example. Consider $\mathbf{CAT}_\eta(n+1)$. Associate to every object M the vector space $Z(M) = \mathbb{C}$. To every arrow f, carried by a triad (W, M_0, M_1), associate the unitary $\mathbb{C}$-linear map

$$Z(f) : Z(M_0) \to Z(M_1),\ \ z \to e^{i\chi(W, M_0)} z\ .$$

By the additive property of χ, it is easy to check that all axioms are satisfied. This shows, at least, that there are not logical contradictions within the given pattern of axioms.

14.7. E-P characteristic of tubular neighbourhoods and the Gauss map

The identity $\chi(X \times D^n) = \chi(X)$ is a special case of the following.

Proposition 14.9. *Let $p : U \to X$ be a closed tubular neighbourhood of a submanifold X of some Y. Then $\chi(U) = \chi(X)$.*

Proof. It is enough to show the equality for an ϵ-neighbourhood $N_\epsilon(X)$ of the zero section X of a vector bundle $\pi : E \to X$ endowed with a field of positive definite scalar products on every fibre. Let v be a tangent field on X with nondegenerate zeros. Define the field on $N_\epsilon(X)$,

$$w(z) = (z - p(z)) + v(p(z)) \ .$$

We check that w is a field on the triad $(N_\epsilon(X), \emptyset, \partial N_\epsilon(X))$ and that the zeros of w coincide with the zeros of v, are nondegenerate, and keep the sign. The proposition follows. ■

In the special case $X \subset \mathbb{R}^k$, assume that U has been constructed using the standard metric on $\mathbb{R}^k$. By removing from the interior of U a system of pairwise disjoint small open disks $\mathcal{D}_p$ around each zero of w, we get a manifold W with boundary $(\amalg_p S_p^{k-1}) \amalg \partial U$ on which the normalized field $\mathfrak{w} := w/||w||$ is well-defined, as well as the map $\mathfrak{w} : W \to S^{k-1}$. The restriction of $\mathfrak{w}$ to ∂U is a field of unitary vectors pointing out from U (in fact normal to the boundary). This restriction, say $g_{\partial U}$, is called the *Gauss map of the hypersurface* ∂U.

Corollary 14.10. *Let* $p : U \to X$ *be a tubular neighbourhood of* X *in* $\mathbb{R}^k$. *Then*

$$\chi(X) = \deg(g_{\partial U})$$

where $g_{\partial U}$ *is the Gauss map of the hypersurface* ∂U.

The corollary follows by computing the characteristic as the sum of zero indices and using the bordism invariance of the degree.

If X itself is an oriented hypersurface in $\mathbb{R}^k$, $k \geq 2$, we can define its Gauss map $g_X : X \to S^{k-1}$, where this field of oriented unitary normal vectors along X is determined by the fact that, for every $x \in X$, $g_X(x) \oplus T_xX = T_x\mathbb{R}^k$ as oriented vector spaces, where $\mathbb{R}^k$ is endowed with the standard orientation. In this case, ∂U consists of two parallel copies of X with opposite orientations. The last corollary specializes to the following:

Corollary 14.11. *Let* X *be an oriented hypersurface of* $\mathbb{R}^k$.

(1) *If* k *is even, then* $\chi(X) = 0$.

(2) *If* k *is odd, then*

$$\chi(X) = 2\deg(g_X)$$

where g_X *is the Gauss map of* X.

The corollary follows by using that the degree of the antipodal map $a_{k-1} : S^{k-1} \to S^{k-1}$ is equal to $(-1)^k$.

Remark 14.12. We can compute inductively the characteristic of real and complex projective spaces by decomposing $\mathbf{P}^n(K)$ as the union of a tubular neighbourhood of $\mathbf{P}^{n-1}(K) \subset \mathbf{P}^n(K)$ and its complement and applying Proposition 14.9 together with the additivity of χ.

14.8. Nontriviality of $\eta_\bullet$ and $\Omega_\bullet$

The integer E-P characteristic is *not* invariant up to bordism. For example, $[S^2] = [S^1 \times S^1] = 0 \in \eta_2$, but $\chi(S^2) = 2 \neq 0 = \chi(S^1 \times S^1)$. On the other hand, the E-P characteristic mod(2) is bordism invariant.

Proposition 14.13. *Let $[X] = 0 \in \eta_n$. Then $\chi_{(2)}(X) = 0 \in \mathbb{Z}/2\mathbb{Z}$.*

Proof. If n is odd, we know in general that $\chi(X) = 0$. Assume that n is even. Let $X = \partial W$, W being a compact manifold with boundary. Take the double $D(W)$. The double $D(W)$ can be presented as the composition of the triad

$$(X \times D^1, \emptyset, (X \times \{-1\} \amalg (X \times \{1\})))$$

followed by two copies of the triad

$$(W, X, \emptyset)$$

glued to $X \times D^1$ along $X \times \{\pm 1\}$, respectively. By the additive property

$$\chi(D(W)) = \chi(X \times D^1) + 2\chi(W, X, \emptyset)\ .$$

By Lemmas 14.8 and 14.7 and the fact that $n+1$ is odd and the double is boundaryless, we have

$$\chi(X) = \chi(D(W)) - 2\chi(W, X, \emptyset) = 2\chi(W) \in \mathbb{Z}$$

so that

$$\chi_{(2)}(X) = 0 \in \mathbb{Z}/2\mathbb{Z}\ .$$ ■

As an immediate corollary, we have the *nontriviality of η_{2n} and Ω_{4n}*.

Corollary 14.14. *For every $n \geq 1$, $\eta_{2n} \neq 0$ and $\Omega_{4n} \neq 0$.*

Proof. We know that $\chi(\mathbf{P}^{2n}(\mathbb{R})) = 1$; hence $[\mathbf{P}^{2n}(\mathbb{R})] \neq 0 \in \eta_{2n}$. Similarly $\chi_{(2)}(\mathbf{P}^{2n}(\mathbb{C})) = 1$; hence $[\mathbf{P}^{2n}(\mathbb{C})] \neq 0 \in \Omega_{4n}$. ■

By using the multiplicative property of χ and the obvious fact that it is additive under disjoint union, we also have the following.

Chapter 1

The smooth category of open subsets of Euclidean spaces

In this book, we will deal with manifolds. Roughly, a manifold is a topological space locally modeled on a Euclidean space $\mathbb{R}^n$, $n \in \mathbb{N}$. Let's recall a few facts about these local models. Since many of them should be familiar to the reader, we will at times omit the proofs or just sketch them out.

1.1. Basic structures on $\mathbb{R}^n$

Every space $\mathbb{R}^n$, $n \in \mathbb{N}$, is endowed with a variety of structures that will be employed case by case.

$\mathbb{R}^n$ is the *vector space* of column vectors (with n rows). We stipulate that if $v \in \mathbb{R}^n$ occurs as a vector in any linear algebra formula, then it is considered as a column.

The space $\mathcal{L}(\mathbb{R}^n, \mathbb{R}^m)$ of linear maps $L : \mathbb{R}^n \to \mathbb{R}^m$ coincides with the space of $m \times n$ matrices, $M(m, n, \mathbb{R})$, so that for every $v \in \mathbb{R}^n$, $v \to Lv$ via the usual "rows by column" product. Using the lexicographic order on the entries of any matrix $L = (l_{i,j})_{i=1,\dots,m;j=1,\dots,n}$, we also fix the identification of $M(m, n, \mathbb{R})$ with $\mathbb{R}^{mn}$.

As with every vector space, $\mathbb{R}^n$ has a canonical structure of *affine space* over itself determined by the map that associates to every pair of *points* $(x, y) \in \mathbb{R}^n \times \mathbb{R}^n$ the *vector* $\overrightarrow{xy} := y - x$. Every element of $\mathbb{R}^n$ can be considered either as a *point* x of the space or as a *vector* v. For every point x and every vector v, there is a unique point $y := x + v$ such that $v = \overrightarrow{xy}$; for every point x, the map $v \to x+v$ is a bijection. Consider $T(\mathbb{R}^n) := \mathbb{R}^n \times \mathbb{R}^n$ where the first (second) factor consists of points (vectors) and the natural projection onto the space factor $\pi_n : T(\mathbb{R}^n) \to \mathbb{R}^n$, $\pi_n(x,v) = x$. For every point x, the fibre $T_x\mathbb{R}^n = \pi^{-1}(x)$ is a copy of the vector space $\mathbb{R}^n$, called the *tangent vector space* to the affine space at the point x. We call $(T(\mathbb{R}^n), \pi_n)$ the *affine tangent vector bundle* of the affine space $\mathbb{R}^n$. The space of points $\mathbb{R}^n$ can be included in $T(\mathbb{R}^n)$ via the *zero section* $s_0(x) = (x, 0)$, so that for every point x, $\pi \circ s_0(x) = x$. For every *affine map* $f : \mathbb{R}^n \to \mathbb{R}^m$, there is a unique linear map $L_f : \mathbb{R}^n \to \mathbb{R}^m$, called the *linear part* of the affine map, such that for every point x and every vector v, $f(x+v) = f(x) + L_f v$. The map f is an affine isomorphism if and only if L_f is a linear isomorphism (in such a case, $n = m$). In other words, the *tangent map* of f,

$$Tf := (f, L_f) : \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R}^m \times \mathbb{R}^m,\ (x,v) \to (f(x), L_f v)\ ,$$

verifies $\pi_m \circ Tf = f \circ \pi_n$, so that for every point x, the tangent space $T_x\mathbb{R}^n$ goes to the tangent space $T_{f(x)}\mathbb{R}^m$ via the linear map L_f.

$\mathbb{R}^n$ is a *complete metric space* endowed with the *Euclidean distance* $d = d_n$ defined by

$$d(x,y) = \sqrt{\sum_{j=1}^{n} (x_j - y_j)^2}\ .$$

The *standard positive definite scalar product* $(*,*) = (*,*)_n$ on $\mathbb{R}^n$ is defined by

$$(x,y) := \sum_{j=1}^{n} x_j y_j = x^t I y$$

with the associated *norm* $||x|| = \sqrt{(x,x)}$. We note that

$$d^2(x,y) = (x-y, x-y)$$

and that the familiar formula

$$(x,y) = ||x|| \cdot ||y|| \cos\theta$$

allows us to recover the measure of the angle formed by the ordered and oriented lines spanned by two nonzero vectors x, y; in particular, they are orthogonal iff $(x,y) = 0$. We see that many basic objects of elementary geometry can be expressed analytically using the standard scalar product.

$\mathbb{R}^n$ is a *topological space* endowed with the topology $\tau = \tau_n$ induced by the distance d_n. As for any metrizable topological space, a subset U of $\mathbb{R}^n$ is *open* (i.e., it belongs to τ) if and only if for every $x \in U$, there is $r > 0$ such that the *"open" n-ball of centre x and radius r*

$$B^n(x,r) := \{y \in \mathbb{R}^n;\ d(x,y) < r\}$$

is contained in U. We will denote by

$$D^n = \overline{B}^n(0,1)$$

the *closed unitary n-ball* also called the unitary *n-disk*, and by

$$S^{n-1} = \partial D^n = \{x \in \mathbb{R}^n;\ d(0,x) = ||x|| = 1\}$$

the *unitary sphere*. It is not hard to verify that "open" balls are indeed open sets and that the open balls with the centre in $\mathbb{Q}^n \subset \mathbb{R}^n$ and rational radius form a *countable basis of open sets of τ* (every open set is a union of such balls). Any other scalar product

$$(x,y)_A := x^t A y$$

defined by a positive definite symmetric matrix $A = A^t$ determines (by the same formulas as above) a norm $||.||_A$, a distance d_A, and an associated topology τ_A. All these distances are *topologically equivalent*; that is, every $\tau_A = \tau$. This can be proved using the version of the elementary *spectral theorem* stating that there exists a basis of $\mathbb{R}^n$ which is simultaneously orthonormal for $(*,*)$ and orthogonal for $(*,*)_A$. Another topologically equivalent distance on $\mathbb{R}^n$ is defined by $\delta(x,y) := \max\{|x_j - y_j|;\ j = 1,\dots,n\}$.

According to general topological definitions, for every $X \subset \mathbb{R}^n$, $\tau \cap X = \{U \cap X;\ U \in \tau\}$ is the topology on X that makes it a *topological subspace* of $(\mathbb{R}^n, \tau)$; given subspaces $X \subset \mathbb{R}^n$, $Y \subset \mathbb{R}^m$, a map $f : X \to Y$ is *continuous* if for every open set $U \subset Y$, the *inverse image* $f^{-1}(U) = \{x \in X;\ f(x) \in U\}$ is an open set of X. A continuous map $f : X \to Y$ is a *homeomorphism* if it is bijective and also the *inverse map* $f^{-1} : Y \to X$ is continuous.

Every subspace $X \subset \mathbb{R}^n$ is metrizable (hence, in particular, *Hausdorff*) by the restriction to X of the distance d (or of any distance topologically equivalent to d); the restriction of any (countable) basis of open sets of τ is a (countable) basis of $\tau \cap X$.

As for every Hausdorff space with a countable basis, a subspace X of $\mathbb{R}^n$ is *compact* (i.e., every open covering of X admits a *finite* subcovering) if and only if it is *sequentially compact* (i.e., every sequence a_n of points of X admits a subsequence a_{j_n} converging to some point x of X). A subspace is compact if and only if it is *closed* (i.e., the complementary is open) and *bounded* (i.e., it is contained in some ball $B^n(0,r)$). $\mathbb{R}^n$ is *locally compact* (for every $x \in \mathbb{R}^n$ the family of *closed balls* $\overline{B}^n(x,r) = \{y \in \mathbb{R}^n;\ d(x,y) \leq r\}$, when $r > 0$ varies, is a basis of compact neighbourhoods of x). The same holds for every subspace X which is a closed subset of $\mathbb{R}^n$.

We recall that a nonempty open subset $U \subset \mathbb{R}^n$ is *connected* if U is the only open-and-closed nonempty subset of U; U is *path-connected* if for every two points x_0, x_1 of U, there is a continuous path $\alpha : [0,1] \to U$ such that

$\alpha(0) = x_0$, $\alpha(1) = x_1$. We have:

Proposition 1.1. *A nonempty open set U of $\mathbb{R}^n$ is connected if and only if it is path-connected.*

Proof. The "if" implication holds in general for arbitrary topological spaces and it is due to the basic fact that intervals in the real line are connected; for "only if", note that "being connected by a continuous path" defines an equivalence relation on U. The equivalence classes are called the *path-connected components* of U. As every open ball $B^n(x, r) \subset U$ is contained in the path-connected component of U which contains $x \in U$, then every path-connected component of U is open; hence there is only one if U is connected. ■

1.2. Differential calculus

Another fundamental structure carried by the spaces $\mathbb{R}^n$ is the *differential calculus*. Let $U \subset \mathbb{R}^n$, $W \subset \mathbb{R}^m$ be open sets. A map

$$f = (f_1, \dots, f_m) : U \to W$$

is said to be $\mathcal{C}^0$ if it is continuous. The map is *differentiable* at $x \in U$ if there is a (necessarily unique) linear map $d_x f \in \mathcal{L}(\mathbb{R}^n, \mathbb{R}^m)$ that "well" approximates $g(h) = f(x+h) - f(x)$ in a neighbourhood of $h = 0$. Precisely, for every $\epsilon > 0$, there is $\delta > 0$ such that for every h such that $||h|| < \delta$, $x + h \in U$ and

$$||g(h) - d_x f(h)|| \leq \epsilon ||h|| \ .$$

The linear map $d_x f$ is called the *differential of f at x*. The map f is (globally) *differentiable* if it is differentiable at every point $x \in U$. In such a case it is defined as the *differential map*

$$df : U \to M(m, n, \mathbb{R}), \ df(x) := d_x f \ .$$

We say f is $\mathcal{C}^1$ if it is differentiable and df is continuous (being $M(m, n, \mathbb{R})$, that is, $\mathcal{L}(\mathbb{R}^n, \mathbb{R}^m)$, identified with $\mathbb{R}^{mn}$ as we said above). Every $\mathcal{C}^1$-map is $\mathcal{C}^0$. By induction, for every $r \geq 1$, we say that f is $\mathcal{C}^r$ if df is $\mathcal{C}^{r-1}$. In practice, f is $\mathcal{C}^r$, $r \geq 1$, if and only if it is $\mathcal{C}^0$ and for every multi-index $J = j_1 \dots j_n$ of *order* $|J| := j_1 + \cdots + j_m \leq r$, for every $i = 1, \dots, m$, the *partial derivative function*

$$\frac{\partial^J f_i}{\partial^{j_1} x_1 \dots \partial^{j_n} x_n} : U \to \mathbb{R}$$

is defined and continuous. For every $x \in U$, the partial derivatives of the first order can be organized in an $m \times n$ matrix so that

$$d_x f := \left(\frac{\partial f_i}{\partial x_j}(x) \right)_{i=1,\dots,m; \ j=1,\dots,n} \in M(m, n, \mathbb{R}) \ .$$

$f(x_n) = 0$ for every n. Hence $||\frac{f(x_n)-x_n}{x_n}|| = 1$ against the fact that $d_0 f = I_n$. As for the third point, consider the function $g(x) = f(x) - x$, so that

$$||x - z|| - ||f(x) - f(z)|| \leq ||g(x) - g(z)|| \; .$$

As

$$\frac{\partial g_i}{\partial x_j}(x) = \frac{\partial f_i}{\partial x_j}(x) - \frac{\partial f_i}{\partial x_j}(0)$$

we can take ϵ to make $|\frac{\partial g_i}{\partial x_j}(x)| < \frac{1}{2n^2}$ uniformly on $\overline{B}$. Then the conclusive inequality

$$||g(x) - g(z)|| \leq \frac{1}{2}||x - z||$$

is obtained by applying several times the main value theorem for functions of one variable.

Proof of Claim 2. It is enough to prove that for every $y \in B'$ there is a unique $x \in U$ such that $f(x) = y$. The smooth function $h(x) = ||y - f(x)||^2$ has a minimum point p on the compact set $\overline{B}$ and by construction p belongs necessarily to the open ball B. A simple computation shows that $d_p f(y - f(p)) = 0$; hence $y - f(p) = 0$ because $d_p f$ is invertible. As for the uniqueness, this follows by the inequality $||p_1 - p_2|| \leq 2||f(p_1) - f(p_2)||$, so that $p_1 = p_2$ if $f(p_1) = f(p_2) = y$.

Proof of Claim 3. The same inequality implies that $||\phi^{-1}(y_1) - \phi^{-1}(y_2)|| \leq 2||y_1 - y_2||$ and the continuity of ϕ^{-1} follows.

Proof of Claim 4. As we know, it is enough to show that ϕ^{-1} is differentiable. By using directly the definition of the differential, you can prove that $d_y\phi^{-1} = (d_x\phi)^{-1}$, where $y = \phi(x)$.

■

1.9. Topologies on spaces of smooth maps

Let $U \subset \mathbb{R}^n$, $W \subset \mathbb{R}^m$ be open sets. For every $k \geq 0$, we define a topology δ_k on $\mathcal{C}^k(U, W)$; we will denote by $\mathcal{E}^k(U, W)$ the set $\mathcal{C}^\infty(U, W) \subset \mathcal{C}^k(U, W)$ endowed with the subspace topology. We determine δ_k by giving, for every $f = (f_1, \dots, f_m) \in \mathcal{C}^k(U, W)$, a basis of open neighbourhoods $\mathcal{U}_k(f, K, \epsilon)$ where the varying arguments are a compact subset $K \subset U$ and a real $\epsilon > 0$. Then, by definition, $g \in \mathcal{C}^k(U, W)$ belongs to $\mathcal{U}_k(f, K, \epsilon)$ if and only if:

(1) For every $x \in K$, $||g(x) - f(x)|| < \epsilon$.

(2) For every multi-index J such that $|J| = r \leq k$, for every $i = 1, \dots, m$, for every $x \in K$, we have

$$\left\| \frac{\partial^J (g_i - f_i)}{\partial x_1^{j_1} \dots \partial x_n^{j_n}}(x) \right\| < \epsilon \ .$$

We omit the verification that these define bases of neighbourhoods of a topology.

We denote by $\mathcal{E}(U, W)$ the set $\mathcal{C}^\infty(U, W)$ endowed with the *union topology* $\delta = \bigcup_k \delta_k$.

All of these are called *weak topologies*. There are other so-called *strong* topologies, σ_k, on the same sets of maps. By considering, for example, $\mathcal{E}(\mathbb{R}^n, \mathbb{R})$, we can control the difference of two functions, up to an arbitrarily prescribed order, on an arbitrarily given compact set K, but we have not any control "at infinity". The strong topologies σ_k, which contain δ_k being *heavily finer*, allow instead such control at infinity. On another hand, the weak topologies δ_k have nice properties; for example, we can prove that they are metrizable; hence every f has a countable basis of open neighbourhoods. On the contrary, this is not the case for the strong topologies; for example, if we have a converging sequence $g_n \to f$ in $\mathcal{C}^k(\mathbb{R}^n, \mathbb{R})$ for the strong topology, then there exists a compact set K in $\mathbb{R}^n$ such that g_n definitely equals f on the complement of K. *We do not define the strong topologies.* For our purposes, the control at compact sets will suffice.

Let us recall (a particular case of) the classical *Stone-Weierstrass theorem* (see [**Stone**]).

Theorem 1.9. *For every $f \in \mathcal{C}^k(U, \mathbb{R}^m)$, for every $k \geq 0$, for every neighbourhood $\mathcal{U} = \mathcal{U}_k(f, K, \epsilon)$, there exists a polynomial map $p : \mathbb{R}^n \to \mathbb{R}^m$ such that the restriction of p to U belongs to $\mathcal{U}$. In other words, the polynomial maps are dense in $\mathcal{C}^k(U, \mathbb{R}^m)$ for every $k \geq 0$ and in $\mathcal{E}(U, W)$.*

1.10. Stability of submersions and immersions at a compact set

Let $f \in \mathcal{C}^k(U, W)$ be as above, $k \geq 1$, $K \subset U$ a compact set. We say that f is *a submersion (resp. an immersion) at* K if, for every $x \in K$, $d_x f$ is surjective (resp. injective). This is equivalent to the fact that there exists an open neighbourhood $U' \subset U$ of K such that the restriction of f to U' is a submersion (immersion). Here are the stability results.

Proposition 1.10. *If f is either* (1) *a submersion,* (2) *an immersion, or* (3) *an injective immersion at K, then there is a neighbourhood $\mathcal{U} = \mathcal{U}_1(f, K, \epsilon)$ such that every $g \in \mathcal{U}$ shares the same properties of f, respectively.*

Proof. If $n \geq m$ (resp. $n < m$), then every $m \times n$ matrix A has $\binom{n}{m}$ $m \times m$ (resp. $\binom{m}{n}$) submatrices A_j; in any case define

$$\delta(A) = \sum_j (\det A_j)^2 \ .$$

In both cases (1) and (2) the hypothesis is equivalent to $d(x) := \delta(d_x f) > 0$ for every $x \in K$. As d is continuous and K is compact, then

$$\sup_{x \in K} \{d(x)\} = \max_{x \in K} \{d(x)\} = d_0 > 0 \ .$$

It is clear that if g is close enough to f at K in $\mathcal{C}^1(U, W)$, then $\delta(d_x g) > 0$ for every $x \in K$. As for (3), assume that the thesis fails. Then there exist a sequence $g_n \in \mathcal{C}^1(U, W)$ and sequences of points x_n, y_n in the compact set K such that the follwoing hold:

(1) Every g_n is an immersion at K (by (2) as above).

(2) $g_n \to f$ and $dg_n \to df$ uniformly on K.

(3) $x_n \to x$, $y_n \to y$ in K, $x_n \neq y_n$ and $g_n(x_n) = g_n(y_n)$ for every n.

(4) $v_n := \frac{x_n - y_n}{||x_n - y_n||} \to v \in S^{n-1}$ (by the compactness of the unitary sphere S^{n-1}).

Then $g_n(x_n) \to f(x)$, $g_n(y_n) \to f(y)$; hence $x = y$ because f is injective. Hence

$$||g_n(x_n) - g_n(y_n) - d_{y_n} g_n(x_n - y_n)|| / ||x_n - y_n|| \to 0$$

uniformly, so that

$$||d_{y_n} g_n(v_n)|| \to ||d_x f(v)|| = 0 \ .$$

This is absurd because $d_x f$ is injective. ■

1.11. Morse lemma

Let $f \in \mathcal{C}^\infty(U, \mathbb{R})$, U an open set of $\mathbb{R}^n$. A point $p \in U$ is *regular* for f if $d_p f \neq 0$ (that is, f is a submersion near p); we say that p is *critical* (or also *singular*) otherwise. We are interested in the local behaviour of f at p (actually to the germ $[f]_p$). Up to pre- or post-composition with a translation, we can normalize the situation so that $p = 0$ and $f(0) = 0$. Moreover, we can assume that $U = B^n(0, \epsilon_0)$ for some $\epsilon_0 > 0$ and, case by case, we can restrict f to any $U_\epsilon = B^n(0, \epsilon)$, $0 < \epsilon \leq \epsilon_0$. For every ϵ, the commutative ring $\mathcal{C}^\infty(U_\epsilon, \mathbb{R})$ has a canonical ideal

$$\mathfrak{m}_\epsilon = \{g \in \mathcal{C}^\infty(U_\epsilon, \mathbb{R}); \ g(0) = 0\}$$

a bit of direct computation, we see that it is indeed an immersion. Finally, if Ω is a sufficiently small neighbourhood of H in $S(n,\mathbb{R})$ and $W=\Omega\cap\mathfrak{G}_{n,k}$, then for every $A\in W$, V_A belongs $\tilde{U}$; the restriction to W of $A\to L_V$ is a chart of $\mathfrak{G}_{n,k}$ with values in an open neighbourhood U of $0\in M(n-k,k,\mathbb{R})$. We have now proved again that $\mathfrak{G}_{n,k}$ is an embedded smooth manifold of dimension $k(n-k)$ in $S(n,\mathbb{R})$.

3.4. Stiefel manifolds as fibre bundles over Grassmann manifolds

There are natural surjective maps

$$\mathfrak{l}_{n,k}: L_{n,k}\to\mathfrak{G}_{n,k}\ ,$$

$$s_{n,k}: S_{n,k}\to\mathfrak{G}_{n,k}$$

defined in both cases by $B\to A_{[B]}$ where $[B]$ denotes the linear k-subspace of $\mathbb{R}^n$ generated by the columns of B.

Let us concentrate on the map $s_{n,k}$. Note that $[B]=[C]$ if and only if there exists $Q\in O(k)$ such that $C=BQ$, and note that $A_{[B]}=H$ if and only if it is of the form

$$B=\begin{pmatrix}Q\\0\end{pmatrix},\ Q\in O(k)\ .$$

It follows that every fibre of $s_{n,k}$ is diffeomorphic to $O(k)$ and there is a transitive action (on the *right*) of $O(k)$ itself on each fibre.

The map $s_{n,k}$ is *equivariant* for the actions of $O(n)$: $(P,B)\to PB$ on $S_{n,k}$, $(P,A)\to P^tAP$ on $\mathfrak{G}_{n,k}$, respectively. Recall that "equivariant" means that for every (P,B), $A_{[PB]}=P^tA_{[B]}P$. Then it is enough to analyze the behaviour of the restriction of the map to the inverse image $\tilde{\Omega}:=s^{-1}_{n,k}(\Omega)$ (which is an open neighbourhood of J in $S_{n,h}$) of some open neighbourhood Ω of H in $\mathfrak{G}_{n,h}$. For every $B\in S_{n,k}$, if P is the top $k\times k$ submatrix of B, let us express this by writing $B=(P|D)$. Let $\tilde{\Omega}$ be the open neighbourhood of J in $S_{n,k}$ formed by the matrices $B=(P|D)$ such that P is nonsingular. If $B\in\tilde{\Omega}$, then $[B]\cap\mathbb{R}^{n-k}=\{0\}$; hence its image Ω in $\mathfrak{G}_{n,k}$ is an open set. Moreover, if $[(P|D)]=[(R|S)]$, then there is $Q\in O(k)$ such that $(P|D)=(RQ|SQ)$. If P is nonsingular, then R is also necessarily nonsingular. This means that $\tilde{\Omega}=s^{-1}_{n,k}(\Omega)$ is a *saturated* open set of $S_{n,k}$ for the surjective map $s_{n,k}$. We can make explicit $s_{n,k}(B)$ on $\tilde{\Omega}$ by applying to every $[B]$ and its orthonormal basis given by B itself the construction already used above to construct a local parametrization of $\mathfrak{G}_{n,k}$ at H. This shows that $s_{n,k}$ is smooth. Moreover, define $\phi:\tilde{\Omega}\to M(k,n-k,\mathbb{R})$ by $\phi((P|D))=DP^{-1}$. If

$(P|D) = (RQ|SQ)$ as above, then $SQQ^{-1}R^{-1} = SR^{-1}$. Then there is an induced smooth map $\Omega \to M(k, n-k, \mathbb{R})$ whose inverse map is

$$\psi : M(k, n-k, \mathbb{R}) \to \Omega,\ \psi(Z) = A_{[\mathfrak{r}_{n,k}(I_k|Z)]}$$

providing once again a local parametrization of $\mathfrak{G}_{n,k}$ at H. We can summarize this discussion by saying that there is a locally trivializing commutative diagram at H

$$\begin{tikzcd}
\Omega \times O(k) \arrow[r, "\Psi"] \arrow[d, "\pi_\Omega"] & \tilde{\Omega} \arrow[d, "s_{n,k}"] \\
\Omega \arrow[r, "\mathrm{id}_\Omega"] & \Omega
\end{tikzcd}$$

where $\Psi(A, Q) = \psi(Z)Q$, $A = \psi(Z)$. Its orbit by the action of $O(n)$ provides a fibred atlas for the submersion $s_{n,k}$. So we have proved

Proposition 3.2. *The map* $s_{n,k} : S_{n,k} \to \mathfrak{G}_{n,k}$ *is a fibre bundle with fibre* $O(k)$. *Every change of trivialization*

$$\Phi' \circ \Psi(\Omega \cap \Omega') \times O(k) \to (\Omega \cap \Omega') \times O(k)$$

is of the form

$$(p, P) \to (p, PQ(p))$$

where $p \to Q(p)$ *defines a smooth map* $\Omega \cap \Omega' \to O(k)$.

We also have the following topological consequences.

Corollary 3.3. *Every* $\mathfrak{G}_{n,k}$ *is a compact and connected embedded smooth manifold. As a topological space it has the quotient space topology* $S_{n,k}/s_{n,k}$.

- *Real projective spaces.* A particular case of the above discussion is when $k = 1$. In such a case $\mathfrak{G}_{n,1}$ is also denoted by $\mathbf{P}^{n-1}(\mathbb{R})$ and is called the (real) $(n-1)$-*projective space.* In this case, $S_{n,1} = S^{n-1}$ and the map $s = s_{n,1} : S^{n-1} \to \mathbf{P}^{n-1}(\mathbb{R})$ is a *smooth covering map of degree* 2.

- *Complex Stiefel and Grassmann manifolds.* As a smooth manifold $\mathbb{C}^n = \mathbb{R}^{2n}$; hence $M(n, \mathbb{C})$ is a submanifold of $M(2n, \mathbb{R})$, etc. Throughout the above discussion, let us replace:
  - $\mathbb{R}^n$ with $\mathbb{C}^n$. The real linear subspaces of $\mathbb{R}^n$ with the *complex* linear subspaces of $\mathbb{C}^n$.
  - The standard positive definite scalar product on $\mathbb{R}^n$ with the standard positive definite *Hermitian product* on $\mathbb{C}^n$, $\langle v, w \rangle = v^t \bar{w}$.
  - The (real) orthogonal groups $O(n)$ with the *unitary groups*

    $$U(n) := \{A \in \mathrm{GL}(n, \mathbb{C});\ A^{-1} = A^* := \bar{A}^t\}\ .$$

  - The spaces of real symmetric matrices $S(n, \mathbb{R})$ with the spaces of *Hermitian matrices*

    $$H(n, \mathbb{C}) = \{A \in M(n, \mathbb{C});\ A = A^*\}\ .$$

- The spectral theorem for real symmetric matrices with the *spectral theorem for complex Hermitian matrices.*

Then, by repeating *verbatim* the above constructions, for every (n,k) as above, we realize the (unitary) *complex Stiefel manifold* $S_{n,k}(\mathbb{C})$ as a compact embedded smooth manifold in $M(n,k,\mathbb{C})$, the complex Grassmann manifold $\mathfrak{G}_{n,k}(\mathbb{C})$ as a compact embedded smooth manifold in $H(n,\mathbb{C})$ (defined by the usual equations $A^2 - A = 0$, $\mathrm{trace}(A) = k$), the complex projective spaces $\mathbf{P}^{n-1}(\mathbb{C}) = \mathfrak{G}_{n,1}(\mathbb{C})$, and so on. Although we are dealing with spaces based on the *complex numbers*, we stress that in this way we have realized them as *real* embedded smooth manifolds.

We understand that also the next considerations about Stiefel and Grassmann manifolds would have a counterpart for the complex version.

3.5. A cellular decomposition of the Grassmann manifolds

We describe a natural partition of $\mathfrak{G}_{n,k}$ by a finite number of subsets, each one diffeomorphic to some $\mathbb{R}^h$, $0 \leq h \leq \dim \mathfrak{G}_{n,k}$ (i.e., an *open h-cell*) and such that its closure in $\mathfrak{G}_{n,k}$ is a union of cells of lower dimension. Let $L \in \mathfrak{G}_{n,k}$; that is, L is a k-dimensional linear subspace of $\mathbb{R}^n$ (here we make the abuse of identifying $G_{n,k}$ and $\mathfrak{G}_{n,k}$). For every $i = 0, \dots, n$, denote by

$$p_i : \mathbb{R}^n \to \mathbb{R}^{n-i}$$

the projection to the first $n-i$ coordinates, $p_i((x_1, \dots, x_n)^t) = (x_1, \dots, x_{n-i})^t$. The dimensions of $p_i(L) \subset \mathbb{R}^{n-i}$ decrease from k to 0 in exactly k steps; that is, there are integers

$$1 \leq \sigma_1 < \sigma_2 < \cdots < \sigma_k \leq n$$

such that for j that decreases from k to 1,

$$\dim p_{\sigma_j + 1}(L) - \dim p_{\sigma_j}(L) = 1 \ .$$

We call

$$\sigma(L) := (\sigma_1, \dots, \sigma_k)$$

the *Schubert symbol* of L. There is a concrete, elementary way to determine $\sigma(L)$:

- Fix any rank k, $n \times k$ matrix $A \in L_{n,k}$ which projects to $L \in \mathfrak{G}_{n,k}$.

- Apply to A the Gauss algorithm via elementary operations on the columns and get a matrix

$$\hat{A} \in L_{n,k}$$

in *column echelon form* which also projects to L.

(%$%

Pág. 2(33) →

$\mathbb{R}^n$ is a topological space endowed with the topological $T = T_n$ induced by the distance d_n.

As for any metrizable topological space, a subset U of $\mathbb{R}^n$ is open (i.e., it belongs to T) if and only if for every $x \in U$ there is $r > 0$ such that (de tal modo que) the "open" n-ball of centre x and radius r

$$B^n(x, r) := \{y \in \mathbb{R}^n ; d(x, y) < r\}$$

CHAPTER II

THE FIRST PERIOD

Earliest traces of the problem

THE earliest traces of a determination of π are to be found in the Papyrus *Rhind* which is preserved in the British Museum and was translated and explained* by Eisenlohr. It was copied by a clerk, named Ahmes, of the king Raaus, probably about 1700 B.C., and contains an account of older Egyptian writings on Mathematics. It is there stated that the area of a circle is equal to that of a square whose side is the diameter diminished by one ninth; thus $A = (\frac{8}{9})^2 d^2$, or comparing with the formula $A = \frac{1}{4}\pi d^2$, this would give

$$\pi = \frac{256}{81} = 3 \cdot 1604 \ldots .$$

No account is given of the means by which this, the earliest determination of π, was obtained; but it was probably found empirically.

The approximation $\pi = 3$, less accurate than the Egyptian one, was known to the Babylonians, and was probably connected with their discovery that a regular hexagon inscribed in a circle has its side equal to the radius, and with the division of the circumference into $6 \times 60 \equiv 360$ equal parts.

This assumption ($\pi = 3$) was current for many centuries; it is implied in the Old Testament, 1 Kings vii. 23, and in 2 Chronicles iv. 2, where the following statement occurs:

"Also he made a molten sea of ten cubits from brim to brim, round in compass, and five cubits the height thereof; and a line of thirty cubits did compass it round about."

The same assumption is to be found in the Talmud, where the statement is made "that which in circumference is three hands broad is one hand broad."

---

* Eisenlohr, *Ein mathematisches Handbuch der alten Ägypter* (Leipzig, 1877).

The earlier Greek Mathematicians

It is to the Greek Mathematicians, the originators of Geometry as an abstract Science, that we owe the first systematic treatment of the problems of the quadrature and rectification of the circle. The oldest of the Greek Mathematicians, Thales of Miletus (640—548 B.C.) and Pythagoras of Samos (580—500 B.C.), probably introduced the Egyptian Geometry to the Greeks, but it is not known whether they dealt with the quadrature of the circle. According to Plutarch (in *De exilio*), Anaxagoras of Clazomene (500—428 B.C.) employed his time during an incarceration in prison on Mathematical speculations, and constructed the quadrature of the circle. He probably made an approximate construction of an equal square, and was of opinion that he had obtained an exact solution. At all events, from this time the problem received continuous consideration.

About the year 420 B.C. Hippias of Elis invented a curve known as the τετραγωνίζουσα or Quadratrix, which is usually connected with the name of Dinostratus (second half of the fourth century) who studied the curve carefully, and who shewed that the use of the curve gives a construction for π.

This curve may be described as follows, using modern notation.

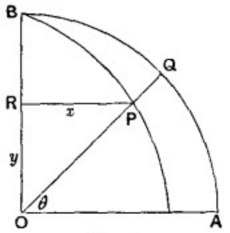

Fig. 1.

Let a point Q starting at A describe the circular quadrant AB with uniform velocity, and let a point R starting at O describe the radius OB with uniform velocity, and so that if Q and R start simultaneously they will reach the point B simultaneously. Let the point P be the intersection of OQ with a line perpendicular to OB drawn from R. The locus of P is the quadratrix. Letting $\angle QOA = \theta$, and $OR = y$, the ratio y/θ is constant, and equal to $2a/\pi$, where a denotes the radius of the circle. We have

$$x = y \cot\theta, \text{ or } x = y \cot \frac{\pi y}{2a},$$

the equation of the curve in rectangular coordinates. The curve will intersect the x axis at the point

$$x = \lim_{y=0} \left(y \cot \frac{\pi y}{2a} \right) = 2a/\pi.$$

If the curve could be constructed, we should have a construction for the length $2a/\pi$, and thence one for π. It was at once seen that the construction of the curve itself involves the same difficulty as that of π.

The problem was considered by some of the Sophists, who made futile attempts to connect it with the discovery of "cyclical square numbers," *i.e.* such square numbers as end with the same cipher as the number itself, as for example $25 = 5^2$, $36 = 6^2$; but the right path to a real treatment of the problem was discovered by Antiphon and further developed by Bryson, both of them contemporaries of Socrates (469—399 B.C.). Antiphon inscribed a square in the circle and passed on to an octagon, 16agon, &c., and thought that by proceeding far enough a polygon would be obtained of which the sides would be so small that they would coincide with the circle. Since a square can always be described so as to be equal to a rectilineal polygon, and a circle can be replaced by a polygon of equal area, the quadrature of the circle would be performed. That this procedure would give only an approximate solution he overlooked. The important improvement was introduced by Bryson of considering circumscribed as well as inscribed polygons; in this procedure he foreshadowed the notion of upper and lower limits in a limiting process. He thought that the area of the circle could be found by taking the mean of the areas of corresponding in- and circum-scribed polygons.

Hippocrates of Chios who lived in Athens in the second half of the fifth century B.C., and wrote the first text book on Geometry, was the first to give examples of curvilinear areas which admit of exact quadrature. These figures are the menisci or lunulae of Hippocrates.

If on the sides of a right-angled triangle ACB semi-circles are described on the same side, the sum of the areas of the two lunes AEC, BDC is equal to that of the triangle ACB. If the right-angled triangle is isosceles, the two lunes are equal, and each of them is half the area of the triangle. Thus the area of a lunula is found.

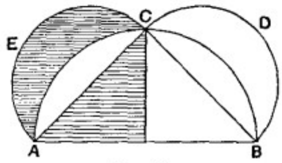

FIG. 2.

If $AC = CD = DB =$ radius OA (see Fig. 3), the semi-circle ACE is $\frac{1}{4}$ of the semi-circle $ACDB$. We have now

$$\mathrm{D}AB - 3\mathrm{D}AC = ACDB - 3 \,.\, \text{meniscus } ACE,$$

and each of these expressions is $\frac{1}{4}\mathrm{D}AB$ or half the circle on $\frac{1}{2}AB$ as diameter. If then the meniscus AEC were quadrable so also would be the circle on $\frac{1}{2}AB$ as diameter. Hippocrates recognized the fact that the meniscus is not quadrable, and he made attempts to find other quadrable lunulae in order to make the quadrature of the circle depend on that of such quadrable lunulae. The question of the existence of various kinds of quadrable lunulae was taken up by Th. Clausen* in 1840, who discovered four other quadrable lunulae in addition to the one mentioned above. The question was considered in a general manner by Professor Landau † of Göttingen in 1890, who pointed out that two of the four lunulae which Clausen supposed to be new were already known to Hippocrates.

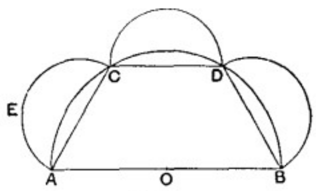

FIG. 3.

From the time of Plato (429—348 B.C.), who emphasized the distinction between Geometry which deals with incorporeal things or images of pure thought and Mechanics which is concerned with things in the external world, the idea became prevalent that problems such as that with which we are concerned should be solved by Euclidean determination only, equivalent on the practical side to the use of two instruments only, the ruler and the compass.

The work of Archimedes

The first really scientific treatment of the problem was undertaken by the greatest of all the Mathematicians of antiquity, Archimedes (287—212 B.C.). In order to understand the mode in which he actually established his very important approximation to the value of π it is necessary for us to consider in some detail the Greek method of dealing with problems of limits, which in the hands of Archimedes provided a method of performing genuine integrations, such as his determination of the area of a segment of a parabola, and of a considerable number of areas and volumes.

This method is that known as the method of exhaustions, and rests on a principle stated in the enunciation of Euclid X. 1, as follows:

"Two unequal magnitudes being set out, if from the greater there be subtracted a magnitude greater than its half, and from that which

Gauss's Law

Skills & Knowledge You'll Need

- Coulomb's law (Section 20.2)
- The dot product of two vectors (Section 6.2)

Learning Outcomes

After finishing this chapter you should be able to:

LO 21.1 Describe electric fields using field lines.

LO 21.2 Explain the concept of electric flux in relation to field lines.

LO 21.3 Describe Gauss's law and explain how it relates to Coulomb's law.

LO 21.4 Use Gauss's law to determine electric fields for charge distributions with sufficient symmetry.

LO 21.5 Approximate electric fields of general charge distributions using what you know about simpler distributions.

LO 21.6 Describe electrostatic equilibrium in conductors and use Gauss's law to determine electric fields associated with charged conductors.

Huge sparks jump to the operator's cage in the Hall of Electricity at the Boston Museum of Science, but the operator is unharmed. Why?

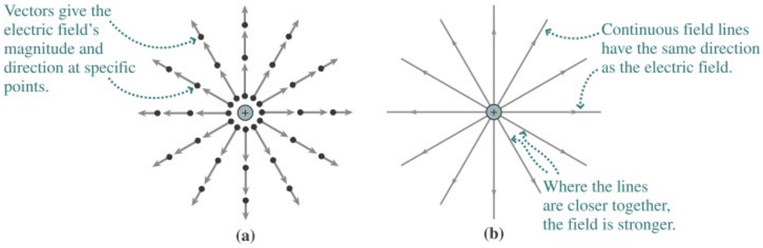
In this chapter we introduce an elegant way of describing electric fields that makes it much easier to calculate the fields of certain charge distributions. In the process we'll formulate one of the four fundamental laws of electromagnetism—a statement that embodies Coulomb's law but that gives deeper insights into the electric field.

21.1 Electric Field Lines

LO 21.1 *Describe electric fields using field lines.*

We can visualize electric fields by drawing **electric field lines**, continuous lines whose direction is everywhere the same as that of the electric field. To draw a field line, determine the field direction at some point. Move a small distance in the direction of the field, and evaluate the field direction at the new point. Extending the process in both directions from your starting point traces out an electric field line. You'll find that field lines begin on positive charges and either end on negative charges or extend to infinity. Drawing many field lines gives a picture of the overall field.

To explore the field of a positive point charge, as shown in Fig. 21.1*a*, start near the charge. The field points radially outward, so move a little way outward. The field is still radial. Repeat the process, and you'll trace a straight line that extends indefinitely. So the field lines of a positive point charge are straight lines that begin on the charge and extend radially to infinity (Fig. 21.1*b*).



Vectors give the electric field's magnitude and direction at specific points.
Continuous field lines have the same direction as the electric field.
Where the lines are closer together, the field is stronger.
(a)
(b)

FIGURE 21.1 Vectors (a) and field lines (b) provide two ways to visualize the electric field.

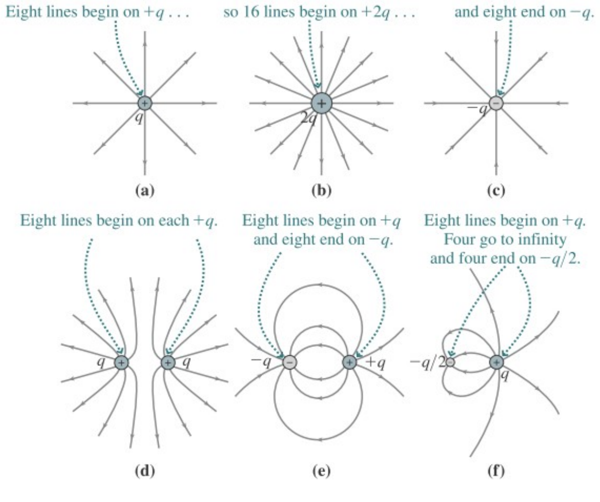
Field is strongest where lines are closest.
(b)

FIGURE 21.2 Field of an electric dipole. (a) At each point, the field-line direction is that of the *net* electric field, $\vec{E} = \vec{E}_+ + \vec{E}_-$ (b) Tracing many field lines shows the overall dipole field.

In Fig. 21.1*b* the field lines spread apart as they extend farther from the point charge. Coulomb's law shows that the field weakens farther from the charge, so in Fig. 21.1*b* the field is stronger where the lines are closer and weaker where they're farther apart. This is generally true, and lets us infer the field's relative magnitude as well as direction from field-line pictures.

To trace the field lines of a charge distribution, follow the net field—the vector sum of the field contributions from all charges in the distribution. Usually the field direction varies, so the line is curved. Figure 21.2*a* shows the details for one field line of a dipole. Figure 21.2*b* shows a number of dipole field lines; here you can see that the field is strongest near the individual charges and in the region between them. The electric field exists everywhere, so there are really infinitely many field lines. We can't draw them all, but in order to make field-line pictures somewhat precise, we associate a fixed number of field lines with a charge of a given magnitude. In Fig. 21.3, for example, eight field lines correspond to a charge of magnitude q. Study the figure, and you'll see how all the fields shown are consistent with this convention.



Eight lines begin on $+q$ . . .
so 16 lines begin on $+2q$ . . .
and eight end on $-q$.

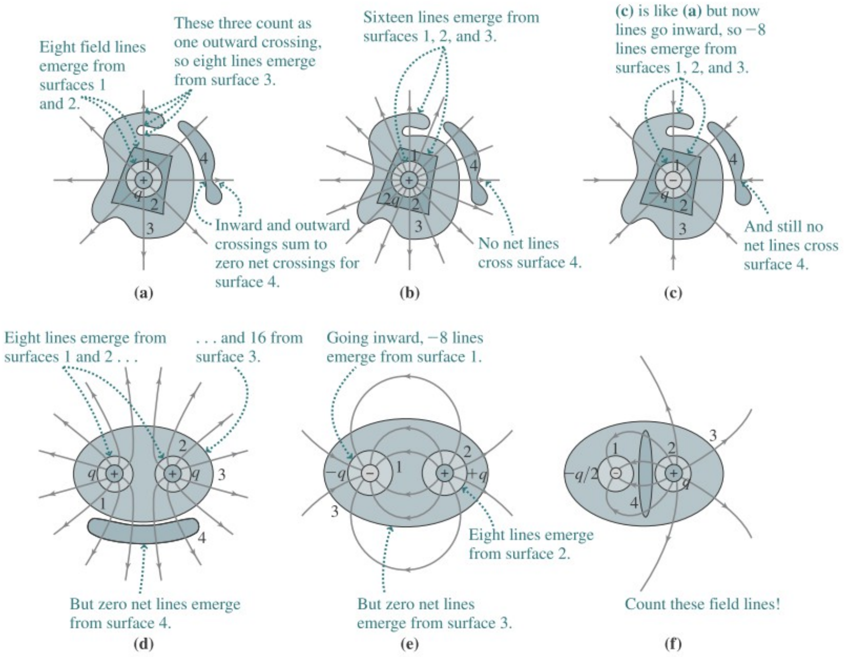
21.2 Electric Field and Electric Flux

LO 21.2 *Explain the concept of electric flux in relation to field lines.*

In Fig. 21.4 we've surrounded each charge distribution from Fig. 21.3 with several surfaces. Each surface is closed, so it's impossible to get from inside to outside without crossing the surface. (Figure 21.4 shows only the two-dimensional cross section of each surface.) How many field lines emerge from within each surface?

In Fig. 21.4*a* the answer for surfaces 1 and 2 is eight. For surface 3 one field line crosses twice going out and once going in; if we count the inward-going line as negative, then there's still a net of eight lines going out. *Any* closed surface surrounding $+q$ will have eight lines emerging from it, for the simple reason that eight lines begin on the charge and extend to infinity; to get there they all have to cross the closed surface.



Eight field lines emerge from surfaces 1 and 2.
These three count as one outward crossing, so eight lines emerge from surface 3.
Inward and outward crossings sum to zero net crossings for surface 4.

FIGURE 21.4 The number of field lines emerging from a closed surface depends only on the net charge enclosed.

If $\vec{E}$ is parallel to some parts of the area—as happens in line and plane symmetry— then $\vec{E} \perp d\vec{A}$, so $\vec{E} \cdot d\vec{A} = 0$ and there's no contribution to the flux from those areas.

- Evaluate the *enclosed* charge. This may or may not be the same as the total charge, depending on whether the position at which you're evaluating the field lies outside or inside the charge distribution.
- Evaluate the field E by invoking Gauss's law, equating the flux to $q_{\text{enclosed}}/\epsilon_0$, and solving for E. This is the field magnitude; the direction should be evident from symmetry.

ASSESS Does your answer make sense? Does the field behave as you would expect given what you know of simpler charge distributions—point charges, line charges, or charged sheets, depending on the symmetry?

You'll quickly get the hang of this strategy because Gauss's law is useful for finding the field only in the three common symmetries. That means you need to evaluate the integral for the flux just once for a given symmetry.

Spherical Symmetry

A charge distribution has spherical symmetry when the charge density depends only on the radial distance r from the center of the distribution—also called the *point of symmetry*. A point charge is one example, as are the three charge distributions we'll now treat in Examples 21.1 through 21.3. In fact, *any* spherical charge distribution has spherical symmetry, provided the charge density varies solely with distance from the center. The only electric field consistent with spherical symmetry is a field that points in the radial direction, either away from or toward the point of symmetry. We'll start with the simplest case, a charged spherical shell.

EXAMPLE 21.1 Gauss's Law: A Hollow Spherical Shell

A thin, hollow spherical shell of radius R has total charge Q distributed uniformly over its surface. Find the electric field (a) outside and (b) inside the shell.

INTERPRET This is a spherically symmetric charge distribution, so we can use Gauss's law to find the field.

DEVELOP With spherical symmetry, the field lines have to point radially outward for a positive charge and inward for a negative one. We've sketched the charged shell and some field lines outside it in Fig. 21.11. With spherical symmetry, the appropriate Gaussian surfaces are also spheres centered on the center of the shell. Since we're asked for the field both outside and inside the shell, we've sketched one such surface outside the shell and one inside.

EVALUATE

- We first evaluate the flux integral $\Phi = \oint \vec{E} \cdot d\vec{A}$ that appears on the left-hand side of Gauss's law. With our choice of a spherical Gaussian surface, the field is everywhere perpendicular to the surface, or parallel to the normal vector $d\vec{A}$ (recall Fig. 21.9). So $\cos\theta = 1$, and the dot product becomes just $E\,dA$. With our Gaussian surface being a sphere centered on the point of symmetry, the field magnitude E is the same all over the Gaussian surface. So E comes outside the integral, leaving $\Phi = E\oint dA$. The remaining integral is the sum of all the little areas dA over the spherical Gaussian surface—and that's the surface area of a sphere, $A = 4\pi r^2$. The flux then becomes $\Phi = 4\pi r^2 E$. Note that this result doesn't depend on whether the surface is outside or inside the shell or on the particular value of its radius r; it follows from the symmetry and our choice of a spherical Gaussian surface alone. So it holds for both Gaussian surfaces shown in Fig. 21.11, outside and inside the shell.

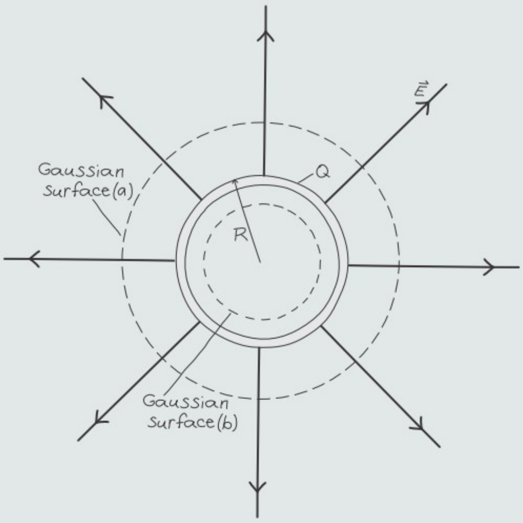

FIGURE 21.11 Finding the field of a charged shell.

(continued)

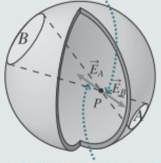
- Now we evaluate the *enclosed* charge. That *is* different for the two surfaces, so we'll deal first with (a), the field outside the shell. For this we consider the Gaussian surface marked (a); it's outside the shell, so it encloses the entire charge Q. Substituting our expression for the flux, $\Phi = 4\pi r^2 E$, into Gauss's law, $\Phi = \oint \vec{E} \cdot d\vec{A} = q_{\text{enclosed}}/\epsilon_0$, gives $4\pi r^2 E = Q/\epsilon_0$. We can then solve for E to get

$$E = \frac{Q}{4\pi\epsilon_0 r^2} \quad \text{(field outside any spherical charge distribution)} \qquad (21.4)$$

- Now let's consider the interior of the shell. With all the charge on the shell's surface, there's no charge inside. So Gaussian surface (b) doesn't enclose any charge. But, as we argued previously, the flux is still $4\pi r^2 E$, so Gauss's law becomes $4\pi r^2 E = 0$. Solving for E gives $E = 0$. We could have drawn Gaussian surface (b) anywhere inside the shell, including right up to its surface, so there's no electric field anywhere inside the shell.

ASSESS

- Consider first the field outside the shell (Equation 21.4). Since $1/4\pi\epsilon_0$ is the Coulomb constant k, this field can be written $E = kQ/r^2$—precisely the field of a point charge! In fact, our argument leading to this result didn't depend on the charge being on a spherical shell; as long as a charge distribution is spherically symmetric and we're evaluating the field *outside* the distribution, we would find the same result. That's why we've made the result a numbered equation and labeled it "field outside any spherical charge distribution." Outside *any* spherical charge distribution, then, its field is *exactly* the same as that of a point charge with the same total charge, located at the center of symmetry. Incidentally, this result also holds for gravity because it, too, obeys an inverse-square law. That's why we can treat planets as though they were point masses located at their centers.
- Now the interior field: How can it be exactly zero everywhere inside the shell? Figure 21.12 shows that this remarkable result is a consequence of the inverse-square law.

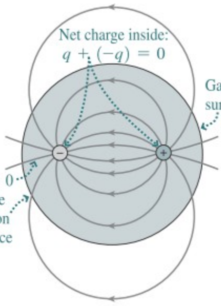


Charges at B contribute $\vec{E}_B$ to the field at P . . .

. . . and charges at A contribute $\vec{E}_A$. The two fields cancel.

FIGURE 21.12 At any point *P* inside a charged shell, the field from the relatively few nearby charges at *A* is exactly canceled by the field from the more numerous but more distant charges at *B*. The result is zero field everywhere inside the shell.

TIP **SYMMETRY MATTERS!** We used the fact that there's no charge inside an empty spherical shell to conclude that the field inside the shell is zero. But be careful: That conclusion follows only when there's enough symmetry, as Fig. 21.13 shows. Here, the Gaussian surface encloses zero net charge, so the flux through the surface is zero. But the electric field both on and inside the surface isn't zero.



Net charge inside: $q + (-q) = 0$

Gaussian surface

$E \neq 0$ inside and on surface

FIGURE 21.13 A spherical Gaussian surface surrounds a dipole. We have $q_{\text{enclosed}} = 0$, but $E \neq 0$ inside the surface because the dipole isn't spherically symmetric.

GOT IT? **21.4** A spherical shell carries charge Q distributed uniformly over its surface. If the charge on the shell doubles, what happens to the electric field (1) inside and (2) outside the shell?

Now let's consider a slightly more complicated charge distribution: a spherical shell with a point charge at the center.

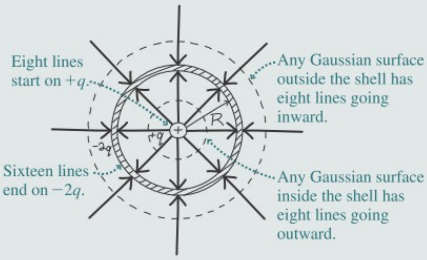
EXAMPLE 21.2 Gauss's Law: A Point Charge within a Shell

Worked Example with Variation Problems

A positive point charge $+q$ is at the center of a spherical shell of radius R carrying charge $-2q$, distributed uniformly over its surface. Find expressions for the field strength inside and outside the shell.

INTERPRET This problem is about a charge distribution with spherical symmetry.

DEVELOP We want to find the fields both inside and outside the distribution, so we show two spherical Gaussian surfaces in our sketch, Fig. 21.14. We've also drawn some field lines, which will help in assessing our answer.



Eight lines start on $+q$.

Sixteen lines end on $-2q$.

Any Gaussian surface outside the shell has eight lines going inward.

Any Gaussian surface inside the shell has eight lines going outward.

FIGURE 21.14 A shell carrying charge $-2q$ surrounds a point charge $+q$. Note that the number of field lines beginning on the point charge and the number ending on the shell correctly reflect their respective charges.

EVALUATE

- We already know that the flux through a spherical Gaussian surface is $\Phi = 4\pi r^2 E$ when we have spherical symmetry, so that's the flux for both surfaces.
- The outer surface encloses the charge $+q$ at the center and $-2q$ on the shell, so the net charge enclosed is $q_{\text{enclosed}} = -q$ for $r > R$. The inner surface encloses only the point charge $+q$, so $q_{\text{enclosed}} = +q$ for $r < R$.
- Now we find the field by equating the flux $\Phi = 4\pi r^2 E$ to $q_{\text{enclosed}}/\epsilon_0$. The result for $r > R$ is $E = -q/4\pi\epsilon_0 r^2$, where the minus sign appears because the enclosed charge is $-q$. For $r < R$ with enclosed charge $+q$, the result is $E = q/4\pi\epsilon_0 r^2$.

ASSESS Make sense? We've seen that the field outside a spherically symmetric charge distribution is that of an equivalent point charge at the center. Here the net charge is $-q$, and our result for $r > R$ is indeed the field of a point charge $-q$. Another way to see this is to apply superposition: The field outside due to the shell alone is that of a point charge $-2q$; that adds to the field of the central point charge $+q$ to give, again, the field of a point charge $-q$ in the region outside the shell. In Example 21.1 we found that the shell produces no field in its interior, so here superposition leaves us with the field of the central point charge alone, just as our result shows. Sketching the field lines, as we've done in Fig. 21.14, also shows how our results make sense.

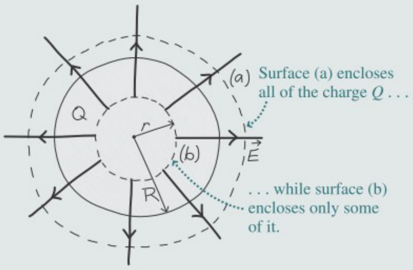
What if we have charge distributed throughout a volume? As long as the distribution is spherically symmetric, we can find the electric field using Gauss's law just as we did in Examples 21.1 and 21.2. The only difference comes when we evaluate the enclosed charge. Example 21.3 considers this situation.

EXAMPLE 21.3 Gauss's Law: A Uniformly Charged Sphere

A charge Q is distributed uniformly throughout a sphere of radius R. Find the electric field at all points, (a) outside and (b) inside the sphere.

INTERPRET The charge distribution has spherical symmetry, so we can use Gauss's law to find the field.

DEVELOP Figure 21.15 is a sketch of the spherical charge distribution. As you've already seen, the field in any case of spherical symmetry must be radial, so we've sketched some field lines on the figure. As in Examples 21.1 and 21.2, Gaussian surfaces appropriate to spherical symmetry are themselves spheres. Since we're asked for the field both outside and inside the charge distribution, we've drawn two such Gaussian surfaces, one outside and one inside the distribution.



Surface (a) encloses all of the charge Q . . .

. . . while surface (b) encloses only some of it.

FIGURE 21.15 Finding the field of a uniformly charged sphere. The field also exists within the inner Gaussian surface, but we haven't shown it.

EVALUATE

- We already know the answer to (a), the field outside the charge distribution. That's because, as we found in Example 21.1, the field outside *any* spherically symmetric charge distribution is exactly that of a point charge located at the center. So the field outside the charged sphere has magnitude $E_{\text{out}} = Q/4\pi\epsilon_0 r^2$ and points radially

(*continued*)

outward for positive Q. You could also recover this result by considering the flux through surface (a) in Fig. 21.15 and equating it to $q_{\text{enclosed}}/\epsilon_0$—which would essentially repeat the calculation for the field outside the spherical shell in Example 21.1.

- For (b), the field inside the charged sphere, we need to apply Gauss's law to surface (b) in Fig. 21.15. In Example 21.1 we found that the left-hand side of Gauss's law—the flux—is given by $4\pi r^2 E$ whenever we have spherical symmetry and are using a spherical Gaussian surface. However, we still need to find the charge enclosed by surface (b). Since surface (b) lies *within* the sphere of charge, it doesn't enclose the entire charge Q. We can find just how much charge it encloses by comparing its volume with that of the entire sphere. Surface (b) has radius r, so its volume is $\frac{4}{3}\pi r^3$. The charged sphere has radius R, so its volume is $\frac{4}{3}\pi R^3$. So our Gaussian surface, (b), encloses a fraction r^3/R^3 of the total volume of the charged sphere. Because charge is distributed *uniformly* throughout the sphere, this is also the fraction of the total charge enclosed by our Gaussian surface. So q_{enclosed} in Gauss's law becomes Qr^3/R^3 for a Gaussian surface of radius r that's inside the charged sphere. We can now write Gauss's law for this situation, equating the flux, $4\pi r^2 E$, to $q_{\text{enclosed}}/\epsilon_0$: $4\pi r^2 E = Qr^3/\epsilon_0 R^3$. Solving for the field magnitude E gives

$$E = \frac{Qr}{4\pi\epsilon_0 R^3} \quad \text{(field inside uniformly charged sphere)} \qquad (21.5)$$

ASSESS: Make sense? The field inside the sphere increases linearly with distance r from the center. This reflects two opposite effects: First, as we move outward from the center, the enclosed charge grows in proportion to the volume enclosed—that is, as r^3. But the distance from the center grows as well, and that causes a $1/r^2$ decrease in the field. The combined effect is a field that grows linearly from the center to the surface of the sphere, as shown in Equation 21.5. But once we're outside the sphere, the enclosed charge no longer grows, so we see only the $1/r^2$ decrease of the point-charge field. Figure 21.16 plots the resulting field magnitude E both inside and outside the sphere. As the figure shows, and as you can convince yourself by comparing Equations 21.4 and 21.5, our results for the exterior and interior fields agree at the sphere's surface, where $r = R$.

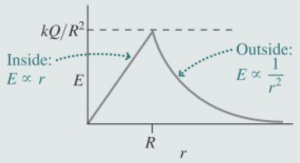


FIGURE 21.16 Field strength versus radial distance for a uniformly charged sphere of radius R.

Before moving on, consider the three examples of Gauss's law in spherical symmetry that you've just seen. In each example we equated the left-hand side of Gauss's law to the right-hand side and solved for the electric field magnitude E. We only had to find the left-hand side once: In every case of spherical symmetry with a spherical Gaussian surface, the left-hand side of Gauss's law is $\Phi = \oint \vec{E} \cdot d\vec{A} = 4\pi r^2 E$. We discovered this in Example 21.1, and you never need to do that calculation again as long as you've got spherical symmetry. So we used $4\pi r^2 E$ for the left-hand side of Gauss's law in both Examples 21.2 and 21.3. Example 21.1 showed us that the field *outside* any spherically symmetric charge distribution is *exactly* that of a point charge located at the center. Again, that's an exact result—not just an approximation that holds at large distances. It's true right up to the surface of the charge distribution, as Figure 21.16 shows graphically.

Example 21.1 also showed us that the field everywhere *inside* a spherical shell of charge is zero. You could think of any spherically symmetric charge distribution as made up of concentric shells—and that means there's never a contribution to the electric field from charge that's further from the center than the position where you're evaluating the field. In that light, here's another take on the most difficult of our three examples, Example 21.3 for the field within a spherical volume of charge: At any position inside that volume, there's no contribution from the charge that's further out. And, as Example 21.1 also showed, the charge interior to that position acts like a point charge. Work out that charge—essentially the calculation leading to q_{enclosed} in Example 21.3—and you'll get Equation 21.5 for the field inside a uniformly charged sphere. So all spherically symmetric charge distributions are similar, in that we apply Gauss's law in exactly the same way. The only difference is in finding the enclosed charge. Problems 69 and 71 provide additional examples involving charge distributions that are spherically symmetric but not uniform.

We'll now consider the two other symmetries where Gauss's law provides a quick route to finding the electric field. As you work through the examples for these symmetries, consider how they're similar to the spherical examples you've just seen. The application of Gauss's law works just the same, but now there's a different expression for the flux on the left-hand side, and calculations of enclosed charge are different.

Line Symmetry

A charge distribution has line symmetry when its charge density depends only on the perpendicular distance r from a line, called the *symmetry axis*. Symmetry then requires that the field point radially and that the field magnitude depend only on distance from the axis. It also requires the charge distribution to be infinitely long, so there's no variation parallel to the line. That's impossible, but nevertheless the infinite line is a reasonable approximation to elongated structures like wires. The next two examples explore the application of Gauss's law to line symmetry.

EXAMPLE 21.4 Gauss's Law: An Infinite Line of Charge

Worked Example with Variation Problems

Use Gauss's law to find the electric field of an infinite line charge carrying charge density λ in coulombs per meter.

INTERPRET An infinite line has line symmetry, so we can apply Gauss's law to find the electric field.

DEVELOP Symmetry requires that the field point radially from the line of charge and that its magnitude be the same at a given distance r from the line. Our job is to find a Gaussian surface that exploits this symmetry—a surface on which the surface integral will turn into a simple product of the field magnitude E and the surface area A. We've sketched an appropriate surface in Fig. 21.17: It's a cylinder of radius r and length L, concentric with the line charge. All points on the cylinder's curved surface are the same distance r from the line charge, so the field magnitude E is the same over the curved part of the surface. And because the field must be radial, the angle between $\vec{E}$ and the normal vectors $d\vec{A}$ is zero, making $\cos\theta$ equal to 1 in the dot product $\vec{E}\cdot d\vec{A}$.

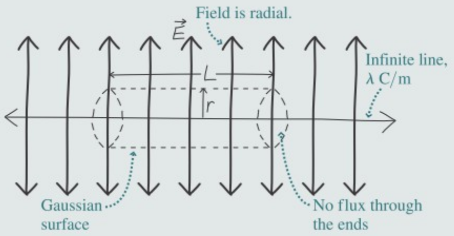

FIGURE 21.17 A cylindrical Gaussian surface surrounds a line charge. The sketch shows a slice in the plane of the page; the field extends radially outward from the line into and out of the page as well.

EVALUATE

- We begin with the left-hand side of Gauss's law, the flux through our Gaussian surface. Unlike the spherical case, this Gaussian surface has two different types of regions—the curved part of the cylinder and its circular ends. For the curved part, we've just seen that $\cos\theta = 1$ in the dot product, so the flux through the curved part becomes $\int \vec{E}\cdot d\vec{A} = \int E\,dA = E\int dA$, where the last equality follows because the magnitude E doesn't change over the curved part of the cylinder. Note that we took the circle off the integral sign because we're just considering the curved part, which alone doesn't constitute a *closed* surface. The remaining integral is just the area of the curved part of the cylinder. Imagine unrolling this curved surface and flattening it out: You'd get a rectangle of length L and width equal to the circumference $2\pi r$, so the flux through the curved part becomes $\Phi = 2\pi rLE$. What about the ends? No field lines emerge from them, so here the flux is zero; mathematically, $\vec{E}\cdot d\vec{A} = 0$ on the ends because the field $\vec{E}$ and the vectors $d\vec{A}$ normal to the ends are perpendicular. The left-hand side of Gauss's law, then, is $2\pi rLE$. This result depends only on the symmetry, so it applies in all situations involving line symmetry.
- Next we need the enclosed charge. The line carries λ C/m and our Gaussian cylinder encloses L meters of the line, so $q_{\text{enclosed}} = \lambda L$.
- Finally, we invoke Gauss's law by equating the flux Φ to $q_{\text{enclosed}}/\epsilon_0$. The result, $2\pi rLE = \lambda L/\epsilon_0$, solves to give

$$E = \frac{\lambda}{2\pi\epsilon_0 r} \quad \text{(field of a line charge)} \tag{21.6}$$

ASSESS Make sense? We worked this same problem in Example 20.7 in a much more difficult calculation involving a complicated integral. Since $1/2\pi\epsilon_0 = 2k$, our result here is the same. But Gauss's law makes the problem much easier!

Although Example 21.4 involved an infinitesimally thin line of charge, you can see from Fig. 21.18 that our result must hold *outside* any charge with line symmetry. And, as we argued in Example 20.7, it's a good approximation for the field of any long, cylindrical structure as long as we're not too near its ends.

Our two examples of line symmetry correspond, respectively, to the case of a point charge and a hollow spherical shell in spherical geometry. In Example Variation 42 you can explore the cylindrical analog of Example 21.3's solid sphere of charge.

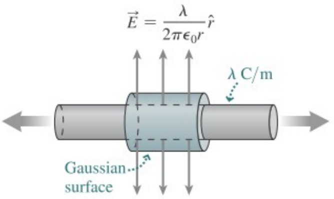

FIGURE 21.18 The arguments of Example 21.4 apply outside *any* cylindrical charge distribution.

EXAMPLE 21.5 Gauss's Law: A Hollow Pipe

A thin-walled pipe 3.0 m long and 2.0 cm in radius carries a net charge $q = 5.7\ \mu\text{C}$ distributed uniformly over its surface. Find the electric field both 1.0 cm and 3.0 cm from the pipe axis, far from either end.

INTERPRET Although the pipe has finite length, both distances are small compared with that length, so we can approximate the pipe as an infinitely long structure with line symmetry.

DEVELOP With line symmetry the appropriate Gaussian surface is a cylinder coaxial with the pipe. We've drawn two such cylinders in Fig. 21.19, one for each radius where we're asked to evaluate the field.

EVALUATE

- We showed in Example 21.4 that the flux integral in line symmetry gives $\Phi = 2\pi rLE$.

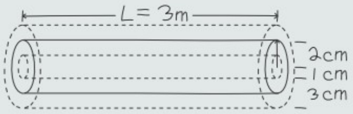

FIGURE 21.19 Gaussian surfaces for Example 21.5.

- Next we need the enclosed charge. At 3 cm we're outside the pipe, so the Gaussian surface with this radius encloses all the charge: $q_{\text{enclosed}} = 5.7\ \mu\text{C}$. The pipe is hollow, so at 1 cm the enclosed charge is zero.
- Equating the flux to $q_{\text{enclosed}}/\epsilon_0$ and solving for E give

$$E = \frac{q_{\text{enclosed}}}{2\pi\epsilon_0 rL} = \frac{5.7\ \mu\text{C}}{(2\pi\epsilon_0)(3.0\times10^{-2}\ \text{m})(3.0\ \text{m})} = 1.1\ \text{MN/C}$$

for the field at 3 cm and $E = 0$ for the field inside the pipe.

ASSESS Make sense? *Inside* the pipe, there's no field, and for the same reason as inside a uniformly charged hollow sphere—namely, that fields from near and far parts of the pipe cancel due, ultimately, to the inverse-square law. Again, be careful: That result follows because of the symmetry, although we'll soon see that with *conducting* pipes and shells there's no interior field even without that symmetry. We argued earlier that the field *outside* any line-symmetric distribution should be given by Equation 21.6, $E = \lambda/2\pi\epsilon_0 r$. In our result, the quantity q_{enclosed}/L is the line charge density λ, so our result is indeed consistent with that equation.

Plane Symmetry

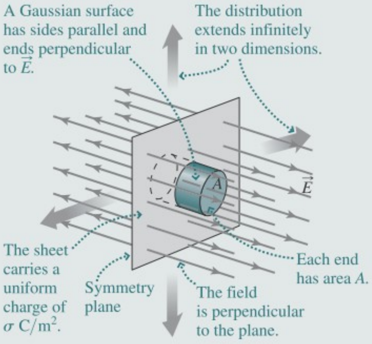
A charge distribution has plane symmetry when its charge density depends only on the perpendicular distance from a plane. The only electric-field direction consistent with this symmetry is perpendicular to the plane. As with line symmetry, true plane symmetry implies a charge distribution that's infinite in extent. That's impossible—but plane symmetry remains a good approximation when charge is spread uniformly over large, flat surfaces or slabs. The next example applies Gauss's law to plane symmetry.

EXAMPLE 21.6 Gauss's Law: A Sheet of Charge

An infinite sheet of charge carries uniform surface charge density σ in coulombs per square meter. Find the resulting electric field.

INTERPRET Since the sheet is infinite, we have plane symmetry with the sheet itself as the symmetry plane.

DEVELOP We need a Gaussian surface chosen so the flux integral $\oint \vec{E}\cdot d\vec{A}$ reduces to a simple multiplication, at least over some parts of the area; over any remaining parts it should be zero. Because the electric field must be perpendicular to our charged sheet, *any* surface with ends parallel to the sheet will have $\cos\theta$ equal to 1 in the dot product. Also, the symmetry dictates that E can't change as we move in a direction parallel to the sheet, since we'd remain the same distance from it. Furthermore, any surface whose sides are perpendicular to the charged sheet will have zero flux through the sides. So we're free to choose for our Gaussian surface any surface with ends parallel to the sheet and sides perpendicular. To ensure that E has the same value over both ends of our surface, we'll have it extend equal distances on either side of the charged sheet. A simple surface that meets these criteria is a cylinder that straddles the charged sheet, as shown in Fig. 21.20.



A Gaussian surface has sides parallel and ends perpendicular to $\vec{E}$.
The distribution extends infinitely in two dimensions.
A
$\vec{E}$
The sheet carries a uniform charge of σ C/m^2.
Symmetry plane
Each end has area A.
The field is perpendicular to the plane.

FIGURE 21.20 An infinite sheet of charge, with a Gaussian surface straddling the sheet.

EVALUATE

- First we evaluate the flux through our Gaussian cylinder. The field is parallel to the sides, so there's no flux contribution here. Then the total flux is through the ends, each of which has area A. Since the field is uniform over each end and perpendicular to the ends, the flux through each end is EA. So the total flux through both ends is $\Phi = 2EA$. This result is independent of the details of the charge distribution, so it holds in all cases of plane symmetry.
- Next we need the enclosed charge. The Gaussian surface encloses an area of the sheet equal to the area A of its ends. With surface charge density σ on the sheet, the enclosed charge is $q_{\text{enclosed}} = \sigma A$.
- Now we apply Gauss's law, equating the flux to $q_{\text{enclosed}}/\epsilon_0$. Thus $2EA = \sigma A/\epsilon_0$, so

$$E = \frac{\sigma}{2\epsilon_0} \quad \text{(field of a charged sheet)} \tag{21.7}$$

The direction of this field on either side of the sheet is outward from the sheet if it's positively charged and inward if negative.

ASSESS Make sense? With an infinite plane, symmetry requires that the field lines be perpendicular to the plane. So they don't spread out, and that means the field doesn't vary with distance—as Equation 21.7 shows because it doesn't involve the distance from the sheet. Although our result is exact only for a truly infinite sheet, it's a good approximation near any large, flat, uniformly charged surface as long as we're not close to an edge.

21.5 Fields of Arbitrary Charge Distributions

LO 21.5 *Approximate electric fields of general charge distributions using what you know about simpler distributions.*

Although Gauss's law is always true, most charge distributions lack the symmetry needed to apply Gauss's law to find the field. The alternative, Coulomb's law, is hard to use in all but the simplest cases. But we can often learn a lot by considering the distributions whose fields we calculated here and in Chapter 20. Figure 21.21 summarizes

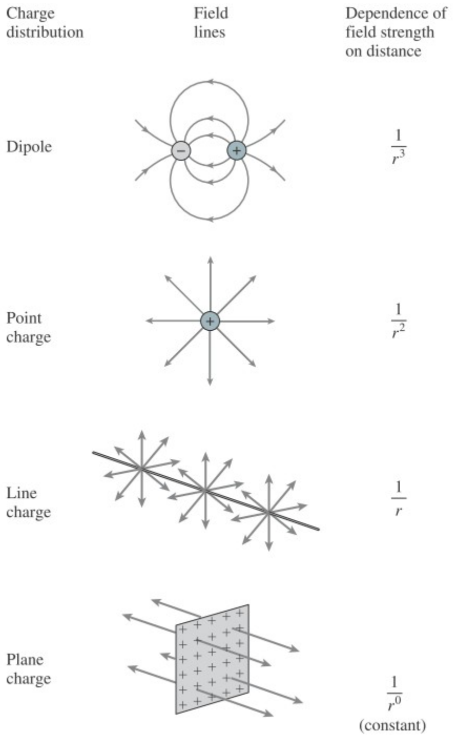


FIGURE 21.21 Electric fields of a dipole, a point charge, a charged line, and a charged plane.

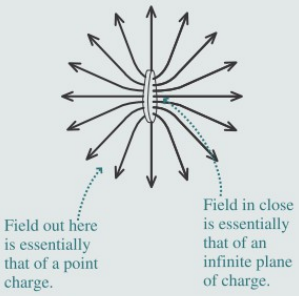
CONCEPTUAL EXAMPLE 21.1 A Charged Disk

Sketch some electric field lines for a uniformly charged disk, starting at the disk and extending out to several disk diameters.

EVALUATE When we're near the disk and not close to its edge, the disk looks like a large, flat, charged plane. Its field is essentially the uniform field of an infinite plane charge, so we draw straight field lines emanating perpendicular to the disk. Far from *any* finite distribution carrying a nonzero net charge, the field approximates that of a point charge, so farther away we draw field lines going radially outward. Field lines begin only on charges—in this case on the charged disk—so we have to connect close-in and far-out lines. We don't know exactly how the field looks in the intermediate region either close to or far from the disk, so we connect them as best we can. Figure 21.22 is the result.

ASSESS Our sketch is a good approximation to the field of a charged disk. And it obeys Gauss's law because the same number of field lines—namely, all 16 lines we chose to draw—cross any closed surface surrounding the entire disk.



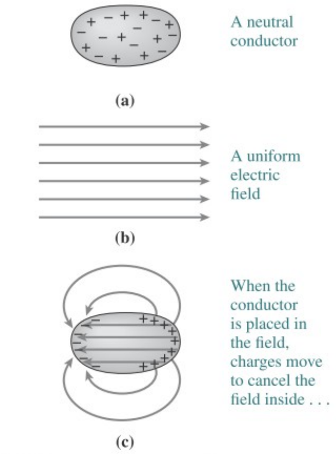
Field out here is essentially that of a point charge.
Field in close is essentially that of an infinite plane of charge.

FIGURE 21.22 The electric field of a charged disk.

MAKING THE CONNECTION Suppose the disk is 1.0 cm in diameter and carries charge 20 nC spread uniformly over its surface. Find the electric field strength (a) 1.0 mm from the disk surface and (b) 1.0 m from the disk.

EVALUATE (a) Close to the disk, assuming we're not near the edge, Equation 21.7 applies: $E = \sigma/2\epsilon_0 = 14\ \text{MN/C}$, where we used the total charge and the disk area to get the surface charge density σ. (b) At 1 meter, the disk is so small it looks essentially like a point charge, so Equation 20.3 applies: $E = kq/r^2 = 180\ \text{N/C}$.

four of these fields. For the last three, note the simple relation between the number of dimensions and the behavior of the field. The plane has two dimensions, and its field doesn't decrease with distance. The line has one dimension, and its field decreases as $1/r$. The point has no dimensions, and its field falls as $1/r^2$. In a sense, the dipole continues this progression. It consists of opposite point charges whose effects nearly cancel; no wonder its field decreases faster still, as $1/r^3$. In fact, there's a hierarchy of charge distributions whose fields decrease ever faster, as dipoles nearly cancel dipoles, and so on. Scientists and engineers use this hierarchy in modeling charged structures ranging from molecules to radio antennas.



A neutral conductor

(d)

FIGURE 21.23 A conductor in a uniform electric field.

GOT IT? **21.5** (1) If you're close to a *finite* line of charge (and not near its ends), does its field vary as (a) $1/r^3$, (b) $1/r^2$, or (c) $1/r$? (2) Repeat for the case when you're far from the line (i.e., much farther than its length).

21.6 Gauss's Law and Conductors

LO 21.6 *Describe electrostatic equilibrium in conductors and use Gauss's law to determine electric fields associated with charged conductors.*

Electrostatic Equilibrium

We've defined conductors as materials that contain free charges, like the free electrons in metals. Figure 21.23 shows what happens when an electric field is applied to a conductor. Free charges respond to the electric force $q\vec{E}$ by moving—in the direction of the field if they're positive, opposite the field if negative. The resulting charge separation gives rise to an electric field within the material that's opposite to the applied field. As more charge

Pág. 416 (51)

I've found that the left-hand side of Gauss's law - the flux - is given $4\pi r^2 E$ whenever we have spherical symmetry and are using a spherical Gaussian surface.

(iii). In E^3 the point $k(K)$ is the centroid of the Gauss curvature of the boundary of K (Gericke [2]). The geometric properties of $k(K)$ in higher dimensions do not seem to have been investigated.

Another problem which seems to be open is whether (in the plane, or in higher dimensions) $k(K)$ is the only s.i. point satisfying (iii).

The additivity of $k(K)$ is of interest in connection with certain properties of some similarity invariant measures of symmetry (see §§ 4, 5, 6). Considering the related properties of affine invariant measures of symmetry, one is naturally led to the question whether there exist a.i. points $p(K)$ with the additivity property (iii). The negative answer follows at once from the following remarks.

(a) The only a.i. point of a triangle, or a square, is its centroid $g(K)$.

(b) Let $T_{\alpha,\beta}$, $T_{\beta,\alpha}$ and $K_{\alpha+\beta}$ denote the sets represented in Figure 2. Obviously $T_{\alpha,\beta} + T_{\beta,\alpha} = K_{\alpha+\beta}$ and therefore, if $p(K)$ had property (iii), we would have $p(K_{\alpha+\beta}) = ((\alpha + \beta)/3; (\alpha + \beta)/3)$. When $\alpha \to 0$ then $p(K_{\alpha+\beta}) \to (\beta/3, \beta/3)$ while $K_{\alpha+\beta}$ tends to a square S for which $p(S) = (\beta/2, \beta/2)$.

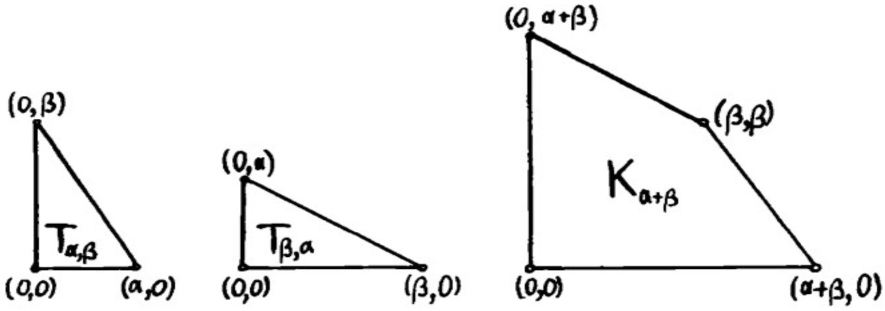

FIGURE 2

Open, and more difficult, is the question whether there exists an a.i. *set* $p(K)$ (with $p(K)$ not identical with K) which satisfies (iii), or the weaker property

$$p(K + K') \supset p(K) + p(K') .$$

If K is a convex body such that there exists a group of affine maps of K onto itself which leave one and only one point of K fixed, then obviously all the a.i. points of K coincide (with that fixed point). Similarly for s.i. points. This implies, in particular, that centrally symmetric sets, and simplices, have a unique a.i. point, an observation which may be used to compute the value of some measures of symmetry for simplices (see, e.g., Fáry-Rédei [1]). The question whether the converse of the above statement is true seems to be open. The same holds for the following problems.

If K is a convex body let K^0 denote the set of all points of E^n (individually) fixed under every affine map of K onto itself. Is the family of all a.i. points

$p(K)$ big enough to ensure $K^0 = \{p(K)\}$? In particular, if $K^0 = E^n$, is $\{p(K)\} = E^n$?

Given a.i. points $p_i(K)$ or K, $1 \leqq i \leqq m$, and reals α_i with $\sum_{i=1}^{m} \alpha_i = 1$, then the combination $\sum_{i=1}^{m} \alpha_i p_i(K)$ is another a.i. point of K. Does there exist, among all the a.i. points of K, a finite "basis" such that each a.i. point is a combination of them?

The same types of problems arise with respect to s.i. points of K.

An additional set of problems is exemplified by the following. For every convex body $K \in \mathfrak{K}^2$, with centroid g and circumellipse-center c, it is easy to show that $g + 2(c - g) \in K$; on the other hand, it is easy to verify that for the set K on Figure 3, $g + 6(g - c) \in K$. What is the greatest interval $[\alpha, \beta]$ such that for every $\lambda \in [\alpha, \beta]$ and every $K \in \mathfrak{K}^2$ the relation $g + \lambda(g - c) \in K$ holds?

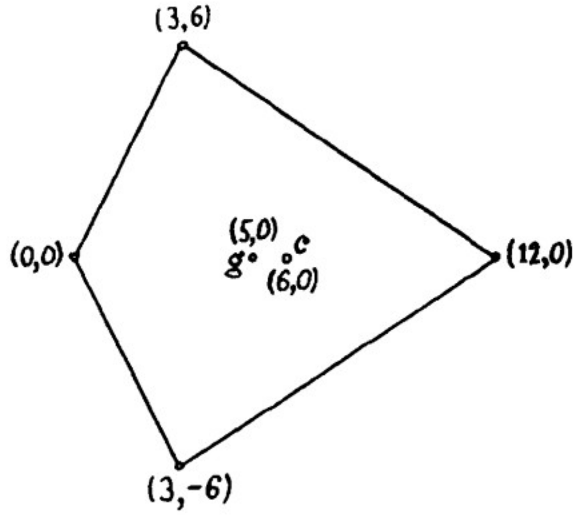

FIGURE 3

A similar problem was suggested by Fenchel (see Pál [1]): In a convex set $K \in \mathfrak{K}^2$ of diameter 1, how far can the centroid of K be from the center of the circumcircle? A partial answer was given by Pál [1]; for a related problem, and an improvement of Pál's result, see Grünbaum [7].

3.3. The most important a.i. and s.i. points considered in the literature are the centroids (centers of gravity) of different mass-distributions related to geometric properties of convex bodies.

(i) The *centroid* $g = g(K)$ of a convex body $K \in \mathfrak{K}^n$ is the centroid of a homogeneous distribution of mass throughout the convex body K. A summary of older results on the properties of the centroid $g(K)$ is given by Bonnesen-Fenchel [1, p. 53]. It would lead us too far to attempt to summarize here the more recent results on this subject (see, however, pp. 249 and 255 for some open problems).

(ii) The *surface-area centroid* $a(K)$ of a convex body $K \in \mathfrak{K}^n$ is the centroid of a homogeneous distribution of mass on the boundary of K. The surface-area centroid received much less attention than $g(K)$. Of the relevant results, not contained in Bonnesen-Fenchel [1], one should mention those by Bose and Roy (published in a series of papers in Bull. Calcutta Math. Soc., starting with Bose-Roy [1]) which generalize and unify many previously known theorems. It seems quite certain that the results of Bose and Roy are susceptible to far-reaching generalizations.[3]

A problem, representative of a whole class of questions about whose solutions nothing seems to be known, is the following. Does there exist, for each convex body $K \subset E^n$, a nonsingular affine transformation T of E^n onto itself such that $a(T(K)) = g(T(K))$?

(iii) The curvature centroid $k(K)$ of a plane convex body K is the centroid of a mass-distribution on the boundary of K, with density proportional to the curvature. (See p. 238 for further properties.) For convex bodies in E^n there are $n-1$ analogs of $k(K)$; very little seems to be known about their properties.

3.4. The circumellipsoid-center $c(K)$ and inellipsoid-center $i(K)$. It is well known that for each convex body $K \in \mathfrak{K}^n$ there exists a unique ellipsoid of minimal volume containing K,—the Löwner-ellipsoid of K. Its center $c(K)$ is an a.i. point of K. The existence of the Löwner-ellipsoids was established by different authors (Behrend [1; 2] for $n = 2$; in the general case, John [1], Danzer-Laugwitz-Lenz [1], Zaguskin [1]).

In a sense dual to Löwner's ellipsoid is the unique ellipsoid of maximal volume contained in the convex body $K \in \mathfrak{K}^n$. This ellipsoid was considered by Behrend [1; 2] for $n = 2$, and by Danzer-Laugwitz-Lenz [1] and Zaguskin [1] for all n. Its center $i(K)$ is an a.i. point of K.

Of considerable interest is the following theorem, first established by John [1] (see also Leichtweiss [2]): For each [centrally symmetric] convex body $K \in \mathfrak{K}^n$ there exists an ellipsoid $E \subset K$ such that the concentric ellipsoid E^*, homothetic to E in the ratio n [resp. $\sqrt{n}$] contains K. If K is not a simplex, the minimal ratio is less than n. (In other words, the d_1 distance (see § 2) of the ball B^n to any element of $\mathfrak{K}^n$ is $\leq \ln n$, while the distance of B^n to any centrally symmetric element of $\mathfrak{K}^n$ is $\leq \ln \sqrt{n}$. See also § 7.)

It is well known (see John [1], Leichtweiss [2]) that the Löwner-ellipsoid of K may be taken for E^* in John's theorem. On the other hand, it is an easy exercise in analytic geometry to prove that the ellipsoid of maximal volume contained in K verifies John's theorem if taken as E. This remark obviously implies the statements about F_1^c and F_1^i (on p. 247).

3.5. The following two a.i. sets should be considered in connection with measures of symmetry of convex bodies in the plane.

(i) The set of *six-partite points* $s(K)$. R. C. Buck and E. F. Buck [1] called *six-partite point* of K each point s with the property that there exist three straight lines through s such that each of the six wedges determined by them contains 1/6 of the area of K. The existence of at least one six-partite point follows from simple continuity arguments applicable not only to the partition of the area of a convex body, but also to the partition of an arbitrary, continuous, distribution of non-negative masses; with a slight change in the definition ("each of the six closed wedges contains at least 1/6 of the total mass") it applies to arbitrary distributions of non-negative masses. Six-partite points, and some of their properties, have been considered by Yaglom-Boltyanskii [1], Eggleston [2; 3; 5], Newman [1].

---

[3] See Note 3 on p. 264.

A convex set may have more than one six-partite point (Eggleston [3, p. 126]); no characterization of convex bodies with a unique six-partite point, or of sets which may serve as the set of all six-partite points of a convex body, seem to be known.

No generalizations of the notion of six-partite points to higher dimensions have been established; for some problems in this direction see Grünbaum [3].

One analogous notion seems to deserve mention. In the plane, for each continuous mass-distribution there exists at least one pair of mutually perpendicular straight lines such that each of the four wedges contains 1/4 of the total mass. Does this generalize in any way to mass-distributions in E^n and to the 2^n wedges formed by n concurrent hyperplanes? The problem seems to be open even for E^3. The only known result is that of Zindler [1]: For every convex body $K \in \mathfrak{K}^3$ and for every plane P_1 bisecting the surface-area of K, there exist planes P_2 and P_3 such that each of the eight wedges determined by P_1, P_2, P_3 contains 1/8 of the surface area of K.

(ii) The set of *hexagonal points* $h(K)$. An affine-regular hexagon is the image of a regular hexagon under a nonsingular affine transformation. Simple continuity arguments prove that each convex body $K \in \mathfrak{K}^2$ admits at least one inscribed affine-regular hexagon (i.e., such that its vertices belong to the boundary of K). This result was established by very many authors, usually as a lemma needed for other results in the geometry of numbers or Minkowski spaces; see Besicovitch [1], Fáry [1], Laugwitz [1], Rešetnyak [1] for typical applications. The center of any affine-regular hexagon inscribed into K is called a hexagonal point $h(K)$ of K. The set of all hexagonal points of K is an a.i. set of K. For a centrally symmetric convex body $K \in \mathfrak{K}^2$, each boundary point of K is the vertex of at least one inscribed affine-regular hexagon. (For further results on inscribed affine-regular hexagons and other regular or affine-regular sets see, e.g., Asplund-Grünbaum [1], Böhme [1], Eggleston [4], Grünbaum [1], Kelly [1], Pucci [1].)

No characterization of convex sets with exactly one inscribed affine-regular hexagon, or of those with only one hexagonal point, seems to be known; the set of all hexagonal points may be a 1-dimensional continuum, but the general nature of such sets is still undetermined.

Another unsolved problem, whose affirmative solution would probably be of interest in various branches of combinatorial geometry, is as follows. The affine-regular hexagon is the vector sum of a triangle and its negative. In analogy with the above, does there exist for each convex body $K \in \mathfrak{K}^n$ at least one inscribed "hyper-hexagon" (i.e., vector sum of a simplex and its negative)? The question is open even in E^3, where the "hyper-hexagon" is a nonsingular affine transform of the Archimedean "cubooctahedron."

It should be mentioned that for circumscribed affine-regular hexagons results completely analogous to those mentioned above hold (L. Danzer, oral communication; it seems that these results are not to be found in the literature). In the same way, the results (Böhme [1], Grünbaum [1]) on inscribed affine-regular pentagons and octagons have their analogues for circumscribed ones.

Another direction which seems to be completely unexplored is that of existence of inscribed affine-regular hexagons (and similar sets) into arbitrary closed Jordan curves.

4. A property of some measures of symmetry. In trying to find additional conditions which are to be satisfied by a function in order to qualify for the name "measure of symmetry," the following property was accepted as "reasonable" by quite a few of the people we consulted.

"The addition of a 'more' symmetric set to a 'less' symmetric one should not decrease the measure of symmetry of the latter set."

More precisely, this "superminimality" condition is: For all $K_1, K_2 \in \mathfrak{K}^n$,

$$f(K_1 + K_2) \geqq \min\{f(K_1), f(K_2)\} . \tag{*}$$

Though an "objective" justification for imposing, or trying to impose, this condition is missing (and seems rather likely to remain so), the intuitive appeal of (*) seems to be sufficient to explain our interest in it. One's enthusiasm is likely to cool off somewhat after noticing that such intuitively "right" measures of symmetry as that of Kovner-Besicovitch (see § 6) fail to have the superminimality property.

We feel that, despite this, the superminimality is of more than marginal interest. Our enlarging on it is due mostly to the fact that (*) is stringent enough to insure that every measure of symmetry (as defined by conditions (1) to (4) in § 1) satisfying it has at least a certain resemblance to the intuitive notion of a measure of symmetry. More precisely, the following theorem holds:

(A) *For every affine [similarity] invariant measure of symmetry for* $\mathfrak{K}^2$ *which satisfies* (*) *we have* $\min\{f(K)\colon K \in \mathfrak{K}^2\} = f(\textit{simplex})$ [*resp.* $\inf\{f(K)\colon K \in \mathfrak{K}^2\} = \inf\{f(T)\colon T \textit{ a simplex } \subset E^2\}$].

Theorem (A) is an immediate consequence of

(B) *Every convex body in* E^2 *is the limit* (*in the Hausdorff metric*) *of finite*

9.8. Order-convexity. A set K in a partially ordered space is *order-convex* provided $y \in K$ whenever $x, z \in K$ with $x < y < z$. For results on extreme points and convex hulls with respect to order-convexity, see Franklin [1]. Apparently the literature contains no results of Helly-type about order-convexity in general partially ordered linear spaces, though in any *linearly* ordered space the family of all order-convex sets is intersectional and has Helly-number 2.

9.9. Metric convexity. The usual definition of metric convexity is due to Menger [1]: A set K in a metric space (M, ρ) is *metrically convex* if for each pair of distinct points $x, z \in K$ there exists a point $y \in K$, different from x and z, such that $\rho(x, z) = \rho(x, y) + \rho(y, z)$. When K is not only convex but also metrically complete, then the points x and z of K must lie in a subset of K which is isometric with a linear interval of length $\rho(x, z)$. A closed subset of E^n (or of any strictly convex Banach space) is metrically convex if and only if it is convex in the usual sense. For geodesic distance on the sphere S^n, a closed set is metrically convex if and only if it is weakly convex in the sense of 9.1.

For various geometric developments involving Menger's and other closely related notions of metric convexity, see Blumenthal [3], Busemann [2], Pauc [1], Aronszajn-Panitchpakdi [1], and references listed by these authors. A theorem of Whitehead [1] asserts that for any point p of a Riemannian manifold with positive definite metric, all sufficiently small "spherical" neighborhoods of p are metrically convex in a rather strong sense. This result was sharpened by Nijenhuis [1].

Several authors have studied the relationship between the topological structure of a metrizable space and the existence of a convex metric compatible with the given topology. Menger [1] asked whether every continuous curve admits a convex metric, and after several partial results the problem was finally settled affirmatively by Bing [1]. See Bing [1; 2; 3], Plunkett [1], and Lelek-Nitka [1] for this and related results and references.

In order to extend some of his selection theorems, Michael [1] formulated the notion of a *convex structure* on a metric space, describing a situation in which, as in a Riemannian manifold, it is meaningful to form "convex combinations" of certain (but not necessarily all) k-tuples of points in the space. For another metric notion related to convexity, see Michael [2].

Danzer [2; 3; 4] formulates and applies yet another concept of convexity in metric spaces. For each pair x and z of distinct points of M, let $H(x, z) = \{y \in M : \rho(x, y) < \rho(y, z)\}$. Such a set is called a *halfspace*, and a set is called convex provided it is an intersection of halfspaces. This is closely related to Leibniz's idea (see Busemann [1]) of defining a plane as the set of all points equidistant from two given points. From results of Busemann [1] it follows that when (M, ρ) is a normed linear space with metric generated by the norm, then the closed Danzer-convex sets in M are all metrically convex (in the sense of Menger) only when (M, ρ) is an inner-product space. Sets of the form $\{y \in M : \rho(x, y) = \rho(y, z)\}$ are studied also by Kalisch and Straus [1].

Defining the convex hull of a set as the intersection of all halfspaces containing it, Danzer [5] proves that in a metric space, *any family of spherical cells having nonempty intersection covers the convex hull of the set of its centers.* This was the principal tool in his proof of 7.12 above.

9.10. Convexity in topological groups. Though another approach to convexity in topological groups has been formulated by Ghika [4; 5], we consider here only the approach of Rådström [1; 2]. Let G be a topological group and 2^G the class of all nonempty subsets of G. A *one-parameter semigroup of subsets of G* is defined by Rådström [2] to be a biunique mapping A of $]0, \infty[$ into 2^G such that $A(\delta_1 + \delta_2) = A(\delta_1) + A(\delta_2)$ for all $\delta_i \in]0, \infty[$, where the right-hand "+" indicates the usual addition of sets. Rådström [2] proves the following, suggested by the observation that in E^n, "high powers of small sets are in some sense almost convex": *In a locally convex Hausdorff linear space, the one-parameter semigroups of compact sets are exactly those of the form $A(\delta) = f(\delta) + \delta K$, where f is a one-parameter semigroup of points and K is a compact convex set.*

In Rådström's earlier paper [1], a slightly different definition of one-parameter semigroup leads to the conclusion that in R^n, the one-parameter semigroups of sets are exactly those of the form $A(\delta) = \delta K$ for compact convex K. This suggests that in an arbitrary topological group G, one might define convex sets in terms of the one-parameter semigroups, or at least that these semigroups may play a role similar to that played by convex sets in R^n. Rådström [1] shows that if G is a Lie group, then every one-parameter semigroup of subsets of G has, in a sense, an infinitesimal generator which is a convex set.

9.11. Complex convexity. We turn finally to the generalized convexity which plays such an important role in the theory of functions of several complex variables. This generalizes simultaneously the notions of convex set and convex function, with striking parallelism between the real and complex theories. (Of course they differ in details of proof, the complex theory being much more difficult in some respects.) See Bremermann [1; 2; 3] for an excellent description of this parallelism and for references to other work in the field. In particular, Bremermann [1] supplies a "real-complex dictionary" with the following translation of terms:

Real

linear function of one real variable
convex function of one real variable
convex function of n real variables
convex region in R^n

Complex

harmonic function of one complex variable
subharmonic function of one complex variable
plurisubharmonic function of n complex variables
region of holomorphy in C^n (the space of n complex variables).

20211014(cont.)|||

The geometric properties of k(K) in higher dimensions do not seem to have been investigated.

Pág.161(173) – 9.9 Metric convexity

A theorem of Whitehead [1] asserts that for any point p of a Riemannian manifold with positive definite metric, all sufficiently small "spherical" neighborhoods of p are metrically convex in a rather strong sense.

This result was sharpened by Nijenhuis [1]. (Nijenhuis)

A. Isometric embedding of surfaces. An important well-known question is to characterize those intrinsic metrics on a surface which can be realized as embeddings into three space. Minkowski made the first major progress on this problem by proving that any convex polyhedron can be so realized [**148**]. For smooth surfaces with positive curvature, this problem is called the Weyl problem, since Weyl found the first significant estimate for the problem [**216**]. H. Lewy solved the problem in the real analytic category [**120**], and Pogorelov [**165**] and Nirenberg [**158**] solved it in the smooth category. There is also recent work by P. Gaun and Y.Y. Li [**83**].

An important reason that the Weyl problem can be solved is that its solutions must be unique a theorem due to Cohn-Vossen [**46**] and Pogorelov [**164**]. Uniqueness here means that any isometric embedding of the surface is related to any other by a rigid motion in three space. Such global rigidity is difficult to prove for nonconvex surfaces. A.D. Alexandrov studied the next easiest case, namely, those surfaces for which the integral of the positive part of the curvature is 4π [**1**]. He could only prove the rigidity for real analytic metrics. Nirenberg made a beautiful attempt to settle the smooth case [**159**]. Nirenberg's argument would succeed if one can prove that there is at most one closed asymptotic curve in the surface. It is still an outstanding question to understand the behavior of the asymptotic curves on a surface. They are of fundamental importance for the global isometric embedding problem for surfaces with negative curvature, as they are the characteristic curves for the isometric embedding problem. The isometric problem for surfaces of negative curvature is a very interesting nonlinear hyperbolic problem. As such, it is very difficult to prove global existence theorems for such surfaces. In fact, the celebrated Hilbert-Efimov theorem says that a complete surface with strongly negative curvature cannot be isometrically embedded into three-dimensional Euclidean space [**54**].

A significant existence theorem was proved by Hong [**96**], who assumes the curvature decays in the right way. It is a challenging problem to give a transparent and quantitative proof of Efimov's theorem. In other words, take a geodesic disk of radius r whose curvature is not greater than -1 and equal to -1 at the center. What is the largest r so that it can be embedded into $\mathbb{R}^3$ and the second fundamental form is bounded by a given constant?

Global rigidity is false for a general compact surface even when the metric is real analytic. However, an important outstanding problem in classical geometry is whether there exists a continuous family of isometric embeddings of compact surfaces in $\mathbb{R}^3$ which does not arise from rigid motions.

R. Connelly [**49**] and D. Bleecker [**15**] gave beautiful counterexamples to this rigidity conjecture among polyhedra. It is unlikely that those methods can be improved to give smooth examples. There should be (extrinsic) invariants for isometric motions of closed surfaces. Hopefully there are only a finite number of such invariants, so that the space of isometric motions is finite-dimensional. Bleecker's examples show that the volume enclosed by such surfaces is not an invariant. One should be able to generalize these polyhedral examples to piecewise-smooth examples and understand how the motions relate to the motions of the edges.

Also, Cohn-Vossen developed a theory of infinitesimal rigidity for closed surfaces [**47**]. The equation involved is linear and thus is easier to handle. But it is only elliptic if the curvature is positive. Hence for surfaces whose curvature changes sign, it is a difficult problem to understand the equation.

We know that there do exist nontrivial first order isometric deformations for some closed surfaces. The question remains how to characterize such surfaces. These are natural uniqueness questions for mixed-type equations on global surfaces.

Of course, we can also ask all the above questions for open surfaces. Cartan proved that every real analytic surface can be locally isometrically embedded into $\mathbb{R}^3$ [**35**]. The question for a smooth metric is much more difficult. It is an important theorem of C.S. Lin that smooth surfaces with nonnegative curvature can be locally isometrically embedded into $\mathbb{R}^3$ [**136**]. He also settled the problem when the gradient of the curvature is not zero [**137**]. It remains an open problem whether such an assumption can be dropped.

One can formulate a boundary value problem for isometric embeddings of compact surfaces with boundary in two different ways. One is the Neumann problem, which is to require the mean curvature of the boundary to be a given function H. (Clearly we require $H^2 \geq K$.) Of course, one may also require the image of the curve to be a subset of some surface. The other is the Dirichlet problem, which is to require the image of the boundary to be a given Jordan curve. In the first problem, if the curvature is positive, the mean curvature can be bounded and regularity can be guaranteed. In the latter problem, an important necessary condition on the given curve is that the length of its second fundamental form must dominate the geodesic curvature of the original boundary. Hong has made important progress on this problem [**95**].

For closed surfaces with no boundary in $\mathbb{R}^3$, there are many constraints on their intrinsic metrics. The first important constraint is that the curvature must be positive at one point and that $\int_\Sigma K^+ \geq 4\pi$, where $K^+ = \max(K, 0)$.

Nirenberg [**159**] proved that if $\int_\Sigma K^+ = 4\pi$, each component of the set $\{K < 0\}$ is bounded and tangential to parallel planes along two closed convex planar curves. The total geodesic curvature of each closed curve must be equal to 2π. This fact gives a constraint on metrics that can be isometrically immersed into $\mathbb{R}^3$. Is there any constraint on the topology of the sets $\{K > 0\}$ and $\{K < 0\}$ in general?

If Σ is embedded into $\mathbb{R}^3$, it bounds a domain Ω. It is interesting to relate the spectrum of Σ to the spectrum of Ω. A simple argument shows that the volume of Ω is bounded by $\frac{\sqrt{2}}{3}\text{Area}(\Sigma)\lambda_1^{-\frac{1}{2}}$, where λ_1 is the first eigenvalue of Σ. It follows from this statement and the work of Korevaar [**112**] that

$\frac{\mu_i(\Omega)^{3/2}}{\lambda_i(\Sigma)\sqrt{\lambda_1(\Sigma)}} \geq C_g > 0$, where $\mu_i(\Omega)$ is the i-th Dirichlet eigenvalue of Ω and $\lambda_i(\Sigma)$ is the i-th eigenvalue of Σ. Here C_g is a constant depending only on the genus of Σ. What is the optimal C_g and is there a surface that realizes such an optimal constant? Does the set $\{\mu_i(\Omega)\}$ determine $\{\lambda_i(\Sigma)\}$ and vice versa? If a surface Σ can be isometrically embedded into $\mathbb{R}^3$, the spectrum $\{\lambda_i(\Sigma)\}$ is probably constrained. What is the constraint? It is known that asymptotic behavior of $\{\lambda_i(\Sigma)\}$ is closely related to the dynamics of the geodesic flow of Σ. Is the dynamics of geodesic flow constrained? Since Σ cannot have curvature everywhere nonpositive, should the geodesic flow of a closed embedded surface Σ be nonergodic? If it is not ergodic, can one describe the invariant regions of the geodesic flow in terms of extrinsic geometry? What is the entropy of the flow?

B. Different geometries. One can study properties of surfaces that are invariant under a bigger group than the orthogonal group. There are the special linear group, the conformal group and the projective group each acting on $\mathbb{R}^3$. We can ask for properties of a surface Σ that are invariant under these groups. They are called affine, conformal and projective geometries respectively. Many interesting questions remain unanswered for these geometries.

For affine geometry, important invariants are the concepts of the affine metric (which is the second fundamental form divided by the fourth root of the Gaussian curvature) and the affine normal. When the affine normals of the surface focus to a point, the surface is called an affine sphere. Such surfaces were studied extensively by Calabi [**23, 24**], Calabi-Nirenberg [**26**] and Cheng-Yau [**39, 40**]. From these works, we know that for any convex cone, there is a complete affine sphere asymptotic to the cone. It would be very interesting to construct such an affine sphere efficiently. Can one find a representation in terms of pseudoholomorphic functions (see [**213**])? Recently, in his Harvard thesis, John Loftin discussed how to construct an affine sphere by a holomorphic section of the tricanonical line bundle of a Riemann surface. Are there many cases that such spheres can be written in closed form? (The surface $xyz = 1$ is asymptotic to the coordinate cone.) This is especially interesting when the cone is a polyhedral cone. Can we compute the affine metric in these cases? Of course, one asks the same question for higher dimensions, and it is related to the linear optimization problem [**106**].

Up to now, most of the progress assumes convexity of the surfaces. What happens if the surface has negative curvature? What are those affine spheres whose induced metrics are complete and have negative curvature?

There is a concept of an affine maximal surface, which is defined by a fourth-order elliptic equation (see e.g. [**25**]). One can therefore fix the boundary and the normal direction along the boundary for the surface. If we fix the boundary to be a triangle, is there an efficient way to solve the boundary value problem for the affine maximal surface? If we fix a polyhedron in $\mathbb{R}^3$, we can attempt to form a C^1-surface that passes through all the edges of the polyhedron so that in each face, the surface is affine maximal. Among all such C^1-surfaces, we can try to find one with maximum total affine area. Recently, Trudinger and Wang [**209**] solved the Bernstein problem for affine maximal surfaces. Hopefully, the future will bring more activities for affine maximal surfaces.

As we discuss in Cheng-Yau [**40**], the affine metric of the affine sphere in $\mathbb{R}^{n+1}$, after a Legendre transform, becomes a projective invariant metric on a convex domain in $\mathbb{R}^n$. It is therefore interesting to relate projective-invariant properties of surfaces in $\mathbb{R}^n$ to affine properties of hypersurfaces of the affine sphere in $\mathbb{R}^{n+1}$.

It is known that if a closed surface in $\mathbb{R}^3$ is infinitesimally (metrically) rigid, its image under a projective transformation is also infinitesimally rigid. Is the statement true for the global rigidity of a closed surface? Can one formulate the rigidity problem in terms of projective or affine geometry?

Algebraic surfaces in $\mathbb{RP}^3$ are clearly important surfaces. However, we know virtually nothing about them. There is some information about the number of their components. But their geometry is clearly special. The number of umbilical points, the number of closed geodesics, the number of closed asymptotic lines, the topology of the regions of positive curvature, and the eigenfunctions of the Laplacian are all interesting invariants related to the polynomials that define the surface. On the one hand, we have techniques and information that we learn from algebraic geometry. We can complexify the surfaces and obtain information related to the topology and the incidence relations among them. On the other hand, we want to understand the classical geometry of these surfaces using classical methods–partial differential equations or connections from real projective geometry. It will be important to bridge these two approaches. When we complexify the surfaces, in most cases, we can find a complete Kähler-Einstein metric with negative scalar curvature [**202**]. Since the metric is invariant under an anti-holomorphic involution, we have a canonical metric on the surface. (Canonical in the sense that if there is a nonsingular bijective projective linear map from one algebraic surface to another one, it is an isometry of the canonical metrics.) Some theorems on real algebraic varieties can be proved using the canonical metrics. How do we relate this canonical metric to the Euclidean metric induced on the surface?

In complex algebraic geometry, it is very important to understand algebraic curves in an algebraic manifold. What is the role of real algebraic curves in a real algebraic surface? What are the topology and geometry of these curves? How do we bound the number of components and the geodesic curvatures of the curves in terms of the degree of polynomials defining them?

Potentially, every closed surface can be approximated by a real algebraic surface of large degree. What is the minimal degree needed to approximate a given surface? In other words, given $\varepsilon > 0$, what is the minimal degree of an algebraic surface whose Hausdorff distance is less than ε from a given surface? Can one estimate it in terms of a suitable calculable geometric quantity of the surface (e.g., the L^2 norm of the mean curvature of the surface)? If we minimize the L^2 norm of the mean curvature of surfaces with degree less than a given integer, what kind of algebraic surfaces do we get?

Real algebraic surfaces provide a rich class of natural singularities. It is very interesting to study the behavior of the principal curvatures near singularities. The behavior of the eigenfunctions of the Laplacian near such points should also be very interesting.

When a surface is defined by a real algebraic set, there is a (singular) foliation attached to it. The study of such a continuous family should be very helpful in understanding the algebraic surface.

Conversely, if we have an algebraic one-form which defines a (possibly singular) foliation, it will be interesting to find the closed leaves and bound the number of such leaves. When are the leaves algebraic?

C. Minimal surfaces in $\mathbb{R}^3$. There are several important surfaces studied in the literature. Most of these are obtained by variational methods.

The first major class is minimal surfaces. These are surfaces with mean curvature equal to zero. When we are given a closed curve in $\mathbb{R}^3$, we look for surfaces bounded by this curve which minimize area. We can restrict the topology of these surfaces to be within certain classes. For example, we can assume all surfaces have genus g. Then the minimum of the area is a number A_g which may depend on the genus. In general, $A_g \geq A_{g+1} \geq \cdots$ [**145**]. When the boundary curve is smooth, it is a celebrated theorem of Hardt-Simon that for some g_0, $A_{g_0} = A_{g_0+1} = \cdots$ [**88**]. There is no effective estimate of g_0 and it will be challenging to find such an estimate.

It is not known whether a smooth simple closed curve in $\mathbb{R}^3$ can bound an infinite number of minimal surfaces. (If the curve is real analytic, this cannot happen (Tomi [**207**]).) Is there a general algorithm to find all minimal surfaces bounded by a given closed curve (or a set of closed curves)? It is still a difficult problem to calculate unstable minimal surfaces bounded by given curves. (There is also no efficient way to calculate area-minimizing surfaces.) It is not clear how big the genus of a stable or unstable minimal surface must be if it is bounded by a given set of smooth curves. Can it be arbitrarily large?

Many fundamental questions remain unsolved regarding the quantitative behavior of minimal surfaces. One well-known question is that of the best constant for the isoperimetric inequality, i.e., what is the best upper bound of $\frac{4\pi A}{L^2}$, where A is the area and L is the length of the boundary. Naturally one conjectures it to be 1. This is known if the boundary is a Jordan curve (see Li-Schoen-Yau [**128**]). This question is related to finding the best constant

the region. We shall always assume that our region is regular, so that the boundary is piecewise regular; for this theorem we orient the boundary *outward*.

Theorem 5.8.5 (Divergence Theorem). [17] *Suppose*

$$\vec{F}(x,y,z) = P(x,y,z)\vec{\imath} + Q(x,y,z)\vec{\jmath} + R(x,y,z)\vec{k}$$

is a $\mathcal{C}^1$ *vector field on the regular region* $\mathfrak{D} \subset \mathbb{R}^3$.

Then the flux integral of $\vec{F}$ *over the boundary* $\partial\mathfrak{D}$*, oriented outward, equals the (triple) integral of its divergence over the interior of* $\mathfrak{D}$:

$$\iint_{\partial\mathfrak{D}} \vec{F} \cdot d\vec{S} = \iiint_{\mathfrak{D}} \operatorname{div}\vec{F}\, dV. \tag{5.33}$$

The proof of this theorem is given in Appendix A.12

We note that, as in the case of Green's Theorem, we can extend the Divergence Theorem to any region which can be partitioned into regular regions.

It can also be extended to regular regions with "holes" that are themselves regular regions. For example, suppose $\mathfrak{D}$ is a regular region and $B_\varepsilon\left(\overrightarrow{x_0}\right)$ is a ball of radius $\varepsilon > 0$ centered at $\overrightarrow{x_0}$ and contained in the interior of $\mathfrak{D}$ (that is, it is inside $\mathfrak{D}$ and disjoint from its boundary). Then the region $\mathfrak{D} \setminus B_\varepsilon\left(\overrightarrow{x_0}\right)$ consisting of points in $\mathfrak{D}$ but at distance at least ε from $\overrightarrow{x_0}$ is "$\mathfrak{D}$ with a hole at $\overrightarrow{x_0}$"; it has two boundary components: one is $\partial\mathfrak{D}$, oriented outward, and the other is the sphere of radius ε centered at $\overrightarrow{x_0}$, and oriented *into* the ball. Suppose for a moment that F is defined inside the ball, as well. Then the flux integral over the boundary of $\mathfrak{D} \setminus B_\varepsilon\left(\overrightarrow{x_0}\right)$ is the flux integral over the boundary of $\mathfrak{D}$, oriented outward, *minus* the flux integral over the boundary of the ball (also oriented outward). The latter is the integral of $\operatorname{div}\vec{F}$ over the ball, so it follows that the flux integral over the boundary of $\mathfrak{D} \setminus B_\varepsilon\left(\overrightarrow{x_0}\right)$ is the integral of $\operatorname{div}\vec{F}$ over its interior. Now, this last integral is independent of what F does inside the hole, provided it is $\mathcal{C}^1$ and agrees with the given value along the boundary. Any $\mathcal{C}^1$ vector field F defined on and outside the sphere can be extended to its interior (Exercise 14), so we have

Corollary 5.8.6. *If the ball* $B_\varepsilon\left(\overrightarrow{x_0}\right)$ *is interior to the regular region* $\mathfrak{D}$*, then the flux integral of a* $\mathcal{C}^1$ *vector field* $\vec{F}$ *over the* boundary *of* $\mathfrak{D}$ *with a hole* $\iint_{\partial(\mathfrak{D}\setminus B_\varepsilon(\overrightarrow{x_0}))} \vec{F} \cdot d\vec{S}$ *equals the integral of* $\operatorname{div}\vec{F}$ *over the interior of* $\mathfrak{D} \setminus B_\varepsilon\left(\overrightarrow{x_0}\right)$:

$$\iint_{\partial(\mathfrak{D}\setminus B_\varepsilon(\overrightarrow{x_0}))} \vec{F} \cdot d\vec{S} = \iiint_{\mathfrak{D}\setminus B_\varepsilon(\overrightarrow{x_0})} \operatorname{div}\vec{F}\, dV. \tag{5.34}$$

In particular, if $\vec{F}$ *s divergence-free in* $\mathfrak{D} \setminus B_\varepsilon\left(\overrightarrow{x_0}\right)$ *then the outward flux of* $\vec{F}$ *over* $\partial(\mathfrak{D} \setminus B_\varepsilon\left(\overrightarrow{x_0}\right))$ *equals the outward flux of* $\vec{F}$ *over the sphere of radius* ε *centered at* $\overrightarrow{x_0}$.

Like Stokes' Theorem, the Divergence Theorem allows us to compute the same integral two different ways. We consider a few examples.

First, let us calculate directly the flux of the vector field

$$\vec{F}(x,y,z) = x\vec{\imath} + y\vec{\jmath} + z\vec{k}$$

out of the sphere $\mathfrak{S}$ of radius R about the origin.

---

[17] This theorem was published by Carl Friedrich Gauss (1777-1855) in 1838 [17] and independently by Mikhail Vasilevich Ostrogradski (1801-1862) in 1831. (see [1]). It is often called *Gauss's Theorem* or the *Gauss-Ostrogradsky Theorem*.

The natural parametrization of this sphere uses spherical coordinates: $x = R\sin\phi\cos\theta$, $y = R\sin\phi\sin\theta$, $z = R\cos\phi$, for $0 \le \phi \le \pi$ and $0 \le \theta \le 2\pi$. The partials are $\frac{\partial\vec{p}}{\partial\phi} = (R\cos\phi\cos\theta)\vec{\imath} + (R\cos\phi\sin\theta)\vec{\jmath} - (R\sin\phi)\vec{k}$ and $\frac{\partial\vec{p}}{\partial\theta} = (-R\sin\phi\sin\theta)\vec{\imath} + (R\sin\phi\cos\theta)\vec{\jmath}$, with cross product

$$\begin{aligned}\frac{\partial\vec{p}}{\partial\phi} \times \frac{\partial\vec{p}}{\partial\theta} &= \begin{vmatrix} \vec{\imath} & \vec{\jmath} & \vec{k} \\ R\cos\phi\cos\theta & R\cos\phi\sin\theta & -R\sin\phi \\ -R\sin\phi\sin\theta & R\sin\phi\cos\theta & 0 \end{vmatrix} \\ &= (R^2\sin^2\phi\cos\theta)\vec{\imath} + (R^2\sin^2\phi\sin\theta)\vec{\jmath} + (R^2\sin\phi\cos\phi)\vec{k}.\end{aligned}$$

To check whether this gives the outward orientation, we compute the direction of this vector at a point where it is easy to find, for example at $(1,0,0) = \vec{p}\left(\frac{\pi}{2}, 0\right)$:

$$\left(\frac{\partial\vec{p}}{\partial\phi} \times \frac{\partial\vec{p}}{\partial\theta}\right)\left(\frac{\pi}{2}, 0\right) = R^2\vec{\imath}$$

which points out of the sphere at $(1,0,0)$. Thus, the element of outward oriented surface area is

$$d\vec{S} = \Big((R^2\sin^2\phi\cos\theta)\vec{\imath} + (R^2\sin^2\phi\sin\theta)\vec{\jmath} + (R^2\sin\phi\cos\phi)\vec{k}\Big)\,d\phi\,d\theta.$$

On the surface, the vector field is $\vec{F}(\phi,\theta) = (R\sin\phi\cos\theta)\vec{\imath} + (R\sin\phi\sin\theta)\vec{\jmath} + (R\cos\phi)\vec{k}$, so

$$\begin{aligned}\vec{F}\cdot d\vec{S} &= \Big((R\sin\phi\cos\theta)(R^2\sin^2\phi\cos\theta) + (R\sin\phi\sin\theta)(R^2\sin^2\phi\sin\theta) \\ &\qquad + (R\cos\phi)(R^2\sin\phi\cos\phi)\Big)\,d\phi\,d\theta \\ &= R^3(\sin^3\phi\cos^2\theta + \sin^3\phi\sin^2\theta + \sin\phi\cos^2\phi)\,d\phi\,d\theta \\ &= R^3\sin\phi(\sin^2\phi + \cos^2\phi)\,d\phi\,d\theta = R^3\sin\phi\,d\phi\,d\theta.\end{aligned}$$

The flux integral is therefore

$$\begin{aligned}\iint_{\mathfrak{S}} \vec{F}\cdot d\vec{S} = \int_0^{2\pi}\int_0^{\pi} R^3\sin\phi\,d\phi\,d\theta &= \int_0^{2\pi} \left(-R^3\cos\phi\right)_{\phi=0}^{\pi}\,d\theta \\ &= 2R^3\int_0^{2\pi} d\theta = 2R^3(2\pi) = 4\pi R^3.\end{aligned}$$

Now let us see how the same calculation looks using the Divergence Theorem. The divergence of our vector field is $\operatorname{div}\vec{F} = 1 + 1 + 1 = 3$, so the Divergence Theorem tells us that

$$\iint_{\mathfrak{S}} \vec{F}\cdot d\vec{S} = \iiint_{\mathfrak{D}} \operatorname{div}\vec{F}\,dV = \iiint_{\mathfrak{D}} 3\,dV = 3\mathcal{V}(\mathfrak{D}),$$

where $\mathfrak{D}$ is the sphere of radius R, with volume $\frac{4\pi R^3}{3}$, and our integral is

$$\iint_{\mathfrak{S}} \vec{F}\cdot d\vec{S} = 4\pi R^3.$$

As another example, let us calculate the flux of the vector field $\vec{F}(x,y,z) = x^2\vec{\imath} + y^2\vec{\jmath} + z^2\vec{k}$ over the same surface. We have already calculated that the element of outward oriented surface area is

$$d\vec{\mathcal{S}} = \left((R^2\sin^2\phi\cos\theta)\vec{\imath} + (R^2\sin^2\sin\theta)\vec{\jmath} + (R^2\sin\phi\cos\phi)\vec{k}\right)d\phi\,d\theta.$$

This time, our vector field on the surface is

$$\vec{F}(\phi,\theta) = (R^2\sin^2\phi\cos^2\theta)\vec{\imath} + (R^2\sin^2\phi\sin^2\theta)\vec{\jmath} + (R^2\cos^2\phi)\vec{k}$$

and its dot product with $d\vec{\mathcal{S}}$ is

$$\begin{aligned}\vec{F}\cdot d\vec{\mathcal{S}} &= \Big((R^2\sin^2\phi\cos^2\theta)(R^2\sin^2\phi\cos\theta) + (R^2\sin^2\phi\sin^2\theta)(R^2\sin^2\sin\theta)\\ &\qquad + (R^2\cos^2\phi)(R^2\sin\phi\cos\phi)\big)\,d\phi\,d\theta\\ &= R^4\left(\sin^4\phi\cos^3\theta + \sin^4\phi\sin^3\theta + \sin\phi\cos^3\phi\right)d\phi\,d\theta\\ &= R^4\big(\frac{1}{4}\left(1 - 2\cos 2\phi + \cos^2\phi\right)\left(\cos^3\theta + \sin^3\theta\right) + \sin\phi\cos^3\phi\big)\,d\phi\,d\theta\\ &= R^4\big(\Big(\frac{3}{8} - \frac{1}{2}\cos 2\phi + \frac{1}{8}\cos 4\phi\Big)\big)(\cos^3\theta + \sin^3\theta) + \sin\phi\cos^3\phi\,d\phi\,d\theta\end{aligned}$$

and our flux integral is

$$\begin{aligned}&\iint_{\mathfrak{S}}\vec{F}\cdot d\vec{\mathcal{S}}\\ &= \int_0^{2\pi}\int_0^{\pi} R^4\big(\Big(\frac{3}{8} - \frac{1}{2}\cos 2\phi + \frac{1}{8}\cos 4\phi\Big)\big)(\cos^3\theta + \sin^3\theta) + \sin\phi\cos^{3\phi}\ d\phi\,d\theta\\ &= R^4\int_0^{2\pi}\big(\Big(\frac{3}{8}\theta - \frac{1}{4}\sin 2\phi + \frac{1}{32}\sin 4\phi\Big)(\cos^3\theta + \sin^3\theta) - \frac{1}{4}\cos^4\phi\big)_{\phi=0}^{\pi}\,d\phi\,d\theta\\ &\qquad = R^4\int_0^{2\pi}\Big(\frac{3\pi}{8}\Big)(\cos^3\theta + \sin^3\theta)\cos^3 + \sin^3)\,d\theta\\ &\qquad = \frac{3\pi}{8}R^4\int_0^{2\pi}\left((1 - \sin^2\theta)\cos\theta + (1 - \sin^2\theta)\cos\theta\right)d\theta\\ &\qquad\qquad = \frac{3\pi}{8}R^4\left(\sin\theta - \frac{1}{3}\sin^3\theta - \cos\theta + \frac{1}{3}\cos^3\theta\right)_0^{2\pi} = 0.\end{aligned}$$

Now if we use the Divergence Theorem instead, we see that the divergence of our vector field is $\operatorname{div}\vec{F} = 2x + 2y + 2z$ so by the Divergence Theorem $\iint_{\mathfrak{S}}\vec{F}\cdot d\vec{\mathcal{S}} = \iiint_{\mathfrak{D}}\operatorname{div}\vec{F}\ dV = \iiint_{\mathfrak{D}} 2(x + y + z)\ dV$, which is easier to do in spherical coordinates:

$$\begin{aligned}
&\int_0^{2\pi}\int_0^{\pi}\int_0^{R} 2(\rho\sin\phi\cos\theta+\rho\sin\phi\sin\theta+\rho\cos\phi)\rho^2\sin\phi\,d\rho\,d\phi\,d\theta\\
&\quad=\int_0^{2\pi}\int_0^{\pi}\int_0^{R} 2\rho^3\sin\phi(\sin\phi\cos\theta+\sin\phi\sin\theta+\cos\phi)\,d\rho\,d\phi\,d\theta\\
&\quad=\int_0^{2\pi}\int_0^{\pi}\left(\frac{\rho^4}{4}\right)_0^R\sin\phi(\sin\phi\cos\theta+\sin\phi\sin\theta+\cos\phi)\,d\rho\,d\phi\,d\theta\\
&\quad=\frac{R^4}{4}\int_0^{2\pi}\int_0^{\pi}\big(\sin^2\phi(\cos\theta+\sin\theta)+\sin\phi\cos\phi\big)\,d\phi\,d\theta\\
&\quad=\frac{R^4}{4}\int_0^{2\pi}\int_0^{\pi}\big(\frac{1}{2}(1-\cos 2\phi)(\cos\theta+\sin\theta)+\sin\phi\cos\phi\big)\,d\theta\\
&\quad=\frac{R^4}{4}\int_0^{2\pi}\Big(\Big(\frac{\phi}{2}-\frac{1}{2}\sin 2\phi\Big)(\cos\theta+\sin\theta)+\frac{1}{2}\sin^2\phi\Big)_{\phi=0}^{\pi}\,d\theta\\
&\quad=\frac{R^4}{4}\int_0^{2\pi}\big(\frac{\pi}{2}(\cos\theta+\sin\theta)+0\big)\,d\theta\\
&\quad=\frac{\pi R^4}{8}(\sin\theta-\cos\theta)_0^{2\pi}=0.
\end{aligned}$$

We note in passing that this triple integral could have been predicted to equal zero on the basis of symmetry considerations. Recall that the integral of an odd function of one real variable $f(t)$ (*i.e.*, if $f(-t)=-f(t)$) over a symmetric interval $[-a,a]$ is zero. We call a region $\mathfrak{D}\subset\mathbb{R}^3$ **symmetric in** z if it is unchanged by reflection across the xy-plane, that is, if whenever the point (x,y,z) belongs to $\mathfrak{D}$, so does $(x,y,-z)$. (The adaptation of this definition to symmetry in x or in y is left to you in Exercise 10.) We say that a function $f(x,y,z)$ is **odd in** z (*resp.* **even in** z) if reversing the sign of z but leaving x and y unchanged reverses the sign of f (*resp.* does not change f): for odd, this means $f(x,y,-z)=-f(x,y,z)$ while for even it means $f(x,y,-z)=f(x,y,z)$.

Remark 5.8.7. *If $f(x,y,z)$ is odd in z and $\mathfrak{D}$ is z-regular and symmetric in z, then*

$$\iiint_{\mathfrak{D}} f(x,y,z)\;dV=0.$$

(To see this, just set up the triple integral and look at the innermost integral.)

Recall that one of the useful consequences of the Fundamental Theorem for Line Integrals was that the line integral of a conservative vector field depends only on the endpoints of the curve, not on the curve itself; more generally, if the curl of a vector field is zero in a region, then the line integral of the field over a curve is not changed if we deform it within that region, holding the endpoints fixed. A similar use can be made of the Divergence Test. We illustrate with an example.

Let us find the flux integral over $\mathfrak{S}$ the upper hemisphere $z=\sqrt{1-x^2-y^2}$, oriented up, of the vector field $\vec{F}(x,y,z)=(1+z)e^{y^2}\vec{\imath}-(z+1)e^{x^2}\vec{\jmath}+(x^2+y^2)\vec{k}$. Whether we think of the hemisphere as the graph of a function or parametrize it using spherical coordinates, the terms involving exponentials of squares are serious trouble. However, note that this vector field is divergence-free:

$$\operatorname{div}\vec{F} = \frac{\partial}{\partial x}\left[(1+z)e^{y^2}\right] + \frac{\partial}{\partial y}\left[(z+1)e^{x^2}\right] + \frac{\partial}{\partial z}\left[(x^2+y^2)\right] = 0.$$

Thus, if we consider the half-ball $\mathfrak{D}$ bounded above by the hemisphere and below by the unit disc in the xy-plane, the Divergence Theorem tells us that

$$\iint_{\partial\mathfrak{D}} \vec{F} \cdot d\vec{\mathcal{S}} = \iiint_{\mathfrak{D}} \operatorname{div}\vec{F}\, dV = 0.$$

Now, the boundary of $\mathfrak{D}$ consists of two parts: the hemisphere, $\mathfrak{S}$, and the disc, $\mathcal{D}$. The outward orientation on $\partial\mathfrak{D}$ means an upward orientation on the hemisphere $\mathfrak{S}$, but a *downward* orientation on the disc $\mathcal{D}$. Thus, the flux integral over the whole boundary equals the flux integral over the upward-oriented hemisphere, plus the flux integral over the downward-oriented disc—which is to say, *minus* the flux over the *upward*-oriented disc. Since the difference of the two upward-oriented discs equals zero, they are equal. Thus

$$\iint_{\mathfrak{S}} \vec{F} \cdot d\vec{\mathcal{S}} = \iint_{\mathcal{D}} \vec{F} \cdot d\vec{\mathcal{S}}.$$

But on $\mathcal{D}$, $d\vec{\mathcal{S}} = \vec{k}\, dA$, so substituting $z = 0$ we see that the vector field on the disc is $\vec{F}(x,y) = e^{y^2}\vec{\imath} - e^{x^2}\vec{\jmath} + (x^2+y^2)\vec{k}$ and $\vec{F} \cdot d\vec{\mathcal{S}} = (x^2+y^2)\, dA$. This is easy to integrate, especially when we use polar coordinates:

$$\iint_{\mathcal{D}} \vec{F} \cdot d\vec{\mathcal{S}} = \int_0^{2\pi} \int_0^1 (r^2)(r\, dr\, d\theta) = \int_0^{2\pi} (\frac{r^4}{4})\, d\theta = \int_0^{2\pi} \frac{1}{4}\, d\theta = \frac{\pi}{2}.$$

Exercises for § 5.8

Answers to Exercises 1a, 2a, 3a, and 5a are given in Appendix A.13.

Practice problems:

(1) Use Green's Theorem to calculate the integral $\int_{\mathcal{C}} \vec{F} \cdot \vec{N}\, d\mathfrak{s}$, where $\vec{N}$ is the outward unit normal and $\mathcal{C}$ is the ellipse $x^2 + 4y^2 = 4$, traversed counterclockwise:
  - (a) $\vec{F}(x,y) = x\vec{\imath} + y\vec{\jmath}$
  - (b) $\vec{F}(x,y) = y\vec{\imath} + x\vec{\jmath}$
  - (c) $\vec{F}(x,y) = x^2\vec{\imath} + y^2\vec{\jmath}$
  - (d) $\vec{F}(x,y) = x^3\vec{\imath} + y^3\vec{\jmath}$

(2) Find the flux integral $\iint_{\mathfrak{S}} \vec{F} \cdot d\vec{\mathcal{S}}$, where $\mathfrak{S}$ is the unit sphere oriented outward, for each vector field below:
  - (a) $\vec{F}(x,y,z) = (x+y^2)\vec{\imath} + (y-z^2)\vec{\jmath} + (x+z)\vec{k}$
  - (b) $\vec{F}(x,y,z) = (x^3+y^3)\vec{\imath} + (y^3+z^3)\vec{\jmath} + (z^3-x^3)\vec{k}$
  - (c) $\vec{F}(x,y,z) = 2xz\vec{\imath} + y^2\vec{\jmath} + xz\vec{k}$
  - (d) $\vec{F}(x,y,z) = 3xz^2\vec{\imath} + y^3\vec{\jmath} + 3x^2z\vec{k}$

(3) For each vector field $\vec{F}$ below, find the flux integral $\iint_{\mathfrak{S}} \vec{F} \cdot d\vec{\mathcal{S}}$, where $\mathfrak{S}$ is the boundary of the unit cube $[0,1] \times [0,1] \times [0,1]$, oriented outward, in two different ways: (*i*) directly (you will need to integrate over each face separately and then add up the results) and (*ii*) using the Divergence Theorem.
  - (a) $\vec{F}(x,y,z) = x\vec{\imath} + y\vec{\jmath} + z\vec{k}$
  - (b) $\vec{F}(x,y,z) = \vec{\imath} + \vec{\jmath} + \vec{k}$
  - (c) $\vec{F}(x,y,z) = x^2\vec{\imath} + y^2\vec{\jmath} + z^2\vec{k}$

Exercises 11.4

1. Use geometric software to produce Dürer's construction of the regular pentagon.

2. The following set of instructions is for constructing a pentagon given a side AB of length d.

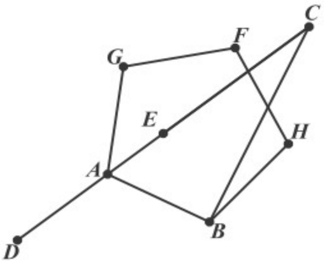

Figure 11.32. Exercise 11.4.2: Constructing a regular pentagon given side AB

- Construct CB perpendicular to AB such that $CB = 2d$.
- Construct segment CA and extend ray CA to a point D such that $AD = d$, where A lies between C and D.
- Bisect CD at point E.
- Let F be the intersection of the two circles centered at A and B, each with radius CE.
- Let G be the intersection of circles with centers A and F and radius AB, and let H be the intersection of circles with centers B and F and radius AB.
- Form pentagon ⬠$ABHFG$ by connecting vertices A, B, H, F and G.

(a) Use geometric software to produce this construction of the regular pentagon.

(b) Prove that if $AB = 1$, then $CE = \dfrac{1+\sqrt{5}}{2}$, and hence, $\triangle FAB$ is a golden triangle.

(c) Use part (b) to prove that ⬠$ABHFG$ is a regular pentagon.

3. Prove that the construction given in Proposition IV.13 works for any regular n-gon.

4. Prove that the construction given in Proposition IV.14 works for any regular n-gon.

5. Prove that the construction given above using central angles of 72° produces a regular pentagon.

6. Prove Lemma 11.13.

11.5 Constructing regular polygons

Euclid constructed both the equilateral triangle and the square in Book I. We had to wait until the eleventh proposition of the fourth book for the construction of the next regular polygon, the more complex regular pentagon. Its construction and proof relies on results from all three of the previous books. In the two remaining propositions, Euclid constructs a regular hexagon and then finishes Book IV with a regular 15-gon. In addition to these two constructions, we consider the more general question of which regular n-gons *can* be constructed using only an unmarked straightedge and compass.

In Proposition IV.15, Euclid inscribes a regular hexagon in a circle. We give a modified version of his construction and leave the verification step to the reader.

Proposition IV.15. *In a given circle to inscribe an equilateral and equiangular hexagon.*

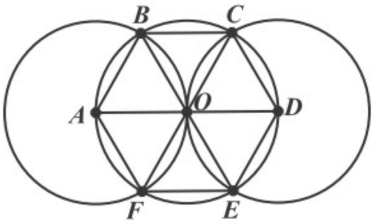

Figure 11.33. Regular hexagon

Construction: Given a circle with center O and point A, construct the diameter AD. Construct two circles, one with center A, the other with center D, and both with radius AO. Label the intersections of these circles with our original circle B, C, E and F so that the letters are in order from A either clockwise or counter-clockwise.

Claim: The hexagon $\hexagon ABCDEF$ is a regular hexagon. The justification is left to the reader. □

Another way to construct a regular hexagon is to notice that it has twice as many sides as an equilateral triangle, which is itself constructible. So, if we circumscribe a circle about the equilateral triangle, bisect each of the central angles and mark the intersection of the angle bisectors with the circle, then we'll have the six vertices of a regular hexagon marked on the circle. We will exploit this method to construct a regular $2n$-gon from any constructible n-gon: start with a constructible regular n-gon, circumscribe a circle around it, bisect each of the central angles and add the points where the angle bisectors meet the circle to the original set of vertices. Alternatively, we could bisect each of the n arcs into which the regular n-gon divides the circle. Either way, we now have $2n$ vertices which, when connected, produce a regular $2n$-gon. While Euclid did not include the following proposition in Book IV, his far more complicated constructions leads us to believe that he chose not to include it. We leave the proof to the reader.

Theorem 11.14. *If a regular n-gon is constructible, then so is a regular $2n$-gon.*

Using this doubling method on an inscribed equilateral triangle, square or regular pentagon, we are thus able to construct regular n-gons for $n = 6, 8, 10, 12, 16, 20, 32, 40, \ldots$.

For the last proposition in Book IV, Euclid constructs a regular 15-gon, also called a regular **pentadecagon**. We give a slightly revised version of his construction.

Proposition IV.16. *In a given circle to inscribe a fifteen-angled figure which shall be both equilateral and equiangular.*

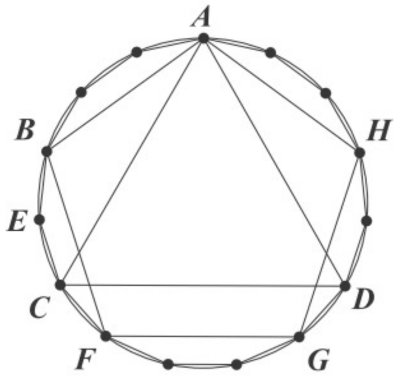

Figure 11.34. Proposition IV.16

Construction: Given a circle with a point A on it, inscribe an equilateral triangle $\triangle ACD$ with vertex A. Also inscribe a regular pentagon ⬠ $ABFGH$. The triangle divides the circumference into three arcs, each one-third of the whole, while the pentagon divides the circumference into five arcs, each one-fifth of the whole. The arc that lies between B and C must be two-fifteenths of the whole since $\frac{1}{3} - \frac{1}{5} = \frac{2}{15}$. If we bisect this arc at E, then $\widehat{BE}$ will be exactly one-fifteenth of the whole. Copying this arc around the circle, we construct a regular 15-gon, as desired. □

At first glance, the construction technique employed in the proof appears fruitful, as if it would yield other new regular n-gons from those that we already know to be constructible. Alas, it does not. (Why not? What makes the regular 3- and 5-gons special?) Euclid ends his regular polygon constructions with the 15-gon, but the hunt for other constructible regular polygons (besides those obtained by doubling) continued for nearly 2000 years until a 19-year-old finally found one. In 1796, a young Gauss constructed the **heptadecagon**, or 17-gon. Better still, he gave the formula to completely classify which regular n-gons are constructible. The reason the resolution to this problem took so long is that it required tools outside of geometry, specifically, tools from the new mathematical areas of abstract algebra and complex numbers. With those tools, Gauss completely classified the constructibility of regular n-gons as given in Theorem 11.15.

Theorem 11.15. [Gauss's Theorem]. *A regular n-gon is constructible if and only if $n = 2^k p_1 p_2 p_3 \ldots p_m$ where $n \geq 3$, $k \geq 0$, and p_i are distinct primes of the form $2^{2^j} + 1$.*

Primes of the form $2^{2^j} + 1$ are called **Fermat primes**, named for Pierre de Fermat (1601–1665). The known Fermat primes are:

$$\begin{gathered} 2^{2^0} + 1 = 3 \\ 2^{2^1} + 1 = 5 \\ 2^{2^2} + 1 = 17 \\ 2^{2^3} + 1 = 257 \\ 2^{2^4} + 1 = 65537. \end{gathered}$$

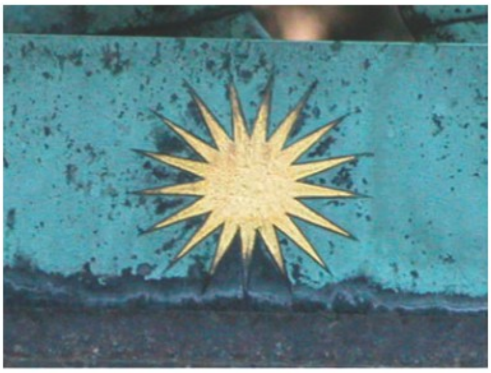

Figure 11.35. Close-up of 17-point star on monument to Gauss, Brunswick, Germany

Euler famously showed that $2^{2^5} + 1 = 4,294,967,297$ is not prime. It is known that $2^{2^j} + 1$ is not prime for $5 \leq j \leq 32$ and a smattering of other values for larger j. However, it is **unknown** whether there are only five primes of this form.[1] Therefore, as of this edition, we have the following:

A regular n-gon is constructible if $n = 2^k \cdot 3^{b_1} \cdot 5^{b_2} \cdot 17^{b_3} \cdot 257^{b_4} \cdot 65537^{b_5}$ *where* $n \geq 3$*,* $k \geq 0$*, and* $b_i \in \{0, 1\}$ *for all i.*

If one day it is shown that there are no other Fermat primes, then this implication becomes an "if and only if."

As for the constructions of the regular 257-gon and the regular 65537-gon, Gauss left them to two other German mathematicians. Friedrich Julius Richelot (1808–1875) constructed the regular 257-gon in 1831, and Johann Gustav Hermes (1846–1912) spent ten years on the regular 65537-gon, finishing in 1894. The manuscript detailing this impossible-to-imagine construction sits in a large box at the University of Göttingen. For now, we are left to wonder why it is impossible to construct a regular n-gon when n does not take this form. For example, why can't we construct a 7-gon or a 9-gon? We will discuss this, as well as the three famous construction problems of antiquity, in Chapter 16.

Surely owing to its personal significance, Gauss remarked that the heptadecagon was a result worthy of being on his tombstone. His desire to memorialize his great accomplishment puts him in fine company. The greatest mathematician of antiquity and the subject of the following section, Archimedes of Syracuse (287–212 BCE), requested a representation of his most significant accomplishment, a cylinder circumscribing a sphere, on his tomb. The Roman philosopher Cicero (106–43 BCE) writes of finding a figure of a sphere in a cylinder when in search of Archimedes' grave [**24**]. On Gauss's simple grave in Göttingen there is no such polygon, but a 17-point star does grace the bottom of the bronze statue that sits in his honor in his native town of Brunswick. In Figure 11.36 we include a similar homage to Gauss in the form of a 17-point star made by Swiss artist Eugen Jost and appearing in a lovely book on art and mathematics, *Beautiful Geometry*.

---

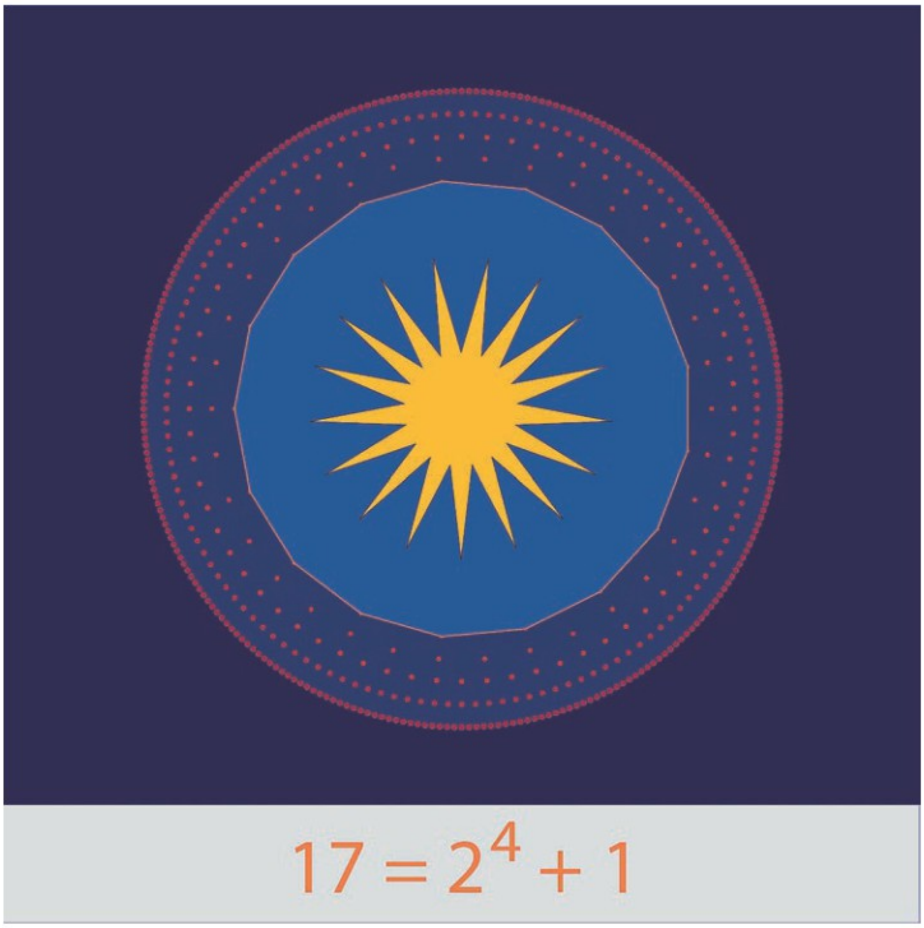

Figure 11.36. Homage to Carl Friedrich Gauss by Eugen Jost (2014) [86]

Exercises 11.5

1. Prove that the construction given for Proposition IV.15 is valid.

2. Construct a regular $2n$-gon given a regular n-gon. Prove that this construction is valid.

3. Given a regular m-gon that is constructible and a regular n-gon that is constructible, prove that if m and n are relatively prime ($\gcd(m, n) = 1$), then a regular mn-gon is also constructible.

4. Find all n such that $3 \leq n \leq 100$ and the regular n-gon is constructible.

5. Find all n such that $101 \leq n \leq 200$ and the regular n-gon is constructible.

6. Use geometric software to produce the following "quadruple quadrisection" construction of a 17-gon due to Herbert W. Richmond (1863–1948), King's College,

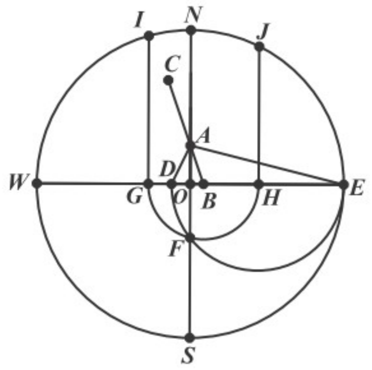

Figure 11.37. Exercise 11.5.6: Richmond's construction of a 17-gon

Cambridge, who gave it in the *Quarterly Journal of Pure and Applied Mathematics* in 1893. To **quadrisect** is to divide something into four equal parts. (Hence, to bisect into halves, and then, bisect each half.)

- Quadrisect the perimeter of the circle of center O by points N, E, S, W.
- Quadrisect the radius ON by the point A where A is closest to O.
- Quadrisect the angle $\angle OAE$ by the line AB (where B lies on OE and is closest to O). See Figure 11.37.
- Form line BAC.
- Quadrisect the straight angle BAC in the direction of W by the line AD, where D is on radius OW, and angle $\angle BAD$ is half of a right angle.
- Construct semicircle DFE, cutting OS at F.
- Construct semicircle GFH, centered at B, cutting OW at G and OE at H.
- Construct $GI \perp WE$ where I is on circle WNE in the 2nd quadrant.
- Construct $HJ \perp WE$ where J is on circle WNE in the 1st quadrant.
- Since arc $\widehat{IJ}$ is two seventeenths of the circumference of the circle, bisecting arc $\widehat{IJ}$ at K produces vertices I, K and J of the regular heptadecagon. Copy arc $\widehat{IK}$ around circle $ENWS$ to construct the other vertices of the heptadecagon.

11.6 The area of a circle & π

At the end of Chapter 10, we gave a decidedly modern proof using limits to show that the ratio of any circle's circumference to its diameter is a constant, and noted that this constant was named π in the eighteenth century. Euclid does not include a proof that this ratio is constant in the *Elements*, which is curious since there is evidence that it was known long before Euclid took brush to papyrus. There are estimates for π in the Bible, in ancient Egyptian papyri, and in ancient Chinese books, all of which predate Euclid. Certainly, a calculation of an estimate for π would have been out of place in the *Elements* for it is not a book that shows any concern for absolute measurement. Most of its propositions are relationships between geometric objects. So, while the lack of an estimate is unsurprising, we are left to wonder why he does not show that all circles satisfy this ratio. On the other hand, Euclid *does* present a different ratio that is satisfied by all circles. With the second proposition of his twelfth book, he proves the following: *Circles are to one another as the squares on the diameters.* Here, given any two circles with areas, $Area(circle_1)$ and $Area(circle_2)$, and diameters, $diameter_1$ and $diameter_2$, respectively, we have

$$XII.2 \qquad \frac{Area(circle_1)}{Area(circle_2)} = \frac{diameter_1^2}{diameter_2^2}.$$

His proof relies on inscribing a sequence of regular polygons of an increasing number of sides. We will not prove this particular result, but we will revisit it after looking at a related proposition from Archimedes, a mathematician who followed closely on the heels of Euclid and is widely regarded as the greatest of antiquity. We present two results from Archimedes' treatise, *Measurement of the Circle.* The first is equivalent to our modern formula for the area of the circle, and the second is an estimate for π. Both of Archimedes' results rely on the same method Euclid uses in XII.2, inscribing and circumscribing regular polygons in and around a circle.

The most important document containing the works of Archimedes was only rediscovered in Constantinople in 1906. Called the *Archimedes Palimpsest*, it contains seven treatises, including *Measurement of the Circle*, which contains the two propositions given in this section, and, notably, the only surviving copy *On Floating Bodies.* A palimpsest is a manuscript that has been erased so that the precious writing material, in this case goatskin parchment, can be reused. Disguised as a book of prayers since the thirteenth century, it laid undiscovered for hundreds of years in a monastery library. It was sold to a private collector in the 1920s, and resold at auction in 1998 at Christie's Auction House in New York City, where it sold to an anonymous buyer for over two million dollars. It has been an object of study at the Walters Art Museum in Baltimore, Maryland, since 1999.

Archimedes' Proposition 1. *The area of a circle is equal to the area of a right triangle in which one of the legs is equal to the radius and the other to the circumference.*

Restating this as a formula, we have $Area = \frac{1}{2}r \cdot Circumference$, where r is the radius of the circle. Since $Circumference = 2\pi r$, we have the familiar formula for area of a circle, $Area = \pi r^2$. Archimedes' proof (as does Euclid's XII.2) employs the **method of exhaustion**, a technique attributed to Eudoxus (408–355 BCE), a Greek mathematician who predates Euclid. Anyone familiar with integral calculus will recognize this method, which entails exhausting the difference between a known area and an unknown area. Here, the area of the circle is approximated by systematically inscribing regular polygons of an increasing number of sides in the circle. As the number of sides increases, the easily computed area of the polygon approaches the area of the circle from below, so that the difference between the unknown area of the circle and the known area of the polygon is less than any given quantity, no matter how small. At heart, this is the same limit method we saw at play in the proof that the ratio of any circle's circumference to its diameter is constant in Theorem 10.3, but here we are working with the two-dimensional area of the inscribed polygon instead of the one-dimensional perimeter. It is the idea that this process can continue forever, theoretically, and thus, that the difference between the unknown and the known can be exhausted, that assuredly places Greek mathematics as a forerunner to calculus.

As a visual aid, Figure 11.38 shows a systematic progression of regular n-gons inscribed in a circle. At this size, it is difficult to distinguish the circle from the regular 24-gon. Clearly, the area of the regular n-gon is a good approximation for the area of the circle when n is large.

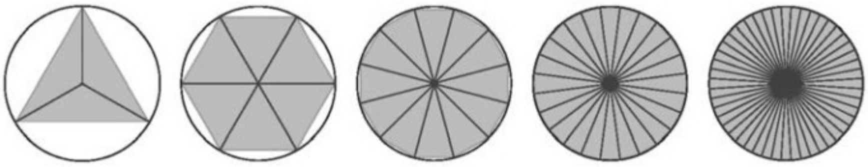

Figure 11.38. Inscribed regular 3-gon, 6-gon, 12-gon, 24-gon and 48-gon

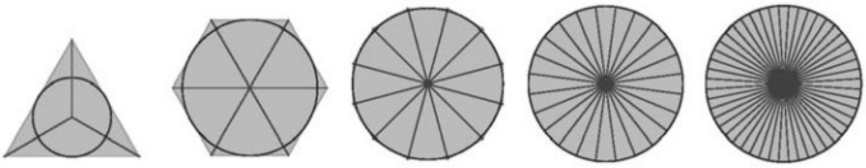

Figure 11.39. Circumscribed regular 3-gon, 6-gon, 12-gon, 24-gon and 48-gon

Archimedes takes Eudoxus' method of exhaustion one step further by approaching the area of the circle from above with circumscribed regular polygons, knowing that the actual area of the circle lies between these bounds. In fact, he uses a double reductio ad absurdum argument to show that the circle and triangle have the equal area, arguing that the other possibilities, when either is bigger than the other, lead to a contradiction. In approaching the area from above and below, those familiar with the work of Isaac Newton (1642–1727) and Gottfried Leibniz (1646–1716) will no doubt see the seeds of integral calculus in this method and want to turn this into a limit problem. We do just that, giving an updated proof of Archimedes' first proposition which relies on the limit concept. First, we need a new definition and a formula for the area of a regular n-gon.

Definition 11.16. The **apothem** of a regular polygon is a line segment from the center to the midpoint of one of its sides.

Lemma 11.17. *A regular polygon with perimeter P and apothem h has an area of* $\frac{1}{2}h \cdot P$.

Proof of Lemma. Suppose the regular polygon has n sides, each of length s. Join each vertex to the center, O. The polygon is composed of n congruent triangles, each with area $\frac{1}{2}hs$. Hence, the area of the polygon is $n \cdot (\frac{1}{2}hs) = \frac{1}{2}h \cdot (ns) = \frac{1}{2}h \cdot P$, as desired. □

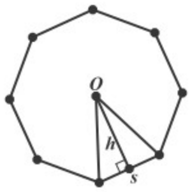

Figure 11.40. Area of a regular polygon

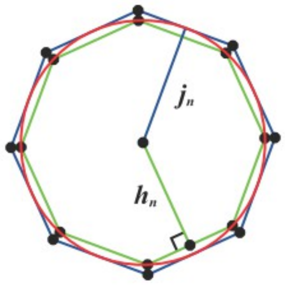

Figure 11.41. Archimedes' Proposition 1: Area of a circle

Proof of Archimedes' Proposition 1. Let *Area(circle)* represent the area of the given circle, B_n be the area of an inscribed regular polygon with n sides, and D_n be the area of a circumscribed regular polygon with n sides. Clearly, $B_n \leq \mathit{Area(circle)} \leq D_n$ for all $n \geq 3$. Let h_n be the apothem of B_n, and P_n be the perimeter of B_n. Likewise, let j_n be the apothem and Q_n the perimeter of D_n. By Lemma 11.17, we have

$$\frac{1}{2}h_n \cdot P_n \;\leq\; \mathit{Area(circle)} \;\leq\; \frac{1}{2}j_n \cdot Q_n.$$

Taking the limit as n approaches infinity, we have

$$\lim_{n\to\infty} \frac{1}{2}h_n \cdot P_n \;\leq\; \mathit{Area(circle)} \;\leq\; \lim_{n\to\infty} \frac{1}{2}j_n \cdot Q_n.$$

But clearly, $\lim\limits_{n\to\infty} h_n = \lim\limits_{n\to\infty} j_n = r$, and $\lim\limits_{n\to\infty} P_n = \lim\limits_{n\to\infty} Q_n = \mathit{Circumference}$. Thus,

$$\frac{1}{2}r \cdot \mathit{Circumference} \;\leq\; \mathit{Area(circle)} \;\leq\; \frac{1}{2}r \cdot \mathit{Circumference},$$

and the area of the circle is $\mathit{Area(circle)} = \frac{1}{2}r \cdot \mathit{Circumference}$. ☐

In light of this proposition, let's revisit Euclid's Proposition XII.2. A notable difference between these results is that Euclid relates geometric figures of the same dimension, whereas Archimedes relates figures of differing dimensions. Consequently, in combination, these two results tell us something very interesting. Neither result relies on the constancy of the ratio of any circle's circumference to its diameter, and together, they provide a proof of this result.

$$\begin{aligned}\frac{\mathit{Circumference}_1}{\mathit{Circumference}_2} &= \frac{\frac{2}{r_1}\cdot \mathit{Area}_1}{\frac{2}{r_2}\cdot \mathit{Area}_2} \quad \text{by Archimedes Prop. 1}\\ &= \frac{2r_2}{2r_1}\cdot\frac{\mathit{Area}_1}{\mathit{Area}_2} \quad \text{by rearranging}\\ &= \frac{d_2}{d_1}\cdot\frac{d_1^2}{d_2^2} \quad \text{by Euclid XII.2}\\ &= \frac{d_1}{d_2}.\end{aligned}$$

Therefore, we have another proof that the ratio of any circle's circumference to its diameter is constant, that is

$$\frac{\mathit{Circumference}_1}{\mathit{diameter}_1} = \frac{\mathit{Circumference}_2}{\mathit{diameter}_2}.$$

For our second result, we consider Archimedes' third proposition in which he provides an estimate for this constant ratio, π.

Archimedes' Proposition 3. *The ratio of the circumference of any circle to its diameter is less than* $3\frac{1}{7}$ *but greater than* $3\frac{10}{71}$.

Archimedes method entails bounding this quantity between two fractions with the use of an inscribed and circumscribed regular 96-gon. He begins by inscribing a regular hexagon in the circle. He then proceeds to double the number of sides, successively producing an inscribed regular 12, 24, 48 and 96-gon. He relates the circumference of the inscribed $2n$-gon to that of the n-gon, and thus, generates a recursive formula to estimate a lower bound for π. Of course, he does all of this without the benefit of algebra or the ease of calculation afforded by our decimal number system. He then circumscribes a regular hexagon around the circle and, once again, doubles the number of sides, successively producing a circumscribed regular 12, 24, 48 and 96-gon. This gives him an upper bound for π. We present a revised argument, and where Archimedes used fractions to estimate square roots, we take full advantage of modern technology when giving our lower and upper bounds.

We begin by inscribing a regular hexagon in a circle of radius 1. Notice that the perimeter of the regular 6-sided polygon, $P_6 = 6$, is an underestimate for the circumference, 2π. More generally, if a_n denotes the length of the side of a regular n-sided polygon inscribed in a circle of radius 1, then its perimeter, P_n, is given by $P_n = n \cdot a_n$. Since the perimeter of any polygon inscribed in the circle is less than the circumference of the circle, that is $P_n < 2\pi$, we have

$$\pi \geq \frac{n \cdot a_n}{2}.$$

We now give the following lemma.

Lemma 11.18. *If a_n denotes the length of the side of a regular n-sided polygon inscribed in a circle of radius* 1*, then*

$$a_{2n} = \sqrt{2 - \sqrt{4 - a_n^2}}.$$

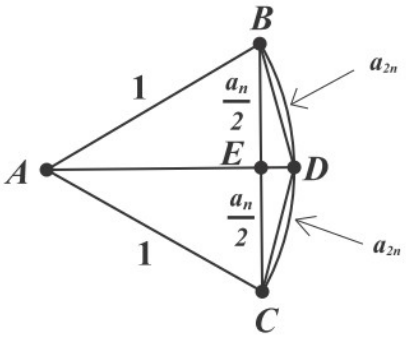

Figure 11.42. Sides of n-gon and $2n$-gon

Proof of Lemma. Let A be the center of the given circle of radius 1, $BC = a_n$ and $CD = a_{2n}$, as shown in Figure 11.42. Note that AD bisects arc $\widehat{BC}$, meeting BC at E. Since angle $\angle AEB$ is a right angle (by proof of Theorem 11.14), then by the Pythagorean Theorem we have $1 = \left(\frac{a_n}{2}\right)^2 + AE^2$, and $a_{2n}^2 = \left(\frac{a_n}{2}\right)^2 + DE^2$. Since $DE = 1 - AE$, this gives

$$\begin{aligned} a_{2n}^2 &= \left(\tfrac{a_n}{2}\right)^2 + (1-AE)^2 \\ &= \left(\tfrac{a_n}{2}\right)^2 + \left(1 - \sqrt{1-\left(\tfrac{a_n}{2}\right)^2}\right)^2 \\ &= \left(\tfrac{a_n}{2}\right)^2 + 1 - 2\sqrt{1-\left(\tfrac{a_n}{2}\right)^2} + 1 - \left(\tfrac{a_n}{2}\right)^2 \\ &= 2 - \sqrt{4-a_n^2}. \end{aligned}$$

□

Substituting the appropriate values for n gives the following:

$$\begin{aligned} a_{12} &= \sqrt{2-\sqrt{3}} \approx 0.5176381 \\ a_{24} &= \sqrt{2-\sqrt{2+\sqrt{3}}} \approx 0.2610524 \\ a_{48} &= \sqrt{2-\sqrt{2+\sqrt{2+\sqrt{3}}}} \approx 0.1308063 \\ a_{96} &= \sqrt{2-\sqrt{2+\sqrt{2+\sqrt{2+\sqrt{3}}}}} \approx 0.0654382. \end{aligned}$$

Thus,

$$\pi \geq 48a_{96} \approx 3.14103 \geq 3\frac{10}{71}.$$

Let's consider the circumscribed polygons that produce the upper bound for π. Suppose b_n denotes the length of the side of a regular n-sided polygon circumscribed about a circle of radius 1. We have two possible plans of attack for the circumscribed polygons. The first is to use the fact that $b_6 = \frac{2}{\sqrt{3}}$, and then prove the following recurrence relationship.

Lemma 11.19. *If b_n denotes the length of the side of a regular n-gon circumscribed about a circle of radius* 1*, then*

$$b_{2n} = \frac{2\left(\sqrt{4+b_n^2}-2\right)}{b_n}.$$

An alternative choice is to establish the following relationship between a_n and b_n.

Lemma 11.20. *If a_n and b_n denote the lengths of the sides of regular n-gons inscribed in and circumscribed about a circle of radius* 1*, respectively, then*

$$b_n = \frac{2a_n}{\sqrt{4-a_n^2}}.$$

A representative diagram for regular pentagons is shown in Figure 11.43. We leave both proofs to the reader, but note that $b_{96} \approx 0.0654732$. Hence,

$$\pi \;\le\; 48b_{96} \;\approx\; 3.142715 \;\le\; 3\frac{1}{7}.$$

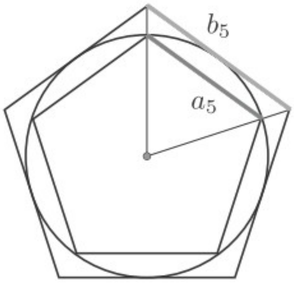

Figure 11.43. Sides of inscribed and circumscribed regular pentagon

Exercises 11.6

1. Prove Lemma 11.19.

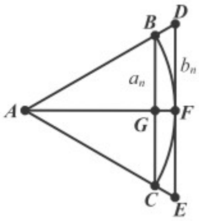

Figure 11.44. Exercise 11.6.2: Sides of inscribed and circumscribed regular n-gons

2. Using Figure 11.44 as a guide, prove Lemma 11.20. Note that the circle of radius 1 is centered at A, $AB = AC = 1$, $BC = a_n$, $DE = b_n$, and DE is tangent to the circle at F. Be sure to justify why $AG \perp BC$, $BG = \frac{a_n}{2}$ and $DF = \frac{b_n}{2}$.

Minkowski made the first major progress on this problem by proving that any convex polyhedron can be so realized [148].

Pag. 356(366) B. Different geometries

One can study properties of surfaces that are invariant under a bigger group than the orthogonal group.

the There are the special linear group, the conformal group and the projective group each acting on $\mathbb{R}^3$!

For affine geometry important invariants are the concepts of the affine metric (which is the second fundamental form divided by the fourth root of the GAUSSIAN curvature) and the affine normal.

John Loftin discussed how to construct an affine sphere by a holomorphic section of the tricanonical line bundle of a Riemann surface.

Chapter 5

Gauss Hypergeometric Equation

5.1 The Pochhammer Symbol (Def.)

If n is a positive integer, then the abbreviation

$$(\alpha)_n = \alpha\ (\alpha + 1)\ (\alpha + 2) \ldots (\alpha + n - 1)$$

with $(\alpha)_0 = 1$

is called the **Pochhammer symbol.**

Another Def. We have

$$(\alpha)_n = \alpha\ (\alpha + 1)\ (\alpha + 2) \ldots. (\alpha + n - 1)$$

$$= \frac{1.2.3 \ldots\ldots (\alpha - 1).\alpha\ (\alpha + 1)\ (\alpha + 2) \ldots. (\alpha + n - 1)}{1.2.3. \ldots. (\alpha - 1)}$$

$$= \frac{\Gamma(\alpha + n)}{\Gamma(\alpha)}$$

Thus, **Pochhammer symbol** in the form of gamma function can also be defined as

$$(\alpha)_n = \frac{\Gamma(\alpha + n)}{\Gamma(\alpha)}, n = 0, 1, 2, 3, \ldots\ldots\ldots$$

Note : The Pochhammer Symbol $(\alpha)_n$ is sometimes replaced by Appel's symbol (α, n). But throughout this chapter we shall use Pochhammer symbol.

5.2 Identities Satisfied by Pochhammer Symbol $(\alpha)_n$

1. $(1)_n = n!$
2. $(\alpha + n)(\alpha)_n = \alpha(\alpha+1)_n = (\alpha)_{n+1}$
3. $\binom{-\alpha}{n} = \frac{(-1)^n}{n!}(\alpha)_n$
4. $(\alpha)_{n+1} = \alpha(\alpha+1)_n$
5. $(\alpha)_{n+k} = (\alpha)_k(\alpha+k)_n = (\alpha)_n(\alpha+n)_k$ (Addition formula)
6. $(\alpha)_{k-n} = (-1)^n(\alpha)_k/(1-\alpha-k)_n$
7. $(\alpha)_{-n} = (-1)^n/(1-\alpha)_n,\ n = 1, 2, 3, \ldots.$
8. $(-k)_n = \begin{cases} \frac{(-1)^n k!}{(k-n)!}, & 0 \le n \le k \\ 0, & n > k \end{cases}$

Proof: 1. $(1)_n = 1(1+1)(1+2)\ldots(1+n-1) = 1.2.3\ldots.n = n!$

2. $(\alpha+n)(\alpha)_n = (\alpha)_n.(\alpha+n) = \alpha(\alpha+1)(\alpha+2)\ldots.(\alpha+n-1).(\alpha+n)$

$$= \alpha.\{(\alpha+1)(\alpha+2)\ldots.(\alpha+1+n-1)\} = \alpha(\alpha+1)_n$$

Also $(\alpha+n)(\alpha)_n = \alpha(\alpha+1)(\alpha+2)\ldots(\alpha+n-1).(\alpha+n+1-1) = (\alpha)_{n+1}$

Hence $(\alpha+n)(\alpha)_n = \alpha(\alpha+1)_n = (\alpha)_{n+1}$

3. $$\binom{-\alpha}{n} = \frac{(-\alpha)(-\alpha-1)(-\alpha-2)\ldots(-\alpha-n+1)}{n!}$$

$$= \frac{(-1)^n \alpha(\alpha+1)(\alpha+2)\ldots.(\alpha+n-1)}{n!} = \frac{(-1)^n}{n!}(\alpha)_n$$

4. $(\alpha)_{n+1} = \alpha(\alpha+1)(\alpha+2)\ldots.(\alpha+n+1-1)$

$$= \alpha.(\alpha+1)(\alpha+1+1)\ldots(\alpha+1+n-1) = \alpha.(\alpha+1)_n$$

5. $(\alpha)_{n+k} = \alpha(\alpha+1)(\alpha+2)\ldots(\alpha+k-1)(\alpha+k)\ldots(\alpha+n+k-1)$

$$= \{\alpha(\alpha+1)(\alpha+2)\ldots(\alpha+k-1)\}\{(\alpha+k)(\alpha+k+1)\ldots\ldots(\alpha+k+n-1)\}$$

$$= (\alpha)_k.(\alpha+k)_n \quad \text{if } k < n.$$

Also,

$$(\alpha)_{n+k} = \{\alpha(\alpha+1)(\alpha+2)\ldots(\alpha+n-1)\}\{(\alpha+n)(\alpha+n+1)\ldots.(\alpha+n+k-1)\}$$

$$= (\alpha)_n.(\alpha+n)_k \quad \text{if } k > n$$

Hence $(\alpha)_{n+k} = (\alpha)_k(\alpha+k)_n = (\alpha)_n.(\alpha+n)_k$

6. $(\alpha)_{k-n} = \alpha(\alpha+1)(\alpha+2)\dots(\alpha+k-n-1)$

$$= \frac{\alpha(\alpha+1)(\alpha+2)\dots(\alpha+k-n-1)(\alpha+k-n)(\alpha+k-n+1)\dots(\alpha+k-1)}{(\alpha+k-n)(\alpha+k-n+1)\dots(\alpha+k-1)}$$

$$= \frac{(\alpha)_k}{(-1)^n(1-\alpha-k)(1-\alpha-k+1)\dots(1-\alpha-k+n-1)}$$

$$= \frac{(-1)^n(\alpha)_k}{(1-\alpha-k)_n}$$

7. In (6) we have proved that

$$(\alpha)_{k-n} = \frac{(-1)^n(\alpha)_k}{(1-\alpha-k)_n}$$

Putting $k = 0$, we get $(\alpha)_{-n} = \dfrac{(-1)^n}{(1-\alpha)_n}, \quad \because (\alpha)_0 = 1$

8. $(-k)_n = (-k)(-k+1)(-k+2)\dots\dots(-k+n-1)$

$$= \frac{(-1)^n . k(k-1)(k-2)\dots(k-(n-1)).(k-n)\dots 2.1}{(k-n)(k-n-1)\dots 2.1} \text{ if } 0 \le n \le k$$

$$= \frac{(-1)^n k!}{(k-n)!} \text{ if } 0 \le n \le k$$

$$= 0 \text{ if } n > k, \quad \because \quad (-p)! = \infty, p > 0$$

5.3 Hypergeometric Series

The series defined by

$$1 + \frac{\alpha\beta}{\gamma}x + \frac{\alpha(\alpha+1)\beta(\beta+1)}{\gamma(\gamma+1)}\frac{x^2}{2!} + \dots\dots = \sum_{r=0}^{\infty}\frac{(\alpha)_r(\beta)_r}{(\gamma)_r}\frac{x^r}{r!} \qquad \dots(1)$$

is called the **hypergeometric series.**

Note : 1. Throughout this chapter α, β, γ are assumed to be real.

2. Above series is given the name hypergeometric series from the fact that, for $\alpha = 1, \gamma = \beta$, this series reduces to the geometric series

$$1 + x + x^2 + \dots = \sum_{n=0}^{\infty} x^n$$

The above series (1) converges absolutely if $|x| < 1$ and it is divergent for all $|x| > 1$. if $|x| = 1$ then the series converges absolutely if $\gamma - \alpha - \beta > 0$ *i.e.*, $\gamma > \alpha + \beta$

5.4 Hypergeometric Function

The function defined by the hypergeometric series $\sum\limits_{r=0}^{\infty} \frac{(\alpha)_r (\beta)_r}{(\gamma)_r} \frac{x^r}{r!}, |x| < 1$ is called the **hypergeometric function.** It is commonly denoted by the symbol ${}_2F_1(\alpha, \beta; \gamma; x)$ or simply $F(\alpha, \beta, \gamma, x)$

Thus $${}_2F_1(\alpha, \beta; \gamma; x) = \sum_{r=0}^{\infty} \frac{(\alpha)_r (\beta)_r}{(\gamma)_r} \frac{x^r}{r!} \qquad \ldots(1)$$

where 2 and 1 refer to the number of numerator and denominator parameters respectively, in its series representation. The semicolons separate the numerator parameter α and β (which are themselves separated by a comma), the denominator parameter γ and the argument x.

Note : 1. If $\gamma = 0$ or a negative integer, then the series (1) does not exist and so the function ${}_2F_1(\alpha, \beta; \gamma; x)$ is not defined.

2. If either α or β (or both) is zero or a negative integer, then the series is finite and thus converges for all x.

$\because$ If $\alpha = -m$ then

$(\alpha)_n = (-m)_n = 0$ when $n > m$

5.5 Different Forms of Hypergeometric Function

The hypergeometric function $F(\alpha, \beta, \gamma, x)$ can be put in the following forms as well

$$\begin{aligned} F(\alpha, \beta, \gamma, x) &= (1-x)^{\gamma-\alpha-\beta} F(\gamma-\alpha, \gamma-\beta; \gamma; x) \\ &= (1-x)^{-\alpha} F\left(\alpha, \gamma-\beta; \gamma; \frac{x}{x-1}\right) \\ &= (1-x)^{-\beta} F\left(\beta, \gamma-\alpha; \gamma; \frac{x}{x-1}\right) \end{aligned}$$

5.6 Confluent Hypergeometric Function (Kummer Function)

The function denoted by ${}_1F_1(\alpha; \beta; x)$ and defined by

$${}_1F_1(\alpha; \beta; x) = \sum_{r=0}^{\infty} \frac{(\alpha)_r}{(\beta)_r} \frac{x^r}{r!}$$

is called the **Confluent Hypergeometric Function** or **Kummer Function**

The Confluent Hypergeometric Function ${}_1F_1(\alpha\,;\beta\,;x)$ is also denoted by $M(\alpha,\beta,x)$

5.7 General Hypergeometric Function

The general hypergeometric function denoted by ${}_mF_n(\alpha_1,\alpha_2,\dots\alpha_m;\beta_1,\beta_2,\dots\beta_n;x)$ is defined by

$$ {}_mF_n(\alpha_1,\alpha_2,\dots\alpha_m;\beta_1,\beta_2,\dots\beta_n;x)=\sum_{r=0}^{\infty}\frac{(\alpha_1)_r(\alpha_2)_r\dots(\alpha_m)_r}{(\beta_1)_r(\beta_2)_r\dots(\beta_n)_r}\frac{x^r}{r!} $$

Another notation often used for general hypergeometric function is

$$ {}_mF_n\left[\begin{matrix}\alpha_1,\alpha_2,\dots\dots,\alpha_m\,; \\ \beta_1,\beta_2,\dots\dots,\beta_n\,;\end{matrix}\;x\right] $$

Note : 1. Confluent hypergeometric function (5.6) is special case of general hypergeometric function when $m=n=1$.

2. Hypergeometric function (5.4) is special case of general hypergeometric function when $m=2$ and $n=1$.

5.8 Symmetric Property of Hypergeometric Function

[Kanpur 2002, 03]

Hypergeometric function does not change if the parameters α and β are interchanged, keeping γ fixed *i.e.*, $F(\alpha,\beta;\gamma;x)=F(\beta,\alpha\,;\gamma;x)$

Proof: By the definition of hypergeometric function, we have

$$ F(\alpha,\beta;\gamma;x)=\sum_{r=0}^{\infty}\frac{(\alpha)_r(\beta)_r}{(\gamma)_r}\frac{x^r}{r!} $$

$$ =\sum_{r=0}^{\infty}\frac{(\beta)_r(\alpha)_r}{(\gamma)_r}\frac{x^r}{r!}=F(\beta,\alpha\,;\gamma;x) $$

5.9 Particular Cases of Hypergeometric Series

Here we give some well known series which can be denoted by hypergeometric function.

1. $e^x={}_1F_1(\alpha\,;\alpha\,;x)$

2. $(1-x)^{-1}={}_2F_1(\alpha,1;\alpha\,;x)={}_2F_1(1,\alpha\,;\alpha\,;x)\,,|x|<1$ **[Kanpur 2004]**

3. $(1-x)^{-\alpha}={}_2F_1(\alpha,\beta;\beta;x)={}_2F_1(\beta,\alpha\,;\beta;x)$

4. $(1+x)^n = {}_2F_1\,(-n, 1; 1; -x) = {}_2F_1\,(1, -n; 1; -x)$ **[Meerut 2011 (Sem. I)]**

5. $\log_e\,(1+x) = x\,{}_2F_1\,(1, 1; 2; -x)$

6. $\log_e\,(1-x) = -x\,{}_2F_1\,(1, 1; 2; x)$ **[Kanpur 2000]**

7. $\log\left(\frac{1+x}{1-x}\right) = 2x\,{}_2F_1\,(1/2, 1; 3/2; x^2) = 2x\,{}_2F_1\,(1, 1/2; 3/2; x^2)$

8. $\sin^{-1} x = x\,{}_2F_1\,(1/2, 1/2; 3/2; x^2)$

9. $\tan^{-1} x = x\,{}_2F_1\,(1/2, 1; 3/2; -x^2) = x\,{}_2F_1\,(1, 1/2; 3/2; -x^2)$

Proof: 1. $e^x = 1 + \frac{x}{1!} + \frac{x^2}{2!} + \frac{x^3}{3!} + \ldots$

$$= 1 + \frac{\alpha}{\alpha}\cdot\frac{x}{1!} + \frac{\alpha\,(\alpha+1)}{\alpha\,(\alpha+1)}\cdot\frac{x^2}{2!} + \ldots. = {}_1F_1,(\alpha; \alpha; x)$$

2. $(1-x)^{-1} = 1 + x + x^2 + x^3 + \ldots.$

$$= 1 + \frac{\alpha\,.1}{\alpha}\,\frac{x}{1!} + \frac{\alpha\,(\alpha+1)\,.1\,(1+1)}{\alpha\,(\alpha+1)}\,\frac{x^2}{2!} + \frac{\alpha\,(\alpha+1)\,(\alpha+2)\,.1\,(1+1)\,(1+2)}{\alpha\,(\alpha+1)\,(\alpha+2)}\,\frac{x^3}{3!} + \ldots.$$

$$= {}_2F_1\,(\alpha, 1; \alpha; x) = {}_2F_1\,(1, \alpha; \alpha; x)$$

(By symmetric property)

3. $(1-x)^{-\alpha} = 1 + (-\alpha)\,(-x) + \frac{(-\alpha)\,(-\alpha-1)}{2!}\,(-x)^2 + \frac{(-\alpha)\,(-\alpha-1)\,(-\alpha-2)}{3!}\,(-x)^3 + \ldots$

$$= 1 + \alpha\,x + \frac{\alpha\,(\alpha+1)}{2!}\,x^2 + \frac{\alpha\,(\alpha+1)\,(\alpha+2)}{3!}\,x^3 + \ldots.$$

$$= 1 + \frac{\alpha\,.\beta}{\beta}\,x + \frac{\alpha\,(\alpha+1)\,.\beta\,(\beta+1)}{\beta\,(\beta+1)}\,\frac{x^2}{2!} + \frac{\alpha\,(\alpha+1)\,(\alpha+2)\,.\,\beta\,(\beta+1)\,(\beta+2)}{\beta\,(\beta+1)\,(\beta+2)}\,\frac{x^3}{3!} + \ldots..$$

$$= {}_2F_1\,(\alpha, \beta; \beta; x) = {}_2F_1\,(\beta, \alpha; \beta; x)$$

(By symmetric property)

4. $(1+x)^n = 1 + n\,x + \frac{n\,(n-1)}{2!}\,x^2 + \frac{n\,(n-1)\,(n-2)}{3!}\,x^3 + \ldots.$

$$= 1 + \frac{(-n)\,.1}{1}\cdot\frac{(-x)}{1!} + \frac{(-n)\,(-n+1)\,.1\,(1+1)}{1\,(1+1)}\cdot\frac{(-x)^2}{2!}$$

$$+ \frac{(-n)\,(-n+1)\,(-n+2)\,.1\,(1+1)\,(1+2)}{1\,(1+1)\,(1+2)}\cdot\frac{(-x)^3}{3!} + \ldots.$$

$$= {}_2F_1\,(-n, 1; 1; -x) = {}_2F_1\,(1, -n; 1; -x)$$

(By symmetric property)

5. $$\log_e (1+x) = x - \frac{x^2}{2} + \frac{x^3}{3} - \frac{x^4}{4} + \dots$$

$$= x\left[1 - \frac{x}{2} + \frac{x^2}{3} - \frac{x^3}{4} + \dots\right]$$

$$= x\left[1 + \frac{1.1}{2}\cdot\frac{(-x)}{1!} + \frac{1\,(1+1).1\,(1+1)}{2\,(2+1)}\cdot\frac{(-x)^2}{2\,!} + \frac{1\,(1+1)\,(1+2)\,1\,(1+1)\,(1+2)}{2\,(2+1)\,(2+2)}\cdot\frac{(-x)^3}{3\,!} + \dots\right]$$

$$= x\;{}_2F_1\,(1, 1; 2\,; -x)$$

6. $$\log_e (1-x) = -x - \frac{x^2}{2} - \frac{x^3}{3} - \frac{x^4}{4} - \dots = -x\left[1 + \frac{x}{2} + \frac{x^2}{3} + \frac{x^3}{4} + \dots\right]$$

$$= -x\left[1 + \frac{1.1}{2}\cdot\frac{x}{1!} + \frac{1\,(1+1)\,.\,1\,(1+1)}{2\,(2+1)}\cdot\frac{x^2}{2\,!} + \frac{1\,(1+1)\,(1+2)\,.\,1(1+1)\,(1+2)}{2\,(2+1)\,(2+2)}\cdot\frac{x^3}{3\,!} + \dots\right]$$

$$= -x\;{}_2F_1\,(1, 1; 2\,; x)$$

7. $$\log\left(\frac{1+x}{1-x}\right) = 2\left(x + \frac{x^3}{3} + \frac{x^5}{5} + \dots\dots\right)$$

$$= 2x\left(1 + \frac{x^2}{3} + \frac{x^4}{5} + \dots\right)$$

$$= 2x\left[1 + \frac{(1/2).1}{3/2}\cdot\frac{x^2}{1!} + \frac{(1/2)\,(1/2+1)\,.\,1\,(1+1)}{(3/2)\,(3/2+1)}\cdot\frac{(x^2)^2}{2\,!} + \dots\right]$$

$$= 2x\;{}_2F_1\,(1/2, 1; 3/2\,; x^2) = 2x\;{}_2F_1\,(1, 1/2\,; 3/2\,; x^2) \qquad \text{(By symmetric property)}$$

8. $$\sin^{-1} x = x + 1^2\cdot\frac{x^3}{3\,!} + 1^2\cdot 3^2\cdot\frac{x^5}{5\,!} + 1^2\cdot 3^2\cdot 5^2\cdot\frac{x^7}{7!} + \dots$$

$$= x\left[1 + 1^2\cdot\frac{x^2}{3\,!} + 1^2\cdot 3^2\cdot\frac{x^4}{5\,!} + 1^2\cdot 3^2\cdot 5^2\cdot\frac{x^6}{7!} + \dots\right]$$

$$= x\left[1 + \frac{1/2\,.\,1/2}{3/2}\cdot\frac{x^2}{1!} + \frac{(1/2)\,(1/2+1)\,(1/2)\,(1/2+1)}{(3/2)\,(3/2+1)}\cdot\frac{(x^2)^2}{2\,!} + \dots\right]$$

$$= x\;{}_2F_1\,(1/2, 1/2\,; 3/2\,; x^2)$$

Aliter We have ${}_2F_1\,(\alpha, \beta; \gamma; x) = 1 + \dfrac{\alpha\,.\,\beta}{\gamma}\,\dfrac{x}{1!} + \dfrac{\alpha\,(\alpha+1)\,\beta\,(\beta+1)}{\gamma\,(\gamma+1)}\,\dfrac{x^2}{2\,!} + \dots$

Replacing α, β, γ, x by 1/2, 1/2, 3/2, x^2 respectively, we get

$$x \,. {}_2F_1\,(1/2, 1/2; 3/2; x^2)$$

$$= x\left[1 + \frac{1/2 \,.\, 1/2}{3/2}\,\frac{x^2}{1!} + \frac{(1/2)\,.\,(1/2+1)\,.\,1/2\,(1/2+1)}{(3/2)\,(3/2+1)}\,.\,\frac{(x^2)^2}{2\,!} + \ldots .\right]$$

$$= x + 1^2 \,.\, \frac{x^2}{3\,!} + 1^2 \,.\, 3^2 \,.\, \frac{x^5}{5\,!} + 1^2 \,.\, 3^2 \,.\, 5^2\, \frac{x^7}{7\,!} + \ldots .$$

9. $\tan^{-1} x = x - \dfrac{x^3}{3} + \dfrac{x^5}{5} - \dfrac{x^7}{7} + \ldots .$

$$= x\left[1 - \frac{x^2}{3} + \frac{x^4}{5} - \frac{x^6}{7} + \ldots\right]$$

$$= x\left[1 + \frac{1/2 \,.\, 1}{3/2}\,\frac{(-x^2)}{1!} + \frac{(1/2)\,(1/2+1)\,.\,1\,(1+1)}{(3/2)\,(3/2+1)}\,\frac{(-x)^2}{2\,!} + \ldots .\right]$$

$$= x\;{}_2F_1\,(1/2, 1; 3/2; -x^2) = x\;{}_2F_1\,(1, 1/2; 3/2; -x^2)$$

(By symmetric property)

Aliter : We have, ${}_2F_1\,(\alpha, \beta; \gamma; x) = 1 + \dfrac{\alpha \,.\, \beta}{\gamma}\,\dfrac{x}{1!} + \dfrac{\alpha\,(\alpha+1)\,.\,\beta\,(\beta+1)}{\gamma\,(\gamma+1)}\,.\,\dfrac{x^2}{2\,!} + \ldots .$

Replacing α, β, γ, x by 1/2, 1, 3/2, $-x^2$, we get

$$x \,. {}_2F_1\,(1/2, 1; 3/2; -x^2)$$

$$= x\left[1 + \frac{1/2 \,.\, 1}{3/2}\,.\,\frac{(-x^2)}{1!} + \frac{(1/2)\,(1/2+1)\,.\,1\,(1+1)}{(3/2)\,(3/2+1)}\cdot\frac{(-x^2)^2}{2\,!} + \ldots .\right]$$

$$= x - \frac{x^3}{3} + \frac{x^5}{5} - \frac{x^7}{7} + \ldots .$$

5.10 Gauss's Hypergeometric Equation or Gauss's Equation or Hypergeometric Equation

The differential equation

$$x\,(1-x)\,\frac{d^2 y}{dx^2} + \{\gamma - (\alpha + \beta + 1)\,x\}\,\frac{dy}{dx} - \alpha\beta\; y = 0$$

is called **Gauss's hypergeometric equation** or **Gauss's equation** or **hypergeometric equation.**

5.11 Solution of the Hypergeometric Equation

[Meerut 2010 (Sem. I); Kanpur 2006]

Hypergeometric equation is

$$x(1-x)\frac{d^2y}{dx^2}+\{\gamma-(\alpha+\beta+1)x\}\frac{dy}{dx}-\alpha\beta y=0 \qquad \ldots(1)$$

Dividing by $x(1-x)$, we get $\dfrac{d^2y}{dx^2}+\dfrac{\gamma-(\alpha+\beta+1)x}{x(1-x)}\dfrac{dy}{dx}-\dfrac{\alpha\beta}{x(1-x)}y=0$

Comparing with $\dfrac{d^2y}{dx^2}+P(x)\dfrac{dy}{dx}+Q(x)\,y=0$, we get

$$P(x)=\frac{\gamma-(\alpha+\beta+1)x}{x(1-x)} \text{ and } Q(x)=-\frac{\alpha\beta}{x(1-x)}$$

Since $P(x)$ and $Q(x)$ are not finite at $x=0$ and $x=1$, and $x\,P(x)$ and $x^2Q(x)$ are both finite and so analytic at $x=0$ also $(x-1)\,P(x)$ and $(x-1)^2\,Q(x)$ are also both finite and so analytic at $x=1$.

Thus the points $x=0$ and $x=1$ are both regular singular points of (1).

To find series solution of (1) near $x=0$ **[Kanpur 2006]**

Let $$y=\sum_{r=0}^{\infty}C_r x^{m+r},\quad C_0\neq 0 \qquad \ldots(2)$$

be series solution of (1) near $x=0$

Diff. (2), we get

$$\frac{dy}{dx}=\sum_{r=0}^{\infty}C_r(m+r)\,x^{m+r-1} \text{ and } \frac{d^2y}{dx^2}=\sum_{r=0}^{\infty}C_r\,(m+r)(m+r-1)\,x^{m+r-2}$$

Substituting in (1), we get

$$\sum_{r=0}^{\infty}C_r\,[(x-x^2)(m+r)(m+r-1)\,x^{m+r-2}$$
$$+\{\gamma-(\alpha+\beta+1)x\}(m+r)\,x^{m+r-1}-\alpha\beta\,x^{m+r}]=0$$

or $$\sum_{r=0}^{\infty}C_r\,[\{(m+r)(m+r-1)+\gamma(m+r)\}\,x^{m+r-1}$$
$$-\{(m+r)(m+r-1)+(\alpha+\beta+1)(m+r)+\alpha\beta\}\,x^{m+r}]=0$$

or $$\sum_{r=0}^{\infty} C_r \left[(m+r)(m+r+\gamma-1)\, x^{m+r-1} - \{(m+r)^2 + (\alpha+\beta)(m+r) + \alpha\beta\}\, x^{m+r}\right] = 0$$

or $$\sum_{r=0}^{\infty} C_r \left[(m+r)(m+r+\gamma-1)\, x^{m+r-1} - (m+r+\alpha)(m+r+\beta)\, x^{m+r}\right] = 0 \quad \ldots(3)$$

which is an identity, so we can equate to zero the coefficients of various powers of x,

Equating to zero the coefficient of lowest power of x *i.e.*, of x^{m-1}, the *indicial equation* is :

$$C_0 m (m+\gamma-1) = 0 \Rightarrow m = 0 \text{ or } m = 1-\gamma$$

which are unequal and not differing by an integer as γ is not an integer.

Also equating to zero the coefficient of x^{m+r-1}, we get

$$C_r (m+r)(m+r+\gamma-1) - (m+r-1+\alpha)(m+r-1+\beta)\, C_{r-1} = 0$$

$$\Rightarrow \quad C_r = \frac{(m+r-1+\alpha)(m+r-1+\beta)}{(m+r)(m+r+\gamma-1)}\, C_{r-1}, \quad \text{for } r \geq 1 \quad \ldots(4)$$

Case I. When $m = 0$ Putting $m = 0$, in (4), we get

$$C_r = \frac{(\alpha+r-1)(\beta+r-1)}{r(\gamma+r-1)}\, C_{r-1}, \quad \text{for } r \geq 1$$

Putting $r = 1, 2, 3$ .... ,

$$C_1 = \frac{\alpha . \beta}{1 . \gamma} C_0,\ C_2 = \frac{(\alpha+1)(\beta+1)}{2(\gamma+1)} C_1 = \frac{\alpha(\alpha+1)\beta(\beta+1)}{2!\,\gamma(\gamma+1)} C_0$$

$$C_3 = \frac{(\alpha+2)(\beta+2)}{3(\gamma+2)} C_2 = \frac{\alpha(\alpha+1)(\alpha+2)\beta(\beta+1)(\beta+2)}{3!\,\gamma(\gamma+1)(\gamma+2)} C_0 \text{ and so on.}$$

Putting in (2), we get

$$y = C_0 \left[1 + \frac{\alpha . \beta}{\gamma} \frac{x}{1!} + \frac{\alpha(\alpha+1)\beta(\beta+1)}{\gamma(\gamma+1)} \frac{x^2}{2!} + \frac{\alpha(\alpha+1)(\alpha+2)\beta(\beta+1)(\beta+2)}{\gamma(\gamma+1)(\gamma+2)} \frac{x^3}{3!} + \ldots\right]$$

or $y = C_0\, {}_2F_1(\alpha, \beta; \gamma; x)$

Taking $C_0 = 1$, we see that $\quad y = {}_2F_1(\alpha, \beta; \gamma; x) \quad \ldots(5)$

called hypergeometric function is one solution of (1).

Case II. When $m = 1 - \gamma$

Putting $m = 1 - \gamma$ in (4), we get

$$C_r = \frac{(1-\gamma+r-1+\alpha)\,(1-\gamma+r-1+\beta)}{(1-\gamma+r)\,(1-\gamma+r+\gamma-1)}\,C_{r-1}$$

$$\Rightarrow \qquad C_r = \frac{(\alpha'+r-1)\,(\beta'+r-1)}{r\,(\gamma'+r-1)}\,C_{r-1},\ r \geq 1 \qquad \text{...(6)}$$

where $\alpha' = 1-\gamma+\alpha$, $\beta' = 1-\gamma+\beta$ and $\gamma' = 2-\gamma$

Putting $r = 1, 2, 3, \text{.........}$ in (6), we get

$$C_1 = \frac{\alpha', \beta'}{1.\gamma'}\,C_0,\ C_2 = \frac{(\alpha'+1)\,(\beta'+1)}{2\,(\gamma'+1)}\,C_1 = \frac{\alpha'\,(\alpha'+1)\,.\,\beta'\,(\beta'+1)}{2\,!\,\gamma'\,(\gamma'+1)}\,C_0$$

$$C_3 = \frac{(\alpha'+2)\,(\beta'+2)}{3\,(\gamma'+2)}\,C_2 = \frac{\alpha'\,(\alpha'+1)\,(\alpha'+2)\,.\,\beta'\,(\beta'+1)(\beta'+2)}{3\,!\,\gamma'\,(\gamma'+1)\,(\gamma'+2)}\,C_0, \text{ and so on.}$$

Putting in (2), we get

$$y = C_0 x^{1-\gamma}\left[1 + \frac{\alpha'\,.\,\beta'}{\gamma'}\cdot\frac{x}{1!} + \frac{\alpha'\,(\alpha'+1)\,\beta'\,(\beta'+1)}{\gamma'\,(\gamma'+1)}\cdot\frac{x^2}{2\,!} + \frac{\alpha'\,(\alpha'+1)\,(\alpha'+2)\,.\,\beta'\,(\beta'+1)(\beta'+2)}{\gamma'\,(\gamma'+1)\,(\gamma'+2)}\,\frac{x^3}{3\,!} + \ldots\right]$$

or $\qquad y = C_0 x^{1-\gamma}\ {}_2F_1\,(\alpha', \beta'; \gamma'; x)$

or $\qquad y = C_0 x^{1-\gamma}\ {}_2F_1\,(1-\gamma+\alpha, 1-\gamma+\beta; 2-\gamma; x)$

Taking $C_0 = 1,\ y = x^{1-\gamma}\ {}_2F_1\,(1-\gamma+\alpha, 1-\gamma+\beta; 2-\gamma; x)$ ...(7)

Which is another independent solution of (1).

Hence the general solution of (1) near $x = 0$ is

$$y = a.{}_2F_1\,(\alpha, \beta; \gamma; x) + b.x^{1-\gamma}\ {}_2F_1\,(1-\gamma+\alpha, 1-\gamma+\beta, 2-\gamma, x) \qquad \text{...(8)}$$

where a and b are arbitrary constants.

To find series solution of (1) near $x = 1$.

To find series solution of diff. equation (1) near $x = 1$ *i.e.*, in powers of $x - 1$, we change the independent variable from x to z, by the substitution

$$1 - x = z, \text{ so that } \frac{dz}{dx} = -1, \frac{dy}{dx} = \frac{dy}{dz}\frac{dz}{dx} = -\frac{dy}{dz}$$

and $$\frac{d^2y}{dx^2} = \frac{d}{dx}\left(\frac{dy}{dx}\right) = \frac{d}{dx}\left(-\frac{dy}{dz}\right) = -\frac{d^2y}{dz^2}\cdot\frac{dz}{dx} = \frac{d^2y}{dz^2}$$

∴ Diff., equation (1), reduces to

$$(1-z)\,z\,.\frac{d^2y}{dz^2} + \{\gamma - (\alpha+\beta+1)(1-z)\}\left(-\frac{dy}{dz}\right) - \alpha\beta y = 0$$

or $$z(1-z)\frac{d^2y}{dz^2} + \{(\alpha+\beta-\gamma+1) - (\alpha+\beta+1)\,z\}\frac{dy}{dz} - \alpha\beta y = 0 \qquad \ldots(9)$$

which is identical with (1) with γ replaced by $\alpha+\beta-\gamma+1$ and

Hence from (8), solution of (9) is

$$y = a.{}_2F_1(\alpha,\beta;\alpha+\beta-\gamma+1;z) + b\,.\,z^{1-(\alpha+\beta-\gamma+1)}.$$
$$_2F_1(\gamma-\beta,\gamma-\alpha,\gamma-\alpha-\beta+1;z)$$

⇒ Solution of (1) near $x = 1$ is

$$y = a.{}_2F_1(\alpha,\beta;\alpha+\beta-\gamma+1;1-x) + b(1-x)^{\gamma-\alpha-\beta}.$$
$$_2F_1(\gamma-\alpha,\gamma-\beta;\gamma-\alpha-\beta+1;1-x) \quad \ldots(10)$$

5.12 Derivatives of Hypergeometric Functions

We have, $$_2F_1(\alpha,\beta;\gamma;x) = \sum_{n=0}^{\infty}\frac{(\alpha)_n(\beta)_n}{(\gamma)_n}\cdot\frac{x^n}{n!}$$

Differentiating both sides, w.r.t. x

$$\frac{d}{dx}\,{}_2F_1(\alpha,\beta;\gamma;x) = \sum_{n=0}^{\infty}\frac{(\alpha)_n(\beta)_n}{(\gamma)_n}\cdot\frac{n\,x^{n-1}}{n!}$$
$$= \sum_{n=1}^{\infty}\frac{(\alpha)_n(\beta)_n}{(\gamma)_n}\cdot\frac{x^{n-1}}{(n-1)!}$$
$$= \sum_{m=0}^{\infty}\frac{(\alpha)_{m+1}(\beta)_{m+1}}{(\gamma)_{m+1}}\cdot\frac{x^m}{m!}, \quad \text{Taking } n-1 = m$$

Since $$(\alpha)_{m+1} = \alpha(\alpha+1)(\alpha+2)\ldots.(\alpha+m+1-1)$$
$$= \alpha\,.(\alpha+1)(\alpha+2)\ldots.(\alpha+1+m-1)$$
$$= \alpha(\alpha+1)_m \qquad \ldots(1)$$

$$\therefore \qquad \frac{d}{dx}\,{}_2F_1(\alpha,\beta;\gamma;x)=\frac{\alpha\beta}{\gamma}\sum_{m=0}^{\infty}\frac{(\alpha+1)_m(\beta+1)_m}{(\gamma+1)_m}\cdot\frac{x^m}{m!} \qquad \ldots(2)$$

$$\Rightarrow \qquad \frac{d}{dx}\,{}_2F_1(\alpha,\beta;\gamma;x)=\frac{(\alpha)_1\cdot(\beta)_1}{(\gamma)_1},\ {}_2F_1(\alpha+1,\beta+1;\gamma+1;x)$$

$\because \qquad (\alpha)_1=\alpha$ **etc.**

[Kanpur 2005; Kurukshetra 2006; Garhwal 2005]

Differentiating again

$$\frac{d^2}{dx^2}\,{}_2F_1(\alpha,\beta;\gamma;x)=\frac{\alpha\beta}{\gamma}\sum_{m=1}^{\infty}\frac{(\alpha+1)_m\cdot(\beta+1)_m}{(\gamma+1)_m}\cdot\frac{mx^{m-1}}{m!}$$

$$=\frac{\alpha\beta}{\gamma}\sum_{m=1}^{\infty}\frac{(\alpha+1)_m\cdot(\beta+1)_m}{(\gamma+1)_m}\cdot\frac{x^{m-1}}{(m-1)!}$$

$$=\frac{\alpha\beta}{\gamma}\sum_{n=0}^{\infty}\frac{(\alpha+1)_{n+1}\cdot(\beta+1)_{n+1}}{(\gamma+1)_{n+1}}\cdot\frac{x^n}{n!} \qquad \text{Taking } m-1=n$$

$$=\frac{\alpha\beta}{\gamma}\sum_{n=0}^{\infty}\frac{(\alpha+1)(\alpha+2)_n(\beta+1)(\beta+2)_n}{(\gamma+1)(\gamma+2)_n}\cdot\frac{x^n}{n!}$$

$[\because$ From (1), $(\alpha+1)_{n+1}=(\alpha+1)(\alpha+2)_n)]$

$$=\frac{\alpha(\alpha+1)\beta(\beta+1)}{\gamma(\gamma+1)}\cdot\sum_{n=0}^{\infty}\frac{(\alpha+2)_n\cdot(\beta+2)_n}{(\gamma+2)_n}\cdot\frac{x^n}{n!} \qquad \ldots(3)$$

$$\Rightarrow \qquad \frac{d^2}{dx^2}\,{}_2F_1(\alpha,\beta;\gamma;x)=\frac{(\alpha)_2\cdot(\beta)_2}{(\gamma)_2}\,{}_2F_1(\alpha+2,\beta+2;\gamma+2;x)$$

$\because \qquad (\alpha)_2=\alpha(\alpha+2-1)=\alpha(\alpha+1)$ **etc.**

5.13 n-th Derivative of Hypergeometric Function

To Prove $\dfrac{d^n}{dx^n}\,{}_2F_1(\alpha,\beta;\gamma;x)=\dfrac{(\alpha)_n(\beta)_n}{(\gamma)_n}\,{}_2F_1(\alpha+n,\beta+n;\gamma+n;x) \qquad \ldots(1)$

where *n* is a positive integer. **[Meerut 2010 (Sem. I)]**

Proof: In 5.12 we have proved that

$$\frac{d}{dx}\,{}_2F_1(\alpha,\beta;\gamma;x)=\frac{(\alpha)_1(\beta)_1}{(\gamma)_1}\,{}_2F_1(\alpha+1,\beta+1;\gamma+1;x) \qquad \ldots(2)$$

i.e., (1) is true for $n=1$

Now we assume that (1) is true for a positive integer $m<n$, then

$$\frac{d^m}{dx^m}\,{}_2F_1(\alpha,\beta;\gamma;x)=\frac{(\alpha)_m(\beta)_m}{(\gamma)_m}\,{}_2F_1(\alpha+m,\beta+m;\gamma+m;x)$$

Differentiating both sides, w.r.t. x, we get

$$\frac{d^{m+1}}{dx^{m+1}}\,{}_2F_1(\alpha,\beta;\gamma;x)=\frac{(\alpha)_m(\beta)_m}{(\gamma)_m}\cdot\frac{d}{dx}\,{}_2F_1(\alpha+m,\beta+m;\gamma+m;x)$$

$$=\frac{(\alpha)_m(\beta)_m}{(\gamma)_m}\cdot\frac{(\alpha+m)(\beta+m)}{(\gamma+m)}\;{}_2F_1(\alpha+m+1,\beta+m+1;\gamma+m+1;x)$$

(using (1) for $\alpha+m,\beta+m,\gamma+m$ in place of α,β,γ respectively and with $(\alpha)_1=\alpha$)

$$=\frac{(\alpha)_{m+1}(\beta)_{m+1}}{(\gamma)_{m+1}}\cdot\;{}_2F_1(\alpha+m+1,\beta+m+1;\gamma+m+1;x) \qquad ...(3)$$

$$\because \quad (\alpha)_m\,.\,(\alpha+m)=(\alpha)_{m+1}$$

from (3) it follows that (1) is true for $m+1$.

i.e., assuming that (1) is true for positive integer $m<n$, (1) is also true for $m+1$.

But from (2), it is obvious that (1) is true for $n=1$, hence by mathematical induction (1) is true for all positive integral value of n.

5.14 Derivatives of Hypergeometric Function at x = 0

1. $\frac{d}{dx}\,{}_2F_1(\alpha\;\;\beta;\gamma;0)=1$
2. $\frac{d^2}{dx^2}\,{}_2F_1(\alpha,\beta;\gamma;0)=\frac{\alpha.\beta}{\gamma}=\frac{(\alpha)_1(\beta)_1}{(\gamma)_1}$
3. $\frac{d^n}{dx^n}\,{}_2F_1(\alpha,\beta;\gamma;0)=\frac{(\alpha)_n(\beta)_n}{(\gamma)_n}$

Proof: We have,

$${}_2F_1(\alpha,\beta;\gamma;x)=\sum_{n=0}^{\infty}\frac{(\alpha)_n\cdot(\beta)_n}{(\gamma)_n}\cdot\frac{x^n}{n!}$$

$$=\frac{(\alpha)_0\cdot(\beta)_0}{(\gamma)_0}\cdot\frac{1}{0!}+\frac{(\alpha)_1\cdot(\beta)_1}{(\gamma)_1}\cdot\frac{x}{1!}+\frac{(\alpha)_2\cdot(\beta)_2}{(\gamma)_2}\cdot\frac{x^2}{2!}+\ldots+\frac{(\alpha)_n\cdot(\beta)_n}{(\gamma)_n}\cdot\frac{x^n}{n!}+\ldots$$

$$\therefore \quad \frac{d}{dx}\,{}_2F_1(\alpha,\beta;\gamma;x) = 0 + \frac{(\alpha)_1(\beta)_1}{(\gamma)_1}\cdot 1 + \frac{(\alpha)_2(\beta)_2}{(\gamma)_2}\cdot\frac{2x}{2!} + \frac{(\alpha)_3(\beta)_3}{(\gamma)_3}\cdot\frac{3x^2}{3!} + \ldots$$

$$+ \frac{(\alpha)_n(\beta)_n}{(\gamma)_n}\cdot\frac{n\,x^{n-1}}{n!} + \ldots.$$

$$\frac{d^2}{dx^2}\,{}_2F_1(\alpha,\beta;\gamma;x) = 0 + \frac{(\alpha)_2(\beta)_2}{(\gamma)_2}\cdot 1 + \frac{(\alpha)_3(\beta)_3}{(\gamma)_3}\cdot\frac{3.2x}{3!} + \ldots.$$

$$+ \frac{(\alpha)_n(\beta)_n}{(\gamma)_n}\cdot\frac{n(n-1)\,x^{n-2}}{n!} + \ldots$$

Proceeding similarly

$$\frac{d^n}{dx^n}\,{}_2F_1(\alpha,\beta;\gamma;x) = 0 + \frac{(\alpha)_n(\beta)_n}{(\gamma)_n}\cdot\frac{n!}{n!} + \frac{(\alpha)_{n+1}(\beta)_{n+1}}{(\gamma)_{n+1}}\cdot\frac{(n+1)\,n\,(n-1)\ldots 2}{n!}\,x + \ldots$$

Putting $x = 0$ we get

$${}_2F_1(\alpha,\beta;\gamma;x) = \frac{(\alpha)_0(\beta)_0}{(\gamma)_0} = 1$$

$$\frac{d}{dx}\,{}_2F_1(\alpha,\beta;\gamma;0) = \frac{(\alpha)_1(\beta)_1}{(\gamma)_1} \quad \text{or} \quad \frac{\alpha\beta}{\gamma}$$

$$\frac{d^2}{dx^2}\,{}_2F_1(\alpha,\beta;\gamma;0) = \frac{(\alpha)_2(\beta)_2}{(\gamma)_2} \quad \text{or} \quad \frac{\alpha(\alpha+1)\beta(\beta+1)}{\gamma(\gamma+1)}$$

$$\frac{d^n}{dx^n}\,{}_2F_1(\alpha,\beta;\gamma;0) = \frac{(\alpha)_n(\beta)_n}{(\gamma)_n}$$

5.15 Integral Formula for Hypergeometric Function

If $|x| < 1$ ***and*** $\gamma > \beta > 0$***, then***

$${}_2F_1(\alpha,\beta;\gamma;x) = \frac{\Gamma(\gamma)}{\Gamma(\beta)\,\Gamma(\gamma-\beta)}\int_0^1 t^{\beta-1}(1-t)^{\gamma-\beta-1}(1-xt)^{-\alpha}\,dt$$

or
$${}_2F_1(\alpha,\beta;\gamma;x) = \frac{1}{B(\beta,\gamma-\beta)}\int_0^1 t^{\beta-1}(1-t)^{\gamma-\beta-1}(1-xt)^{-\alpha}\,dt$$

[Rajasthan 2000, 09; Garhwal 2004; Kanpur 2004, 07; Purvanchal 2007]

Proof: We have the hypergeometric function

$${}_2F_1(\alpha,\beta;\gamma;x) = \sum_{n=0}^{\infty}\frac{(\alpha)_n(\beta)_n}{(\gamma)_n}\cdot\frac{x^n}{n!} \qquad \ldots(1)$$

where $(\alpha)_n = \alpha(\alpha+1)(\alpha+2)\ldots.(\alpha+n-1)$

$$= \frac{1.2 \ldots. (\alpha - 1)\, \alpha\, (\alpha + 1) \ldots. (\alpha + n - 1)}{1.2 \ldots\ldots (\alpha - 1)} = \frac{\Gamma(\alpha + n)}{\Gamma(\alpha)}$$

$$\therefore \qquad \frac{(\beta)_n}{(\gamma)_n} = \frac{\Gamma(\beta + n)}{\Gamma(\beta)} \cdot \frac{\Gamma(\gamma)}{\Gamma(\gamma + n)} = \frac{\Gamma(\gamma)\, \Gamma(\beta + n)}{\Gamma(\beta)\, \Gamma(\gamma + n)} \cdot \frac{\Gamma(\gamma - \beta)}{\Gamma(\gamma - \beta)}$$

$$= \frac{\Gamma(\gamma)}{\Gamma(\beta)} \cdot \frac{\Gamma(\beta + n)\, \Gamma(\gamma - \beta)}{\Gamma(\beta + n + \gamma - \beta)} \cdot \frac{1}{\Gamma(\gamma - \beta)}$$

$$= \frac{\Gamma(\gamma)}{\Gamma(\beta)\, \Gamma(\gamma - \beta)} \cdot \mathrm{B}(\beta + n, \gamma - \beta)$$

$$= \frac{\Gamma(\gamma)}{\Gamma(\beta)\, \Gamma(\gamma - \beta)} \cdot \int_0^1 t^{\beta + n - 1} \cdot (1 - t)^{\gamma - \beta - 1}\, dt$$

$\therefore$ From (1) ${}_2F_1 (\alpha, \beta; \gamma; x)$

$$= \sum_{n=0}^{\infty} \frac{\Gamma(\gamma)}{\Gamma(\beta)\, \Gamma(\gamma - \beta)} \int_0^1 t^{\beta + n - 1} (1 - t)^{\gamma - \beta - 1} \cdot (\alpha)_n \cdot \frac{x^n}{n!}\, dt$$

$$= \sum_{n=0}^{\infty} \frac{\Gamma(\gamma)}{\Gamma(\beta)\, \Gamma(\gamma - \beta)} \int_0^1 t^{\beta - 1} (1 - t)^{\gamma - \beta - 1} (\alpha)_n \cdot \frac{(tx)^n}{n!}\, dt$$

$$= \frac{\Gamma(\gamma)}{\Gamma(\beta)\, \Gamma(\gamma - \beta)} \int_0^1 t^{\beta - 1} (1 - t)^{\gamma - \beta - 1} \left\{ \sum_{n=0}^{\infty} (\alpha)_n \cdot \frac{(xt)^n}{n!} \right\} dt$$

$$= \frac{\Gamma(\gamma)}{\Gamma(\beta)\, \Gamma(\gamma - \beta)} \int_0^1 t^{\beta - 1} (1 - t)^{\gamma - \beta - 1} \cdot \left\{ (\alpha)_0 \,.\, 1 + (\alpha)_1 \cdot \frac{xt}{1!} + (\alpha)_2 \cdot \frac{(xt)^2}{2!} + \ldots. \right\} dt$$

$$= \frac{\Gamma(\gamma)}{\Gamma(\beta)\, \Gamma(\gamma - \beta)} \int_0^1 t^{\beta - 1} (1 - t)^{\gamma - \beta - 1} \cdot \left\{ 1 + \alpha \,.\, xt + \alpha\, (\alpha + 1) \,.\, \frac{(xt)^2}{2!} + \ldots \right\} dt$$

or
$$ {}_2F_1 (\alpha, \beta; \gamma; x) = \frac{\Gamma(\gamma)}{\Gamma(\beta)\, \Gamma(\gamma - \beta)} \cdot \int_0^1 t^{\beta - 1} (1 - t)^{\gamma - \beta - 1} (1 - xt)^{-\alpha}\, dt$$

which is the required integral formula.

Which can also be written as

$${}_2F_1 (\alpha, \beta; \gamma; x) = \frac{1}{B\, (\beta, \gamma - \beta)} \int_0^1 t^{\beta - 1} (1 - t)^{\gamma - \beta - 1} (1 - xt)^{-\alpha}\, dt$$

Integral formula for hypergeometric function is valid for $|x| < 1, \gamma > \beta > 0$.

5.16 Kummer's Theorem (For Hypergeometric Function)

$$ {}_2F_1(\alpha,\beta;\beta-\alpha+1;-1)=\frac{\Gamma(\beta-\alpha+1)\,\Gamma(\beta/2+1)}{\Gamma(\beta+1)\,\Gamma(\beta/2-\alpha+1)} $$ **[Purvanchal 2005]**

Proof: The integral formula for hypergeometric function is

$$ {}_2F_1(\alpha,\beta;\gamma;x)=\frac{\Gamma(\gamma)}{\Gamma(\beta)\,\Gamma(\gamma-\beta)}\cdot\int_0^1 t^{\beta-1}(1-t)^{\gamma-\beta-1}(1-xt)^{-\alpha}\,dt $$

Putting $x=-1$ and $\gamma=\beta-\alpha+1$, we get

$$ {}_2F_1(\alpha,\beta;\beta-\alpha+1;-1)=\frac{\Gamma(\beta-\alpha+1)}{\Gamma(\beta)\,\Gamma(1-\alpha)}\int_0^1 t^{\beta-1}(1-t)^{-\alpha}(1+t)^{-\alpha}\,dt $$

$$ =\frac{\Gamma(\beta-\alpha+1)}{\Gamma(\beta)\,\Gamma(1-\alpha)}\int_0^1 t^{\beta-1}(1-t^2)^{-\alpha}\,dt $$

$$ =\frac{\Gamma(\beta-\alpha+1)}{\Gamma(\beta)\,\Gamma(1-\alpha)}\int_0^1 z^{(\beta-1)/2}(1-z)^{-\alpha}\cdot\frac{1}{2}z^{-1/2}\,dz $$

Putting $t^2=z\,,\ t=z^{1/2}$ and $dt=\frac{1}{2}z^{-1/2}\,dz$

$$ =\frac{1}{2}\frac{\Gamma(\beta-\alpha+1)}{\Gamma(\beta)\,\Gamma(1-\alpha)}\int_0^1 z^{\beta/2-1}(1-z)^{(1-\alpha)-1}\,dz $$

$$ =\frac{1}{2}\frac{\Gamma(\beta-\alpha+1)}{\Gamma(\beta)\,\Gamma(1-\alpha)}.\mathrm{B}(\beta/2,1-\alpha) $$

$$ =\frac{1}{2}\frac{\Gamma(\beta-\alpha+1)}{\Gamma(\beta)\,\Gamma(1-\alpha)}\cdot\frac{\Gamma(\beta/2).\Gamma(1-\alpha)}{\Gamma(\beta/2+1-\alpha)} $$

$$ =\frac{\Gamma(\beta-\alpha+1).(\beta/2)\,\Gamma(\beta/2)}{\beta\Gamma(\beta)\,\Gamma(\beta/2-\alpha+1)} $$

or $$ {}_2F_1(\alpha,\beta;\beta-\alpha+1;-1)=\frac{\Gamma(\beta-\alpha+1).\Gamma(\beta/2+1)}{\Gamma(\beta+1)\,\Gamma(\beta/2-\alpha+1)} $$

which is the required Kummer's theorem (or formula).

5.17 Gauss's Theorem

$$ {}_2F_1(\alpha,\beta;\gamma;1)=\frac{\Gamma(\gamma).\Gamma(\gamma-\beta-\alpha)}{\Gamma(\gamma-\alpha).\Gamma(\gamma-\beta)} $$

[Kanpur 2005, 06, 07; Meerut 2001, 03, 12 (Sem. I); Rajasthan 2000, 07, 08]

Proof: The integral formula for hypergeometric function is

$${}_2F_1(\alpha, \beta; \gamma; x) = \frac{\Gamma(\gamma)}{\Gamma(\beta)\,\Gamma(\gamma-\beta)} \int_0^1 t^{\beta-1}(1-t)^{\gamma-\beta-1}(1-xt)^{-\alpha}\,dt$$

Putting $x = 1$, we get

$${}_2F_1(\alpha, \beta; \gamma; 1) = \frac{\Gamma(\gamma)}{\Gamma(\beta)\,\Gamma(\gamma-\beta)} \int_0^1 t^{\beta-1}(1-t)^{\gamma-\beta-1}(1-t)^{-\alpha}\,dt$$

$$= \frac{\Gamma(\gamma)}{\Gamma(\beta)\,\Gamma(\gamma-\beta)} \int_0^1 t^{\beta-1}(1-t)^{(\gamma-\beta-\alpha)-1}\,dt$$

$$= \frac{\Gamma(\gamma)}{\Gamma(\beta)\,\Gamma(\gamma-\beta)}\, B(\beta, \gamma-\beta-\alpha)$$

$$= \frac{\Gamma(\gamma)}{\Gamma(\beta)\,\Gamma(\gamma-\beta)} \cdot \frac{\Gamma(\beta).\Gamma(\gamma-\beta-\alpha)}{\Gamma(\beta+\gamma-\beta-\alpha)}$$

or $${}_2F_1(\alpha, \beta; \gamma; x) = \frac{\Gamma(\gamma).\Gamma(\gamma-\beta-\alpha)}{\Gamma(\gamma-\alpha)\,\Gamma(\gamma-\beta)}$$

which is the required Gauss's theorem.

5.18 Vandermonde's Theorem

$${}_2F_1(-n, \beta; \gamma; 1) = \frac{(\gamma-\beta)_n}{(\gamma)_n}$$ **[Kanpur 2000, 01; Meerut 2001, 03]**

Proof: The integral formula for hypergeometric function is

$${}_2F_1(\alpha, \beta; \gamma; x) = \frac{\Gamma(\gamma)}{\Gamma(\beta)\,\Gamma(\gamma-\beta)} \int_0^1 t^{\beta-1}(1-t)^{\gamma-\beta-1}(1-xt)^{-\alpha}\,dt$$

Putting $x = 1$ and $\alpha = -n$, we have

$${}_2F_1(-n, \beta; \gamma; 1) = \frac{\Gamma(\gamma)}{\Gamma(\beta)\,\Gamma(\gamma-\beta)} \int_0^1 t^{\beta-1}(1-t)^{\gamma-\beta-1}(1-t)^{n}\,dt$$

$$= \frac{\Gamma(\gamma)}{\Gamma(\beta)\,\Gamma(\gamma-\beta)} \int_0^1 t^{\beta-1}(1-t)^{(\gamma+n-\beta)-1}\,dt$$

$$= \frac{\Gamma(\gamma)}{\Gamma(\beta)\,\Gamma(\gamma-\beta)}\, B(\beta, \gamma+n-\beta)$$

$$= \frac{\Gamma(\gamma)}{\Gamma(\beta)\,\Gamma(\gamma-\beta)} \cdot \frac{\Gamma(\beta).\Gamma(\gamma+n-\beta)}{\Gamma(\beta+\gamma+n-\beta)} = \frac{\Gamma(\gamma)\,\Gamma(\gamma-\beta+n)}{\Gamma(\gamma-\beta)\,\Gamma(\gamma+n)}$$

$$= \frac{\Gamma(\gamma)\,(\gamma-\beta+n-1)\,(\gamma-\beta+n-2)\ldots(\gamma-\beta)\,\Gamma(\gamma-\beta)}{\Gamma(\gamma-\beta)\,.\,(\gamma+n-1)\,(\gamma+n-2)\,\ldots.\,\gamma\,.\,\Gamma(\gamma)}$$

$$= \frac{(\gamma-\beta)\,(\gamma-\beta+1)\ldots(\gamma-\beta+n-2)\,(\gamma-\beta+n-1)}{\gamma\,(\gamma+1)\,\ldots.\,(\gamma+n-2)\,(\gamma+n-1)}$$

or $\;{}_2F_1\,(-n,\beta;\gamma;1) = \dfrac{(\gamma-\beta)_n}{(\gamma)_n}$

which is the required Vandermonde's theorem.

5.19 Confluent Hypergeometric Equation (Or Kummer's Equation) and its Solution

The hypergeometric differential equation is

$$x\,(1-x)\,\frac{d^2y}{dx^2}\,\{\gamma-(\alpha+\beta+1)\,x\}\,\frac{dy}{dx}-\alpha\beta y=0 \qquad \ldots(1)$$

Replacing x by x/β in (1), we get

$$\frac{x}{\beta}\left(1-\frac{x}{\beta}\right)\beta^2\,\frac{d^2y}{dx^2}+\left\{\gamma-(\alpha+\beta+1)\,\frac{x}{\beta}\right\}\beta\,\frac{dy}{dx}-\alpha\beta y=0$$

$$\Rightarrow \quad x\left(1-\frac{x}{\beta}\right)\frac{d^2y}{dx^2}+\left\{\gamma-\left(1+\frac{1+\alpha}{\beta}\right)x\right\}\frac{dy}{dx}-\alpha y=0 \qquad \ldots(2)$$

Since ${}_2F_1\,(\alpha,\beta;\gamma;x)$ is the solution of (1), $\therefore\ {}_2F_1\,(\alpha,\beta;\gamma;x/\beta)$ is the solution of (2)

When $\beta \to \infty$, the equation (2) reduces to

$$x\,\frac{d^2y}{dx^2}+(\gamma-x)\,\frac{dy}{dx}-\alpha y=0 \qquad \ldots(3)$$

whose solution is given by

$$\lim_{\beta\to\infty}\,{}_2F_1\,(\alpha,\beta;\gamma;x/\beta)=\lim_{\beta\to\infty}\sum_{r=0}^{\infty}\frac{(\alpha)_r\,(\beta)_r}{(\gamma)_r}\cdot\frac{1}{r\,!}\left(\frac{x}{\beta}\right)^r$$

$$=\sum_{r=0}^{\infty}\frac{(\alpha)_r}{(\gamma)_r}\cdot\frac{x^r}{r\,!}={}_1F_1\,(\alpha;\gamma;x)$$

Since $\quad \displaystyle\lim_{\beta\to\infty}\frac{(\beta)_r}{\beta^r}=\lim_{\beta\to\infty}\frac{\beta\,(\beta+1)\,(\beta+2)\,\ldots.\,(\beta+r-1)}{\beta^r}$

$$= \lim_{\beta \to \infty} 1.\left(1+\frac{1}{\beta}\right)\left(1+\frac{2}{\beta}\right)\ldots\left(1+\frac{r-1}{\beta}\right) = 1$$

i.e., solution of equation (3) is ${}_1F_1\,(\alpha\,;\gamma;x)$

This function ${}_1F_1\,(\alpha\,;\gamma;x)$ is called **confluent hypergeometric function** which is the solution of the equation (3) called **Confluent hypergeometric equation or Kummer's equation.**

5.20 Series Solution of Confluent Hypergeometric Differential Equation near x = 0 when γ is not an Integer

The confluent hypergeometric differential equation is

$$x\frac{d^2y}{dx^2} + (\gamma - x)\frac{dy}{dx} - \alpha y = 0 \qquad \ldots(1)$$

Comparing with $\frac{d^2y}{dx^2} + P(x)\frac{dy}{dx} + Q(x)\,y = 0$, we get

$$P(x) = \frac{\gamma - x}{x} \text{ and } Q(x) = -\frac{\alpha}{x}$$

None of which is finite *i.e.*, analytic at $x = 0$ and $xP(x) = \gamma - x$ and $x^2Q(x) = -\alpha x$, which are both finite *i.e.*, analytic at $x = 0$.

So $x = 0$ is a regular singular point of (1).

Let the solution of (1), near the point $x = 0$, be given by the infinite series

$$y = \sum_{r=0}^{\infty} C_r\, x^{m+r}, \quad C_0 \neq 0 \qquad \ldots(2)$$

Diff. $$\frac{dy}{dx} = \sum_{r=0}^{\infty} C_r\,(m+r)\,x^{m+r-1}$$

and $$\frac{d^2y}{dx^2} = \sum_{r=0}^{\infty} C_r\,(m+r)\,(m+r-1)\,x^{m+r-2}$$

Substituting in (1), we get

$$\sum_{r=0}^{\infty} C_r\,[(m+r)\,(m+r-1)\,x^{m+r-1} + (\gamma - x)\,(m+r)\,x^{m+r-1} - \alpha\,x^{m+r}] = 0$$

or $$\sum_{r=0}^{\infty} C_r\,[(m+r)\,(m+r-1+\gamma)\,x^{m+r-1} - (m+r+\alpha)\,x^{m+r}] = 0 \qquad \ldots(3)$$

Which is an identity, so we can equate to zero the coefficients of various powers of x.

Equating to zero the coefficient of lowest power of x *i.e.*, of x^{m-1}, the *indicial equation* is

$$C_0 m(m-1+\gamma)=0 \Rightarrow m=0 \text{ or } 1-\gamma \qquad \because \quad C_0 = 0$$

which are unequal and not differing by an integer.

Now equating to zero the coefficient of x^{m+r-1}, we get

$$C_r (m+r)(m+r-1+\gamma)-(m+r-1+\alpha)\, C_{r-1}=0$$

$$\Rightarrow \qquad C_r = \frac{m+\alpha+r-1}{(m+r)(m+r-1+\gamma)}\, C_{r-1}, \qquad \text{for } r \geq 1 \qquad \ldots(4)$$

Case I : When $m = 0$:

In this case $C_r = \dfrac{\alpha+r-1}{r(r+\gamma-1)}\, C_{r-1}, \qquad r \geq 1$

Putting $\quad r = 1, 2, 3, \ldots\ldots\ldots,$

$$C_1 = \frac{\alpha}{\gamma} C_0,\ C_2 = \frac{\alpha+1}{2.(\gamma+1)} C_1 = \frac{\alpha(\alpha+1)}{1.2\,\gamma(\gamma+1)} C_0$$

$$C_3 = \frac{\alpha+2}{3(\gamma+2)} C_2 = \frac{\alpha(\alpha+1)(\alpha+2)}{1.2.3\,\gamma(\gamma+1)(\gamma+2)} C_0 \text{ and so on.}$$

Putting in (2), we get

$$y = \sum_{r=0}^{\infty} C_r x^r, \text{ when } m=0$$

$$= C_0 + C_1 x + C_2 x^2 + C_3 x^3 + \ldots.$$

or
$$y = C_0 \left[1 + \frac{\alpha}{\gamma}\cdot x + \frac{\alpha(\alpha+1)}{\gamma(\gamma+1)}\cdot\frac{x^2}{2!} + \frac{\alpha(\alpha+1)(\alpha+2)}{\gamma(\gamma+1)(\gamma+2)}\cdot\frac{x^3}{3!} + \ldots.\right]$$

Taking $\quad C_0 = 1$

$$y = \sum_{r=0}^{\infty} \frac{(\alpha)_r}{(\gamma)_r}\cdot\frac{x^r}{r!} = {}_1F_1(\alpha;\gamma;x)$$

which is a solution of (1) and is called the **confluent hypergeometric function of first kind.**

Case II. When $m = 1-\gamma$: In this case, from (4)

$$C_r = \frac{1-\gamma+\alpha+r-1}{(1-\gamma+r)(1-\gamma+r-1+\gamma)} C_0 = \frac{(\alpha-\gamma+1)+r-1}{r\{(2-\gamma)+r-1\}} C_0$$

$$\Rightarrow \qquad C_r = \frac{\alpha' + r - 1}{r\,(\gamma' + r - 1)}\,C_0 \qquad \text{for } r \geq 1$$

where $\alpha' = \alpha - \gamma + 1$ and $\gamma' = 2 - \gamma$

Putting $r = 1, 2, 3, \ldots\ldots\ldots$, we get

$$C_1 = \frac{\alpha'}{1.\gamma'}\,C_0,\ C_2 = \frac{\alpha' + 1}{2\,(\gamma' + 1)}\,C_1 = \frac{\alpha'\,(\alpha' + 1)}{1.2\,\gamma'\,(\gamma' + 1)}\,C_0$$

$$C_3 = \frac{\alpha' + 2}{3\,.(\gamma' + 2)}\,C_2 = \frac{\alpha'\,(\alpha' + 1)\,(\alpha' + 2)}{1.2\,.3\,\gamma'\,(\gamma' + 1)\,(\gamma' + 2)}\,C_0 \text{ and so on.}$$

$\therefore$ from (2), we have

$$y = \sum_{r=0}^{\infty} C_r x^{1-\gamma+r} = C_0 x^{1-\gamma} + C_1 x^{2-\gamma} + C_2 x^{3-\gamma} + \ldots..$$

$$= C_0 x^{1-\gamma}\left[1 + \frac{\alpha'}{\gamma'}\,\frac{x}{1!} + \frac{\alpha'\,(\alpha' + 1)}{\gamma'\,(\gamma' + 1)}\cdot\frac{x^2}{2\,!} + \frac{\alpha'\,(\alpha' + 1)\,(\alpha' + 2)}{\gamma'\,(\gamma' + 1)\,(\gamma' + 2)}\,\frac{x^3}{3\,!} + \ldots\right]$$

Taking $C_0 = 1$

$$y = x^{1-\gamma} \sum_{r=0}^{\infty} \frac{(\alpha')_r}{(\gamma')_r}\cdot\frac{x^r}{r\,!} = x^{1-\gamma}\,{}_1F_1\,(\alpha'\,;\gamma'\,;x)$$

i.e., $y = x^{1-\gamma}\,{}_1F_1\,(\alpha - \gamma + 1; 2 - \gamma; x)$

which is other independent solution of (1) and is called the **confluent hypergeometric function of second kind.**

Hence the general solution of confluent hypergeometric equation (1) is

$$y = A\,{}_1F_1(\alpha\,;\gamma;x) + \mathrm{B}\,x^{1-\gamma}\,{}_1F_1\,(\alpha - \gamma + 1; 2 - \gamma; x)$$

where $\gamma > 0$ is not integral and A, B are arbitrary constants.

5.21 Derivatives of Confluent Hypergeometric Function

The confluent hypergeometric function is given by

$${}_1F_1\,(\alpha\,;\gamma;x) = \sum_{n=0}^{\infty} \frac{(\alpha)_n}{(\gamma)_n}\cdot\frac{x^n}{n!}$$

Differentiating both sides w.r.t. x, we get

$$\frac{d}{dx}\,{}_1F_1\,(\alpha\,;\gamma;\,x) = \sum_{n=0}^{\infty} \frac{(\alpha)_n}{(\gamma)_n}\cdot\frac{n\,x^{n-1}}{n!} = \sum_{n=1}^{\infty} \frac{(\alpha)_n}{(\gamma)_n}\cdot\frac{x^{n-1}}{(n-1)!}$$

$$= \sum_{m=0}^{\infty} \frac{(\alpha)_{m+1}}{(\gamma)_{m+1}}\cdot\frac{x^m}{m!} \qquad \text{Putting } n-1=m$$

$$= \frac{\alpha}{\gamma}\sum_{m=0}^{\infty} \frac{(\alpha+1)_m}{(\gamma+1)_m}\,\frac{x^m}{m!} \qquad [\because (\alpha)_{m+1} = \alpha\,(\alpha+1)_m]$$

$$\therefore \qquad = \frac{\alpha}{\gamma}\,{}_1F_1\,(\alpha+1;\gamma+1;\,x)$$

i.e., $$\boldsymbol{\frac{d}{dx}\,{}_1F_1\,(\alpha\,;\,\gamma;\,x) = \frac{\alpha}{\gamma}\,{}_1F_1\,(\alpha+1;\,\gamma+1;\,x)} \qquad \ldots(1)$$

Differentiating (1) again, w.r.t x we get

$$\frac{d^2}{dx^2}\,{}_1F_1\,(\alpha\,;\gamma;\,x) = \frac{\alpha}{\gamma}\sum_{m=0}^{\infty} \frac{(\alpha+1)_m}{(\gamma+1)_m}\,\frac{m\,x^{m-1}}{m!}$$

$$= \frac{\alpha}{\gamma}\sum_{m=1}^{\infty} \frac{(\alpha+1)_m}{(\gamma+1)_m}\cdot\frac{x^{m-1}}{(m-1)!}$$

$$= \frac{\alpha}{\gamma}\sum_{n=0}^{\infty} \frac{(\alpha+1)_{n+1}}{(\gamma+1)_{n+1}}\,\frac{x^n}{n!} \qquad \text{Taking } m-1=n$$

$$= \frac{\alpha}{\gamma}\sum_{n=0}^{\infty} \frac{(\alpha+1)\,(\alpha+2)_n}{(\gamma+1)\,(\gamma+2)_n}\cdot\frac{x^n}{n!} \quad [\because (\alpha+1)_{n+1} = (\alpha+1)\,(\alpha+2)_n]$$

$$= \frac{\alpha\,(\alpha+1)}{\gamma\,(\gamma+1)}\sum_{n=0}^{\infty} \frac{(\alpha+2)_n}{(\gamma+2)_n}\,\frac{x^n}{n!} = \frac{\alpha\,(\alpha+1)}{\gamma\,(\gamma+1)}\,{}_1F_1\,(\alpha+2\,,\gamma+2\,;x)$$

i.e., $$\frac{d^2}{dx^2}\,{}_1F_1\,(\alpha\,;\gamma;\,x) = \frac{\alpha\,(\alpha+1)}{\gamma\,(\gamma+1)}\,{}_1F_1\,(\alpha+2\,;\gamma+2\,;x) = \frac{(\alpha)_2}{(\gamma)_2}\,{}_1F_1\,(\alpha+2\,;\gamma+2\,;x) \qquad \ldots(2)$$

Proceeding similarly, we can assume that

$$\frac{d^p}{dx^p}\,{}_1F_1\,(\alpha\,;\gamma;\,x) = \frac{(\alpha)_p}{(\gamma)_p}\,{}_1F_1\,(\alpha+p\,;\gamma+p\,;x) \qquad \ldots(3)$$

where p is a positive integer.

Differentiating again, w.r.t. 'x', we get

$$\frac{d^{p+1}}{dx^{p+1}}\,{}_1F_1(\alpha;\gamma;x)=\frac{(\alpha)_p}{(\gamma)_p}\cdot\frac{d}{dx}\,{}_1F_1(\alpha+p;\gamma+p;x)$$

$$=\frac{(\alpha)_p}{(\gamma)_p}\cdot\frac{\alpha+p}{\gamma+p}\,{}_1F_1(\alpha+p+1;\gamma+p+1;x)$$

$$=\frac{(\alpha)_{p+1}}{(\gamma)_{p+1}}\,{}_1F_1(\alpha+p+1;\gamma+p+1;x)$$

$$\because\quad (\alpha)_p.(\alpha+p)=(\alpha)_{p+1}$$

i.e., if (3) is true for positive integer p, then it is also true for positive integer $p+1$. But from (1) it is true for $p=1$. Hence by mathematical induction, (3) is the for every positive integer n.

$$\frac{d^n}{dx^n}\,{}_1F_1(\alpha;\gamma;x)=\frac{(\alpha)_n}{(\gamma)_n}\cdot{}_1F_1(\alpha+n;\gamma+n;x)$$

5.22 Integral Formula for Confluent Hypergeometric Function ${}_1F_1(\alpha;\gamma;x)$

$${}_1F_1(\alpha;\gamma;x)=\frac{\Gamma(\gamma)}{\Gamma(\alpha)\,\Gamma(\gamma-\alpha)}\int_0^1(1-t)^{\gamma-\alpha-1}.t^{\alpha-1}e^{xt}dt$$

or $${}_1F_1(\alpha;\gamma;x)=\frac{1}{B(\alpha,\gamma-\alpha)}\int_0^1(1-t)^{\gamma-\alpha-1}.t^{\alpha-1}e^{xt}dt$$

[Rajasthan 2003; Purvanchal 2006]

Proof: We have, the confluent hypergeometric function

$${}_1F_1(\alpha;\gamma;x)=\sum_{n=0}^{\infty}\frac{(\alpha)_n}{(\gamma)_n}\cdot\frac{x^n}{n!}\qquad\ldots(1)$$

Since $(\alpha)_n=\dfrac{\Gamma(\alpha+n)}{\Gamma(\alpha)}$ (See 5.15)

$$\therefore\quad\frac{(\alpha)_n}{(\gamma)_n}=\frac{\Gamma(\alpha+n)}{\Gamma(\alpha)}\cdot\frac{\Gamma(\gamma)}{\Gamma(\gamma+n)}=\frac{\Gamma(\gamma)}{\Gamma(\alpha)\,\Gamma(\gamma-\alpha)}\cdot\frac{\Gamma(\gamma-\alpha)\,\Gamma(\alpha+n)}{\Gamma(\gamma+n)}$$

$$=\frac{\Gamma(\gamma)}{\Gamma(\alpha)\,\Gamma(\gamma-\alpha)}\cdot\frac{\Gamma(\gamma-\alpha)\,\Gamma(\alpha+n)}{\Gamma(\gamma-\alpha+\alpha+n)}=\frac{\Gamma(\gamma)}{\Gamma(\alpha)\,\Gamma(\gamma-\alpha)}\cdot B(\alpha+n,\gamma-\alpha)$$

$$=\frac{\Gamma(\gamma)}{\Gamma(\alpha)\,\Gamma(\gamma-\alpha)}\int_0^1(1-t)^{\gamma-\alpha-1}\,t^{\alpha+n-1}\,dt$$

$\therefore$ from (1), we have

$$ {}_1F_1\,(\alpha\,;\gamma;x) = \sum_{n=0}^{\infty} \frac{\Gamma(\gamma)}{\Gamma(\alpha)\,\Gamma(\gamma-\alpha)} \int_0^1 (1-t)^{\gamma-\alpha-1}\, t^{\alpha+n-1} \cdot \frac{x^n}{n!}\,dt $$

$$ = \frac{\Gamma(\gamma)}{\Gamma(\alpha)\,\Gamma(\gamma-\alpha)} \int_0^1 (1-t)^{\gamma-\alpha-1}\, t^{\alpha-1} \left(\sum_{n=0}^{\infty} \frac{(x\,t)^n}{n!} \right) dt $$

$$ = \frac{\Gamma(\gamma)}{\Gamma(\alpha)\,\Gamma(\gamma-\alpha)} \int_0^1 (1-t)^{\gamma-\alpha-1}\, t^{\alpha-1} \,.\, e^{xt}\,dt $$

or $$ {}_1F_1\,(\alpha\,;\gamma;x) = \frac{1}{\mathrm{B}\,(\alpha\,,\gamma-\alpha)} \cdot \int_0^1 (1-t)^{\gamma-\alpha-1} . t^{\alpha-1} e^{xt}\,dt $$

5.23 Kummer's Theorem (for Confluent Hypergeometric Function)

$$ {}_1\boldsymbol{F}_1\,(\alpha\,;\,\beta;\,\boldsymbol{x}) = \boldsymbol{e}^{\boldsymbol{x}}\ {}_1\boldsymbol{F}_1\,(\beta-\alpha\,;\,\beta;\,-\boldsymbol{x}) $$

[Kanpur 2000, 01; Rajasthan 2002, 03]

Proof: Integral formula for confluent hypergeometric function is :

$$ {}_1F_1\,(\alpha\,;\beta;x) = \frac{\Gamma(\beta)}{\Gamma(\alpha)\,\Gamma(\beta-\alpha)} \int_0^1 (1-t)^{\beta-\alpha-1}\, t^{\alpha-1} \,.\, e^{xt}\,dt \qquad \ldots(1) $$

Replacing α by $\beta-\alpha$ and x by $-x$, we get

$$ {}_1F_1\,(\beta-\alpha\,;\beta;x) = \frac{\Gamma(\beta)}{\Gamma(\beta-\alpha)\,\Gamma[\beta-(\beta-\alpha)]} \int_0^1 (1-t)^{\beta-(\beta-\alpha)-1} t^{\beta-\alpha-1} e^{-xt}\,dt $$

$$ = \frac{\Gamma(\beta)}{\Gamma(\beta-\alpha)\,\Gamma(\alpha)} \int_0^1 (1-t)^{\alpha-1}\, t^{\beta-\alpha-1}\, e^{-xt}\,dt $$

$$ = \frac{\Gamma(\beta)}{\Gamma(\beta-\alpha)\,\Gamma(\alpha)} \int_1^0 u^{\alpha-1}\,(1-u)^{\beta-\alpha-1} e^{-x\,(1-u)}\,(-1)\ du $$

Putting $1-t=u,\ dt=-du$

$$ = e^{-x}\, \frac{\Gamma(\beta)}{\Gamma(\alpha)\,\Gamma(\beta-\alpha)} \int_0^1 (1-u)^{\beta-\alpha-1}\, u^{\alpha-1}\, e^{xu}\,du $$

$$ = e^{-x}\, \frac{\Gamma(\beta)}{\Gamma(\alpha)\,\Gamma(\beta-\alpha)} \int_0^1 (1-t)^{\beta-\alpha-1}\, t^{\alpha-1}\, e^{xt}\,dt $$

By Prop of D.I.

$$ = e^{-x}\ F(\alpha\,;\beta;x) \text{ from } (1) $$

$$ \Rightarrow \quad {}_1F_1\,(\alpha\,;\beta;x) = e^{x}\ {}_1F_1\,(\beta-\alpha\,;\beta;\ x) $$

5.24 Whittaker's Confluent Hypergeometric Function

The Confluent Hypergeometric equation is

$$x\frac{d^2y}{dx^2}+(\gamma-x)\frac{dy}{dx}-\alpha y=0 \qquad \ldots(1)$$

whose general solution is

$$y=Ay_1(x)+By_2(x) \qquad \ldots(2)$$

where A and B are arbitrary constants and

$$y_1(x)={}_1F_1\,(\alpha\,;\gamma;x) \qquad \ldots(3)$$

and $$y_2(x)=x^{1-\gamma}\;{}_1F_1\,(\alpha-\gamma+1;2-\gamma;x) \qquad \ldots(4)$$

Putting $$y(x)=x^{-\gamma/2}e^{x/2}W(x) \qquad \ldots(5)$$

so that, $$\frac{dy}{dx}=\left\{-\left(\frac{\gamma}{2}\right)x^{-\gamma/2-1}e^{x/2}+\frac{1}{2}x^{-\gamma/2}e^{x/2}\right\}W(x)+x^{-\gamma/2}e^{x/2}\frac{dW}{dx}$$

$$\frac{d^2y}{dx^2}=\left\{-(\gamma/2).x^{-\gamma/2-1}e^{x/2}+\frac{1}{2}x^{-\gamma/2}e^{x/2}\right\}\frac{dW}{dx}$$

$$+\left\{\left(\frac{\gamma}{2}\right)\left(\frac{\gamma}{2}+1\right)e^{-(\gamma/2)-2}.e^{x/2}-\left(\frac{\gamma}{2}\right)x^{-(\gamma/2)-1}.\frac{1}{2}e^{x/2}\right.$$

$$\left.-\frac{\gamma}{4}x^{-(\gamma/2)-1}e^{x/2}+\frac{1}{4}x^{-\gamma/2}e^{x/2}\right\}W(x)$$

$$+x^{-\gamma/2}e^{x/2}\frac{d^2W}{dx^2}+\left\{\left(-\frac{\gamma}{2}\right)x^{-(\gamma/2)-1}e^{x/2}+\frac{1}{2}x^{-\gamma/2}e^{x/2}\right\}\frac{dW}{dx}$$

$$=\{-\gamma\,x^{-\gamma/2-1}e^{x/2}+x^{-\gamma/2}e^{x/2}\}\frac{dW}{dx}$$

$$+\left\{\left(\gamma\frac{(\gamma+2)}{4}\right)x^{-(\gamma/2)-2}e^{x/2}-\left(\frac{\gamma}{2}\right)x^{-(\gamma/2)-1}e^{x/2}+\left(\frac{1}{4}\right)e^{-\gamma/2}e^{x/2}\right\}.$$

$$W(x)+x^{-\gamma/2}e^{x/2}\frac{d^2W}{dx^2}$$

in (1), it reduces to

$$x\,.\,x^{-\gamma/2}e^{x/2}\left[\frac{d^2W}{dx^2}+(-\gamma\,x^{-1}+1)\frac{dW}{dx}+\left\{\left(\gamma\frac{(\gamma+2)}{4}\right)x^{-2}-\left(\frac{\gamma}{2}\right)x^{-1}+\frac{1}{4}\right\}W(x)\right]$$

$$+(\gamma-x)\,.\,x^{-\gamma/2}e^{x/2}\left[\frac{dw}{dx}+\left\{\left(-\frac{\gamma}{2}\right)x^{-1}+\frac{1}{2}\right\}W(x)\right]-\alpha\,x^{-\gamma/2}e^{x/2}\,W(x)=0$$

or $$x\frac{d^2W}{dx^2}+\left[\left(\frac{\gamma(\gamma+2)}{4}\right)x^{-1}-\frac{\gamma}{2}+\frac{x}{4}+(\gamma-x)\left\{\left(-\frac{\gamma}{2}\right)x^{-1}+\frac{1}{2}\right\}-\alpha\right]W(x)=0$$

or $$\frac{d^2W}{dx^2}+\left[-\frac{1}{4}+\frac{\gamma/2-\alpha}{x}-\frac{(-\gamma^2/4+\gamma/2)}{x^2}\right]W(x)=0$$

or $$\frac{d^2W}{dx^2}+\left[-\frac{1}{4}+\frac{\gamma/2-\alpha}{x}+\frac{1/4-(\gamma/2-1/2)^2}{x^2}\right]W(x)=0$$

or $$\frac{d^2W}{dx^2}+\left[-\frac{1}{4}+\frac{k}{x}+\frac{1/4-m^2}{x^2}\right]W(x)=0 \qquad \text{....(6)}$$

where $k=\gamma/2-\alpha$ and $m=\gamma/2-1/2$

The solutions $W(x)$ of (6) are called the Whittaker's Confluent Hypergeometric Functions

If $2m$ is neither 1 nor an integer then the solution of equation (6) is given by (2) where $\gamma=2m+1$ and $\alpha=\gamma/2-k=1/2+m-k$

Thus the solutions of (6) *i.e.*, **Whittaker's Confluent hypergeometric functions** are given by

$$M_{k,\,m}(x)=x^{\gamma/2}\,e^{-x/2}\,y_1(x)$$

$$=x^{m+1/2}\,.e^{-x/2}\,{}_1F_1\,(1/2+m-k;2m+1;x)$$

and $$M_{k,\,-m}(x)=x^{\gamma/2}e^{-x/2}\,y_2(x)$$

$$=x^{1/2-m}\,.e^{-x/2}\,{}_1F_1\,(1/2-m-k;1-2m;x)$$

5.25 Contiguous Hypergeometric Functions

According to Gauss, the function $F(\alpha';\beta';\gamma';x)$ is said to be contiguous to function $F(\alpha,\beta;\gamma;x)$ if it is obtained by increasing or decreasing one and only one of the parameters α, β, γ by unity.

Thus there exist six hypergeometric functions contiguous to $F(\alpha,\beta;\gamma;x)$ and are denoted as given below

$$F(\alpha+1,\beta;\gamma;x)=F_{\alpha+}, \qquad F(\alpha-1,\beta;\gamma;x)=F_{\alpha-}$$
$$F(\alpha,\beta+1;\gamma;x)=F_{\beta+}, \qquad F(\alpha,\beta-1;\gamma;x)=F_{\beta-}$$
$$F(\alpha,\beta;\gamma+1;x)=F_{\gamma+}, \qquad F(\alpha,\beta;\gamma-1;x)=F_{\gamma-}$$

5.26 Theorem : Contiguity Relationship

There exists a linear relation with polynomial coefficients between a hypergeometric function $F(\alpha, \beta; \gamma; x)$ and its any two contiguous hypergeometric functions

i.e., $(\alpha - \beta)\, F(\alpha, \beta; \gamma; x) = \alpha . F_{\alpha +} - \beta . F_{\beta +}$ ***(etc.)***

Which holds for $|x| < 1$.

Proof: We have,

$$\alpha . F_{\alpha+} - \beta . F_{\beta+} = \alpha . F(\alpha + 1, \beta; \gamma; x) - \beta . F(\alpha, \beta + 1; \gamma; x)$$

$$= \alpha \cdot \frac{(\alpha + 1)_r (\beta)_r}{(\gamma)_r} \cdot \frac{x^r}{r\,!} - \beta \cdot \frac{(\alpha)_r (\beta + 1)_r}{(\gamma)_r} \cdot \frac{x^r}{r\,!}$$

$$= \Big[\, [\alpha\, (\alpha + 1)]_r\, (\beta)_r - (\alpha)_r\, \beta\, (\beta + 1)_r \Big] \cdot \frac{x^r}{(\gamma)_r\, r\,!}$$

$$= \Big[[(\alpha)_r\, .\, (\alpha + r)\, .\, (\beta)_r - (\alpha)_r\, (\beta)_r\, (\beta + r)] \Big] \frac{x^r}{(\gamma)_r\; r\,!}$$

$\because$ $$\alpha\, (\alpha + 1)_r = \alpha\, (\alpha + 1)\, (\alpha + 2) \ldots .\, (\alpha + 1 + r - 1)$$

$$= \{\alpha\, (\alpha + 1)\, (\alpha + 2) \ldots .\, (\alpha + r - 1)\}\, (\alpha + r)$$

$$= (\alpha)_r . (\alpha + r)$$

Similarly, $\beta\, (\beta + 1)_r = (\beta)_r (\beta + r)$

$\therefore$ $$\alpha . F_{d+} - \beta . F_{\beta+} = [(\alpha + r) - (\beta + r)]\, \frac{(\alpha)_r (\beta)_r}{(\gamma)_r} \cdot \frac{x^r}{r\,!}$$

$$= (\alpha - \beta)\, \frac{(\alpha)_r\, .\, (\beta)_r}{(\gamma)_r} \cdot \frac{x^r}{r\,!} = (\alpha - \beta)\; F\, (\alpha, \beta; \gamma; x)$$

Solved Examples

Example 1: ***Show that*** $(1 + n)_n = 4^n\; (1/2)_n$

Solution: $$(1 + n)_n = (1 + n)\, (1 + n + 1)\, (1 + n + 2) \ldots .\, (1 + n + n - 1)$$

$$= (n + 1)\, (n + 2)\, (n + 3) \ldots .\, (2n)$$

$$= \frac{n!}{n!} \cdot (n + 1)\, (n + 2) \ldots (2n) = \frac{2n!}{n!}$$

$$= \frac{2n\, (2n - 1)\, (2n - 2)\, (2n - 3) \ldots 4 . 3 . 2 . 1}{n!}$$

through every point of X there is a geodesic segment which is mapped isometrically to a geodesic segment in M. The injectivity radius of X is bounded above in terms of S (because its area is determined by Gauss-Bonnet), so we obtain an upper bound on the injectivity radius in the convex core of M.

To find sufficiently many pleated surfaces, one interpolates between pairs of such surfaces by interpolating between their pleating laminations. This idea completes the proof when M is quasifuchsian, since the boundary faces of the convex core are pleated surfaces. In general one must establish that the ends of the thick part of the convex core of M are *geometrically tame*, meaning any neighborhood of the end contains a pleated surface. This is established for $M \in \overline{QF(S)}$ in [Th1] and for all $M \in AH(S)$ in [Bon]. (It is conjectured that these two sets of manifolds are actually the same.) A detailed proof of the Theorem above appears in [Can, Thm. 6.2].

The same discussion leads to a proof of:

Theorem 3.5 (Tameness) *Any M in $AH(S)$ is homeomorphic to* $\mathrm{int}(S) \times \mathbb{R}$.

3.3 The mapping class group

The *mapping class group* $\mathrm{Mod}(S)$ is the group of isotopy classes of orientation-preserving homeomorphisms from S to itself. It is canonically isomorphic to the group of outer automorphisms of $\pi_1(S)$ that preserve orientation and stabilize the set of conjugacy classes of boundary curves.

A mapping class $\psi : S \to S$ acts on $\mathrm{Teich}(S)$ by sending (f, X) to $(f \circ \psi^{-1}, X)$. There are similar actions on $\mathrm{Teich}(\overline{S})$ and on $AH(S)$. These actions are compatible with the mapping

$$Q : \mathrm{Teich}(S) \times \mathrm{Teich}(\overline{S}) \to AH(S);$$

that is, $\psi(Q(X, Y)) = Q(\psi(X), \psi(Y))$.

A mapping class also acts on a Bers slice B_Y by $Q(X, Y) \mapsto Q(\psi(X), Y)$. The action of $\mathrm{Mod}(S)$ on B_Y is *not* the restriction of its action on $AH(S)$; the latter sends B_Y to $B_{\psi(Y)}$.

A mapping class ψ is *reducible* if there is a finite system of disjoint essential simple closed curves on S, none parallel to ∂S, which are

$$\frac{\left\lfloor \frac{2\sigma}{\sqrt{3}} \right\rfloor}{2}\left(\left\lfloor \sigma - \frac{1}{2}\right\rfloor + \lfloor\sigma\rfloor + 2\right) + \lfloor\sigma\rfloor + 1, \quad \text{if } \left\lfloor\frac{2\sigma}{\sqrt{3}}\right\rfloor + 1 \text{ is odd.}$$

In both cases, it is easy to see that we have placed at least $\frac{2}{\sqrt{3}}\sigma^2$ points in total, as because of $\lfloor \sigma - \frac{1}{2}\rfloor + \lfloor\sigma\rfloor + 2 > 2\sigma$, $\left\lfloor \frac{2\sigma}{\sqrt{3}}\right\rfloor > \frac{2}{\sqrt{3}}\sigma - 1$, and $\lfloor\sigma\rfloor > \sigma - 1$, we get

$$\frac{\left\lfloor \frac{2\sigma}{\sqrt{3}} \right\rfloor + 1}{2}\left(\lfloor\sigma\rfloor + \left\lfloor \sigma - \frac{1}{2}\right\rfloor + 2\right) > \frac{\frac{2\sigma}{\sqrt{3}} - 1 + 1}{2}2\sigma = \frac{2}{\sqrt{3}}\sigma^2$$

in the even case, and

$$\frac{\left\lfloor \frac{2\sigma}{\sqrt{3}} \right\rfloor}{2}\left(\left\lfloor \sigma - \frac{1}{2}\right\rfloor + \lfloor\sigma\rfloor + 2\right) + \lfloor\sigma\rfloor + 1 > \frac{\frac{2\sigma}{\sqrt{3}} - 1}{2}2\sigma + \sigma - 1 + 1 = \frac{2}{\sqrt{3}}\sigma^2$$

in the odd case, respectively. □

Theorem 3.1 supplies lower bounds of general validity; that is, the inequality (3.1) is applicable for each $n \geq 2$ integer. For individual n values, computer methods, say, can be used to deliver good lower bounds for the optimum values—provided that either a geometric construction with exact values is derived from the numerical solutions, or the mathematical correctness of the numerical bounds is *validated* (verified) by some guaranteed reliability numerical method. A stochastic algorithm for finding approximate numerical solutions of the point arrangement problems is introduced in Chapter 4.

Besides this, it is known that for several values of n, the optimal solutions are regular arrangements. Keeping this observation in mind, one can speculate that other types of regular arrangements may also provide good lower bounds for the optimum values of Problem 2.2 (see also as (2.1)). Indeed, a detailed investigation of these special patterns resulted in further improvements on the theoretical lower bounds for several n values. These results will be discussed in Chapter 10.

3.2 Upper bounds for the optimal radius $\overline{r}_n$

As one might expect, it is somewhat harder to determine non-trivial upper bounds for $\overline{m}_n$ and $\overline{r}_n$ than those for lower bounds. The main difficulty for this is that lower bounds can be obtained in a constructive way by trying out proper approximate (feasible) solutions, but for the upper bounds some knowledge about the properties of the optimal solutions is required beforehand.

As we already mentioned in Subsection 1.2.5, in [21] it was proved that the densest packing of circles in the plane is a regular (hexagonal) arrangement, and the density of this packing is $\pi/\sqrt{12} \approx 0.9068996821$. Moreover, it can be proved that this value is an upper bound for the density of any circle packings in the unit square (see Chapter 11). However, when Problem 2.2 itself is investigated, this general upper bound can be substantially improved:

Theorem 3.2. *For each $n \geq 2$ integer, an upper bound of the $\overline{r}_n$ optimal radius is*

$$\overline{r}_n \leq \min\left(U_1(n), U_2(n)\right),$$

with

$$U_1(n) := \frac{1}{\sqrt{2\sqrt{3}n + (4\lfloor\sqrt{n}\rfloor - 2)(2-\sqrt{3})}},$$

and

$$U_2(n) := \frac{1 + \sqrt{1 + \frac{2}{\sqrt{3}}(n-1)}}{2n + 2\sqrt{1 + \frac{2}{\sqrt{3}}(n-1)}},$$

where $\lfloor\cdot\rfloor$ denotes the greatest integer not greater than the argument.

PROOF. The proof is in two parts. First we show that $U_1(n)$ is the upper bound of $\overline{r}_n$, then we do likewise with $U_2(n)$.

- $U_1(n)$: Suppose that for a fixed $n \geq 2$ an optimal circle packing in the unit square $[0,1]^2$ exists, and that the common radius of the circles is $\overline{r}_n$. Partition the square into *Dirichlet cells* (*Voronoi polygons*) according to the centres of the circles: the interior of each cell consists of exactly those points of the square which are closer to a circle centre than to any other. Then, each cell belonging to a circle centre will contain the respective circle itself as well. Obviously the total area of the n cells will be equal to 1.

  We will bound the area of the individual cells from below. To achieve this, we divide the cells into two groups, depending on whether or not they share a point with one of the sides of the square.

  Case 1: The cell does not share a point with a side of the square. Then the area of a regular hexagon drawn around the circle in the cell provides a lower bound for the area of the cell. This follows from the following facts. First, among the polygons with k sides drawn around a circle, the regular polygon has the smallest area. Secondly, out of the equilateral triangle, the square, the regular pentagon and the regular hexagon drawn around a circle, the hexagon has the smallest area. In a special case, the area of the cell equals the area of the respective regular hexagon—namely when a circle of the packing is surrounded by six other circles. From this it follows that for Case 1 a lower bound for the area of the cells is the area of a regular hexagon of side $\overline{r}_n$, that is $2\sqrt{3}\overline{r}_n^2$.

  Case 2: The cell shares a point with one or more sides of the square. Although the lower bound obtained in case 1 is also valid for these types of cells, this bound can be improved because the cell makes contact with at least one side of the square: First, notice that the convex hull of the circle centres of the packing is located in the square $[\overline{r}_n, 1-\overline{r}_n]^2$. Let us denote that region of the unit square by R, which is outside of this inner square, i.e. $R := [0,1]^2 \setminus [\overline{r}_n, 1-\overline{r}_n]^2$. It is easy to see

in the odd case, respectively. □

Theorem 3.1 supplies lower bounds of general validity; that is, the inequality (3.1) is applicable for each $n \geq 2$ integer. For individual n values, computer methods, say, can be used to deliver good lower bounds for the optimum values—provided that either a geometric construction with exact values is derived from the numerical solutions, or the mathematical correctness of the numerical bounds is *validated* (verified) by some guaranteed reliability numerical method. A stochastic algorithm for finding approximate numerical solutions of the point arrangement problems is introduced in Chapter 4.

Besides this, it is known that for several values of n, the optimal solutions are regular arrangements. Keeping this observation in mind, one can speculate that other types of regular arrangements may also provide good lower bounds for the optimum values of Problem 2.2 (see also as (2.1)). Indeed, a detailed investigation of these special patterns resulted in further improvements on the theoretical lower bounds for several n values. These results will be discussed in Chapter 10.

3.2 Upper bounds for the optimal radius $\overline{r}_n$

As one might expect, it is somewhat harder to determine non-trivial upper bounds for $\overline{m}_n$ and $\overline{r}_n$ than those for lower bounds. The main difficulty for this is that lower bounds can be obtained in a constructive way by trying out proper approximate (feasible) solutions, but for the upper bounds some knowledge about the properties of the optimal solutions is required beforehand.

As we already mentioned in Subsection 1.2.5, in [21] it was proved that the densest packing of circles in the plane is a regular (hexagonal) arrangement, and the density of this packing is $\pi/\sqrt{12} \approx 0.9068996821$. Moreover, it can be proved that this value is an upper bound for the density of any circle packings in the unit square (see Chapter 11). However, when Problem 2.2 itself is investigated, this general upper bound can be substantially improved:

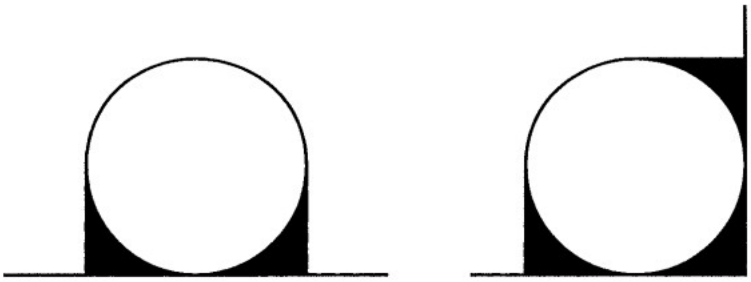

Fig. 3.2. Gaps occurring for circles touching the sides of the square.

that the densest possible way of packing circles into R is to place $4\sqrt{n}-4$ circles on the sides of the unit square.

In this packing, the non-covered regions of R have two different types of 'gaps': the regions defined by two circles and one side of the square, and the regions defined by two sides and a circle located in the corner of $[0,1]^2$ (see Figure 3.2). The sum of the non-covered areas is a lower bound for the area of the non-covered regions of R *for every optimal circle packing* in $[0,1]^2$. A gap increases the estimated lower bound of a regular hexagon by $(2-\sqrt{3})\overline{r}_n^2$. The overall total gap is $(4\lfloor\sqrt{n}\rfloor-2)(2-\sqrt{3})\overline{r}_n^2$. Then the sum of the lower bounds of Dirichlet cells is less than 1 (the area of the unit square), so

$$\overline{r}_n \le \frac{1}{\sqrt{2\sqrt{3}n+(4\lfloor\sqrt{n}\rfloor-2)(2-\sqrt{3})}}.$$

- $U_2(n)$: Using the Oler Theorem [90], J. H. Folkman and R. L. Graham proved the following statement [29]: if X is a compact convex subset of the plane, then the number of points in X with a mutual distance of at least 1 cannot be more than

$$\frac{2}{\sqrt{3}}A(X)+\frac{1}{2}P(X)+1, \tag{3.2}$$

where $A(X)$ is the area, and $P(X)$ is the perimeter of X, respectively.

Applying this result to an $A'(1,\overline{\sigma}_n)$ associated point arrangement (that is, for $X=[0,\overline{\sigma}_n]^2$, $A(X)=\overline{\sigma}_n^2$, and $P(X)=4\overline{\sigma}_n$), we obtain

$$n \le \frac{2}{\sqrt{3}}\overline{\sigma}_n^2+2\overline{\sigma}_n+1.$$

From the relation $\overline{\sigma}_n=(1-2\overline{r}_n)/2\overline{r}_n$ of Corollary 2.15, the lower bound

$$\overline{r}_n \leq \frac{1+\sqrt{1+\frac{2}{\sqrt{3}}(n-1)}}{2n+2\sqrt{1+\frac{2}{\sqrt{3}}(n-1)}}$$

follows, i.e. $U_2(n)$ is also a valid upper bound for $\overline{r}_n$. This completes the proof.

□

T. Tarnai and Zs. Gáspár in some special cases improved the previous upper bound in [122].

3.3 Asymptotic estimation and its error

Based on Corollary 2.15 $\left(\overline{m}_n = \frac{2\overline{r}_n}{1-2\overline{r}_n}\right)$, Theorems 3.1 and 3.2 suggest the following inequality bounds:

$$\sqrt{\frac{2}{\sqrt{3}n}} \leq \overline{m}_n \leq \frac{1}{n-1} + \sqrt{\frac{1}{(n-1)^2} + \frac{2}{\sqrt{3}(n-1)}}.$$

If we multiply these inequalities by $\sqrt{n}$, and let n tend to infinity, then

$$\lim_{n\to\infty} \sqrt{n}\overline{m}_n = \sqrt{\frac{2}{\sqrt{3}}}$$

holds, and this means $\overline{m}_n$ is asymptotically equal to $\sqrt{\frac{2}{\sqrt{3}n}}$ [14].

Theorem 3.3. *An upper bound of the absolute error for the* $\overline{m}_n$ $(\approx \sqrt{\frac{2}{\sqrt{3}n}})$ *asymptotic estimation is*

$$\frac{2}{n-1}.$$

PROOF. The above inequality

$$\frac{1+\sqrt{1+\frac{2}{\sqrt{3}}(n-1)}}{n-1} - \sqrt{\frac{2}{\sqrt{3}n}} < \frac{2}{n-1}$$

is equivalent to

$$\sqrt{1+\frac{2}{\sqrt{3}}(n-1)} - \sqrt{\frac{2(n-1)^2}{\sqrt{3}n}} < 1.$$

After a short calculation we obtain the following relation:

" -256- - -* ! -)! 3 9 * = "!
H A / ' 1"
($% 4 ? :D ! ! : D 1! >! 7! ! !" 1

LEMMA I.5. *Let* $\{f_\alpha\}_{\alpha\epsilon I}$ *be a family of random variables on* (M, Σ, μ). *Let* $\mathfrak{A} = \{F(f_{\alpha_1}, \ldots, f_{\alpha_n}) \mid F \epsilon \mathcal{S}(R^n), \alpha_i \epsilon I\}$. *The following are equivalent*:

(1) $\{f_\alpha\}_{\alpha\epsilon I}$ *is full*

(2) $\mathfrak{A}$, *as a subset of* $L^2(M, d\mu)$, *is dense*

(3) *The von Neumann algebra* $\mathfrak{A}''$, *generated by* $\mathfrak{A}$ *viewed as a family of all multiplication operators, is* $L^\infty(M, d\mu)$.

Proof. We concentrate on (1) $\Longrightarrow$ (2) which is what we will use below. The rest is fairly standard (but somewhat tedious). We will show (1) $\Longrightarrow$ (3) and (3) $\Longrightarrow$ (2). For suppose $\{f_\alpha\}_{\alpha\epsilon I}$ is full and let S be the family of projections in $\mathfrak{A}''$. Each of these projections is also a multiplication operator so S is a subset of $\Sigma/\mathfrak{I}_\mu$. It is easy to see it is a submeasure algebra and that each f_α is measurable with respect to S. Thus S is all of $\Sigma/\mathfrak{I}_\mu$ so $\mathfrak{A}''$ is all multiplication operators. To prove that (3) $\Longrightarrow$ (2) we note that $\overline{\mathfrak{A}1}$ contains $\mathfrak{A}''1$ since $\mathfrak{A}''$ is the strong closure of $\mathfrak{A}$. Thus $\overline{\mathfrak{A}1}$ contains L^∞ which is dense in L^2. ■

Remark:

Here and throughout our L^2 *spaces are always spaces of complex-valued functions*. Similarly $\mathcal{S}$ denotes complex-valued functions. We use $L^2_{\mathbf{R}}$ and $\mathcal{S}_{\mathbf{R}}$ to denote the spaces of real-valued functions.

A preliminary version of the second main object of this section is:

DEFINITION. A random process indexed by V is called a Gaussian random process indexed by V if and only if:

(a) $\{\phi(v) \mid v \epsilon V\}$ is full

(b) Each $\phi(v)$ is a g.r.v.

Remark:

Since V is a vector space, (b) implies that any $\phi(v_1), \ldots, \phi(v_n)$ are jointly Gaussian.

Given a Gaussian random process, the map $v, w \mapsto \langle\phi(v)\phi(w)\rangle$ defines a (semi-definite) inner product on V. In the usual way, we can quotient out by $\{v \mid <\phi(v)^2> = 0\}$ and complete to a Hilbert space, $\mathcal{H}$. It is not hard to see (after developing a part of the theory below!) that nothing is lost by supposing V to be a Hilbert space to begin with:

DEFINITION. Let $\mathcal{H}$ be a real Hilbert space. *The Gaussian random process indexed by* $\mathcal{H}$ is a random process indexed by $\mathcal{H}$ so that

(a) $\{\phi(v) \mid v \in \mathcal{H}\}$ is full.
(b) Each $\phi(v)$ is a g.r.v.
(c) $<\phi(v)\phi(w)> = \frac{1}{2} <v, w>$, the inner product on $\mathcal{H}$.

Remarks:

1. The $\frac{1}{2}$ in $<\phi(v)\phi(w)> = \frac{1}{2}<v, w>$ is somewhat unnatural. We add the $\frac{1}{2}$ so that when we consider the connection with Fock space in Section I.3, we can write $\phi(v) = \frac{1}{\sqrt{2}}(A^*(v) + A(v))$. If one suppressed the $\sqrt{2}$ in this last formula, one could eliminate the $\frac{1}{2}$ above, but we prefer to conform to the usual physicist's convention. Many authors (e.g., [90, 135]) do not include the $\frac{1}{2}$.
2. Notice that the phrase "Gaussian random process indexed by $\mathcal{H}$" means more if $\mathcal{H}$ is a Hilbert space than if $\mathcal{H}$ is merely a vector space. In Section I.6, we will have occasion to deal with two Gaussian processes indexed by the vector space, $\mathcal{H}$. We will then use the phrase "Gaussian random process with general covariance."

Of course, we will have to justify the use of the article "the" by proving a uniqueness theorem. In fact:

THEOREM I.6. *Let* $\mathcal{H}$ *be a real Hilbert space. Let* ϕ *and* ϕ' *be two Gaussian random processes indexed by* $\mathcal{H}$ *on probability measure spaces* (M, Σ, μ) *and* (M', Σ', μ') *respectively. Then there exists an isomorphism between the two probability measure spaces so that for every* $v \in \mathcal{H}$, $\phi(v)$ *corresponds to* $\phi'(v)$ *under the isomorphism.*

PROPOSITION 1.2.1. *Let $\varphi \in \mathcal{H}$, a Hilbert space with $\varphi \neq 0$. Then*

$$\min\{\|\psi\|^2 \mid \langle \psi, \varphi \rangle = 1\} = \frac{1}{\|\varphi\|^2}$$

The minimizing ψ is given by $\psi = \varphi/\|\varphi\|^2$. If ψ is restricted to lie in a closed subspace, $\mathcal{L}$, and P is the projection onto $\mathcal{L}$, then the minimum is $1/\|P\varphi\|^2$.

PROOF. Let $\psi_0 = \varphi/\|\varphi\|^2$. If $\langle \psi, \varphi \rangle = 1$, then $\langle \psi - \psi_0, \varphi \rangle = 0$ so $\|\psi\|^2 = \|\psi_0\|^2 + \|\psi - \psi_0\|^2$, so the minimum occurs at $\psi = \psi_0$. Since $\|\psi_0\|^2 = 1/\|\varphi\|^2$, the result is proven.

For the subspace problem, make $\mathcal{L}$ the Hilbert space and note that for $\psi \in \mathcal{L}$, $\langle \psi, \varphi \rangle = \langle \psi, P\varphi \rangle$ and $P\varphi \in \mathcal{L}$. □

For a moment, it is worthwhile relaxing our requirement that $\mu(\mathbb{R}) = 1$. For general μ, if $\tilde{\mu} = \mu/\mu(\mathbb{R})$, then $P_n(x)$ are unchanged, that is, $P_n(x; d\mu) = P_n(x; d\tilde{\mu})$, but $p_n(x; d\mu) = p_n(x; d\tilde{\mu})\mu(\mathbb{R})^{-1/2}$, and consistent with (1.2.39), $\lambda_n(\zeta, d\mu) = \mu(\mathbb{R})\lambda_n(\zeta, d\tilde{\mu})$. The left, and so, the right side of (1.2.39) is clearly monotone in μ, that is, $\mu < \nu \Rightarrow \lambda_n(\zeta, d\mu) \leq \lambda_n(\zeta, d\mu)$, and we thus have

$$\sum_{j=0}^{n} |p_j(\zeta; d\mu)|^2 \geq \sum_{j=0}^{n} |p_j(\zeta; d\nu)|^2 \tag{1.2.40}$$

a fact that is not obvious without (1.2.39).

Remarks. 1. It is known (see [**17, 974**]) that the moment problem is determinate if and only if for some $\zeta \in \mathbb{C}_+$, $\sum_{j=0}^{\infty} |p_j(\zeta; d\mu)|^2 = \infty$. (1.2.40) implies that if c_n and d_n are two sets of moments and $c_n - d_n$ is also a set of moments, then if the moment problem for c_n is determinate, the same is true for d_n. Alternately, we note if d_n is indeterminate, we can get multiple measures for c_n by adding solutions for d_n to a solution for $c_n - d_n$.

2. If the moment problem is determinate, it is known (see [**974**]) for all $\zeta \in \mathbb{C}$:

$$\sum_{j=0}^{\infty} |p_j(\zeta, d\mu)|^2 = \begin{cases} \mu(\{\zeta\})^{-1} & \text{if } \zeta \in \mathbb{R} \\ \infty & \text{if } \zeta \notin \mathbb{R} \end{cases} \tag{1.2.41}$$

and thus, if the moment problem is determinate and μ has no pure points, then

$$\lim_{n \to \infty} \lambda_n(\zeta) = 0 \tag{1.2.42}$$

for all ζ. We will see the situation for OPUC is very different.

One place that the Christoffel function enters is in the *Gauss-Jacobi* or *Gauss-Christoffel quadrature formula* that

$$\int \pi(x)\, d\mu(x) = \sum_{j=1}^{n} \lambda_n(x_j^{(n)}(d\mu), d\mu)\pi(x_j^{(n)}(d\mu)) \tag{1.2.43}$$

for π a polynomial of degree $2n-1$ and where $\{x_j^{(n)}(d\mu)\}_{j=1}^{n}$ are the zeros of $P_n(x)$. The point of (1.2.43) is that generally if one fixed n points, one can only hope to fit polynomials up to degree $n-1$ by adjusting the constants. But here we get a space of almost twice the dimension. The weights $\lambda_n(x_j^{(n)}, d\mu)$ are called *Cotes numbers.*

Closely related to (1.2.43) is the fact that in the case where the moment problem is determinate,

$$\sum_{j=1}^{n} \lambda_n(x_j^{(n)}(d\mu), d\mu)\delta_{x_j^{(n)}(d\mu)} \to d\mu \tag{1.2.44}$$

weakly, that is, when integrated over with functions in $C_\infty(\mathbb{R})$, the functions vanishing at infinity. Given (1.2.43), we can integrate over any polynomially bounded function.

We will give (nonstandard) proofs of (1.2.43) and (1.2.44) in Subsection 12, but note the following which is part of a proof of (1.2.43): By Lagrange interpolation, there are unique polynomials $L_j^{(n)}(x, d\mu)$ of degree $n-1$ with $L_j^{(n)}(x_k^{(n)}(d\mu), d\mu) = \delta_{jk}$. Then if π is any polynomial, $\pi(x) - \sum_{j=1}^{n} \pi(x_j^{(n)})L_j^{(n)}(x)$ vanishes at the zeros of P_n and so divisible by P_n, that is,

$$\pi(x) - \sum_{j=1}^{n} \pi(x_j^{(n)})L_j^{(n)}(x) = P_n(x)R(x)$$

Since $\deg R \leq \max(\deg(\pi), n-1) - n$, we see that if $\deg(\pi) \leq 2n-1$, $\int P_n(x)R(x)\, d\mu(x) = 0$, that is, (1.2.43) holds with weights $\int L_j^{(n)}(x)\, d\mu$.

Christoffel functions have been turned by Freud and Nevai (see [**363, 809**] and [**697, 717, 721**] for more recent related developments) into powerful tools for analyzing asymptotics and spectral theory.

9. Christoffel-Darboux Formula

If we write (1.2.16) at two real points x and y, multiply the x equation by $p_n(y)$ and the y equation by $p_n(x)$, and subtract, we get

$$(x-y)p_n(x)p_n(y) = Q_{n+1}(x,y) - Q_n(x,y) \tag{1.2.45}$$

where

$$Q_j(x,y) = a_j(p_j(x)p_{j-1}(y) - p_j(y)p_{j-1}(x))$$

Since $Q_0(x,y) = 0$ (since $p_{-1}(x) = 0$), if we write (1.2.45) for $j = 0, 1, \dots$, and sum, we get the Christoffel-Darboux formula,

$$K_n(x,y) = a_{n+1}\, \frac{p_{n+1}(x)p_n(y) - p_n(x)p_{n+1}(y)}{x-y} \tag{1.2.46}$$

where K_n is the reproducing kernel given by (1.2.36). This also has a limit

$$K_n(x,x) = a_{n+1}(p'_{n+1}(x)p_n(x) - p'_n(x)p_{n+1}(x)) \tag{1.2.47}$$

We will not apply the formula here except to note it is often used to prove many of the facts we have obtained by other means, for example, interlacing of zeros and the Gauss-Jacobi quadrature formula. We will use its analog in the OPUC case; see especially Section 2.2.

10. Second Kind Polynomials, Transfer Matrices, and the m-function

Define $a_0 \equiv 1$. The numbers $u_n \equiv p_n(x)$ are the unique solution of the difference equation

$$a_{n+1}u_{n+1} = (x - b_{n+1})u_n - a_n u_{n-1} \qquad n = 0, 1, 2, \dots \tag{1.2.48}$$

with the boundary conditions $u_{-1} = 0$, $u_0 = 1$. The *second kind polynomials*, $q_n(x)$, are the unique solution of (1.2.48) with boundary conditions $u_{-1} = -1$, $u_0 = 0$

*D : D 0 & :

intersects finitely many entries in the array and each entry is met by some arrow.

We take it as clear that f is one-to-one. Let $A_{nm} \in \mathbf{L}_n$. By the above scheme we see that the subscripts lying along the first arrow add up to $1+1=2$, the subscripts lying along the second arrow add up to 3, the subscripts lying along arrow #3 add up to 4, and in general the subscripts lying along arrow $\#k$ add up to $k+1$. Thus A_{nm} lies along arrow $\#n+m-1$. Now consider the number that we will assign A_{nm} with f.

On arrow #1 there is 1 entry. On arrow #2 there are 2 entries, and in general on arrow $\#n$ there are n entries. Thus, when we have finished counting the entries from A_{11} to A_{1n}, we will have counted a total of

$$\begin{array}{llllllll} \text{from arrow} & \#1 & \#2 & \ldots & \#\ell & & \\ & 1 \;+ & 2 \;+ & \ldots \;+ & \ell & = & \dfrac{\ell(\ell+1)}{2} \end{array}$$

entries. We will see why this sum is $\frac{\ell(\ell+1)}{2}$ in a little bit. For now just accept it knowing that there is the promise of a proof. Meanwhile back at the argument, we see that A_{nm} is on arrow $\#n+m-1$ so that

$$\text{there is some } k \leq \frac{(n+m-1)(n+m)}{2} \text{ such that } f(k) = A_{nm}.$$

This proves that $f(k) = A_{mn}$ for some number k, and this in turn proves that f is onto. Since we have already stated that f is one-to-one, $f : \mathbb{N} \longrightarrow A$ is a bijection. We would then send Rationalist A_{nm} to room k. The assignment of rooms is complete.

Let us take a break at this time and examine the sum $1+2+\ldots+\ell$. A German school teacher was feeling a bit hungry so he prepared to go out for coffee and a danish. To keep his pupils busy he instructed them to add up the numbers from 1 to 100. We will do this problem for an arbitray positive integer ℓ. A child, Carl F. Gauss, decided that there must be a faster way. In a flash of genius the 11 year old Gauss discovered the following identity. Let us call the sum S.

$$S = 1+2+\ldots+\ell.$$

Find the sum in two different ways. Start at 1 and end at ℓ, and in the other start at ℓ and end at 1.

$$\begin{array}{ccccccccccc} S & = & 1 & + & 2 & + & \ldots & + & \ell-1 & + & \ell \\ S & = & \ell & + & \ell-1 & + & \ldots & + & 2 & + & 1 \end{array}$$

Notice that in each column we have a sum

$$\ell+1.$$

Add these two sums together to find that

$$\begin{array}{ccccccccccc} S & = & 1 & + & 2 & + & \ldots & + & \ell-1 & + & \ell \\ +S & = & \ell & + & \ell-1 & + & \ldots & + & 2 & + & 1 \\ \hline 2S & = & (\ell+1) & + & (\ell+1) & + & \ldots & + & (\ell+1) & + & (\ell+1) \end{array}$$

There are ℓ terms $\ell+1$ so we have $2S = \ell(\ell+1)$ or equivalently

$$S = 1+2+\ldots+\ell = \frac{\ell(\ell+1)}{2}.$$

Quite a pretty little argument for a child, eh? Before the school teacher could button his coat, Gauss turned his slate over and folded his hands. The teacher, thinking something was amiss, examined the slate and saw the correct sum written there. History does not record whether or not the school teacher got his coffee that day or if he suffered for a lack of it.

The purpose behind the above stories is to develop an intuition for the infinite. The story about Hilbert's Infinite Hotel shows us that in an infinite set there is always *plenty of room.* It would seem that we can make room for any number of guests. Or can we?

The conventions and conferences are over so that the Hotel is empty. Hilbert breathes a sigh of relief and counts his revenue. Accommodating all of those guests has taxed him. There is a knock at the door and Hilbert sees that an infinite collection of Realists

$$\{R_x \mid x \in \mathbb{R} \text{ and } 0 \leq x \leq 1\}$$

is in town for a conference on complex issues. Hilbert sets out to assign each of them a private room, but his first attempt at assigning rooms leaves infinitely many Realists without a room. He tries again and still he cannot assign every Realist a single room. For some reason he does not yet fathom, no matter how he assigns rooms to the Realists, some Realists do not get a single room. The mathematics behind this conundrum is a jolt to our *common sense* and will have to wait until Theorem 4.3.1. The problem of assigning rooms to Realists shows us that our *intuition* about finite sets is useless when we consider matters about infinite sets. We will have to develop entirely new insights if we are to understand the infinite. Hilbert does not yet have the mathematical experience to address this problem. He sends most of these potential guests packing.

Let us discover what Hilbert did not fathom. Let us see why there is no way to accommodate these realists with single rooms in the Infinite Hotel.

Suppose, for the sake of contradiction, that we can make an implied list of these guests and their single rooms. That is, we assign Realists to single rooms and then we make an implied list of the rooms n and the associated occupants R_{x_n}.

room	occupant	decimal					
1	R_{x_1}	$x_1 =$	$.\boxed{d_{11}}$	d_{12}	d_{13}	d_{14}	$\dots$
2	R_{x_2}	$x_2 =$	$.d_{21}$	$\boxed{d_{22}}$	d_{23}	d_{24}	$\dots$
3	R_{x_3}	$x_3 =$	$.d_{31}$	d_{32}	$\boxed{d_{33}}$	d_{34}	$\dots$
4	R_{x_4}	$x_4 =$	$.d_{41}$	d_{42}	d_{43}	$\boxed{d_{44}}$	$\dots$
$\vdots$	$\vdots$						

We have also given the decimal expansion of x_n. In this implied list, each d_{ij} is a digit, a number in the set $\{0, 1, \dots, 9\}$, and we choose the shortest decimal expansion for x_n. That is, if the decimal expansion for x_n ends with $99\bar{9}$ then we replace it with the number that ends in 0's. For instance, the following numbers are equal.

$$\begin{aligned} 1.00\bar{0} &= .99\bar{9} \\ .100\bar{0} &= .099\bar{9} \\ .123\bar{0} &= .12299\bar{9}. \end{aligned}$$

In these cases we choose the shorter finite decimal expansion, *except for* 1. The number 1 is written as a decimal $.99\bar{9}$.

Furthermore, d_{11} represents the first digit in the decimal form of x_1, d_{23} represents digit number 3 in the decimal form of x_2, and in general d_{nm} represents digit number m in the decimal form of x_n. We can now produce a Realist R_x who does not get a room.

Let us define a digit d_1 as follows.

$$d_1 = \begin{cases} d_{11}+1 & \text{if } d_{11} \neq 9 \\ 0 & \text{if } d_{11} = 9 \end{cases} .$$

Notice that we have defined d_1 so that $d_1 \neq d_{11}$. For example, if $d_{11} = 5$ then $d_1 = 6$ and if $d_{11} = 9$ then $d_1 = 0$.

We do the same thing for d_{22}. Let

$$d_2 = \begin{cases} d_{22}+1 & \text{if } d_{22} \neq 9 \\ 0 & \text{if } d_{22} = 9 \end{cases} .$$

Notice that we have defined d_2 so that $d_2 \neq d_{22}$. For example, if $d_{22} = 0$ then $d_2 = 1$ and if $d_{22} = 7$ then $d_2 = 8$.

In general, let us define

$$d_n = \begin{cases} d_{nn}+1 & \text{if } d_{nn} \neq 9 \\ 0 & \text{if } d_{nn} = 9 \end{cases} .$$

Then $d_n \neq d_{nn}$.

The roomless Realist R_x is given by writing down the decimal expansion

$$\boxed{x = .d_1 d_2 d_3 d_4 \ldots .}$$

If x ends in $99\bar{9}$ then we replace it with the shorter decimal representation that ends in $00\bar{0}$. Then $x \neq x_1$ because by our choice of d_1, x and x_1 differ in the first decimal place, $d_1 \neq d_{11}$. Also, $x \neq x_2$ because by our choice of d_2, x and x_2 differ in decimal place number 2, $d_2 \neq d_{22}$. In general, $x \neq x_n$ because by our choice of d_n, x and x_n differ in decimal place number n, $d_n \neq d_{nn}$. Thus R_x is not on the implied list of Realists who got a room. This is the person we have sought. This is why Hilbert could not give each Realist a single room. There are simply too many Realists! No matter what rooms he assigned there would always be a Realist R_x who does not get a room. There are more Realists than there are rooms.

How can that be, reader? There are infinitely many rooms and infinitely many Realists. How can there be more Realists than rooms? Read on.

Let's examine the above choices for d_n and the construction of x on a concrete example. Suppose that we are given specific real numbers x_1, x_2, x_3, ... that form the following implied list.

$$\begin{array}{rclllllll}
x_1 &=& .\boxed{1} & 2 & 3 & 4 & 5 & \ldots \\
x_2 &=& .0 & \boxed{9} & 0 & 1 & 0 & \ldots \\
x_3 &=& .1 & 4 & \boxed{9} & 5 & 7 & \ldots \\
